DISSERTATION

Presented to the Faculty of the Graduate School of

The University of Texas at Austin

in Partial Fulfillment

of the Requirements

for the Degree of

DOCTOR OF PHILOSOPHY

THE UNIVERSITY OF TEXAS AT AUSTIN

August 2019

Dedicated to my parents Li Song and Mei Sun, also my grandparents Kexin Song, Weifeng Guan, Yongzhe Sun, and Fenglin Yang.

Thank Wei Ye for accompanying me over a half of my Ph.D. time.

Acknowledgments

First, I would like to thank my advisor, Professor Eric Price, for all the inspirations and support that he has given me throughout my Ph.D. career. He has been, and will always be, a great source of wisdom and encouragement for me. I genuinely want to thank Eric for giving me so many freedoms during the Ph.D. I thank Eric for allowing me to work on topics from algorithm to complexity, from theoretical computer science to machine learning, and from applications to applied Mathematics. I thank Eric for allowing me to travel around the country to pursue the best scholarship in the field. I also wanted to thank Eric for introducing David and Yin Tat to me. I could never imagine a Ph.D life without Eric as my advisor. It is an honor of life for me to be the first student of Eric.

I am very thankful for my spritual advisor, Professor David P. Woodruff, who had been teaching and training me during the first half of my Ph.D. time.

I really want to thank my informal advisor, Professor Yin Tat Lee, who had been helping and guiding me during the second half of my Ph.D. time.

I would appreciate the contribution from David and Yin Tat on my thesis.

I wish to thank the multitudes of people who helped me. Time would fail me to tell of . . .

Coauthors The main purpose of writing this thesis is to express my gratitude to all co-authors and collaborators. I want to thank all of you x times, where x is the number of pages in this thesis. The list includes, but is not limited to: Alexandr Andoni, Josh Alman, Sanjeev Arora, Zeyuan Allen-Zhu, Maria-Florina Balcan, Duane Boning, Peter L. Bartlett, Aritra Banik, Binay K. Bhattacharya, Dana H. Ballard, Paul Beame, Jan van den Brand, Mitali Bafna, Hongge Chen, Michael Cohen, Xue Chen, Sitan Chen, Constantine Caramanis, Timothy Chu, Chi-Ning Chou, Inderjit S. Dhillon, Luca Daniel, Huaian Diao, Sandip Das, Alexandros G. Dimakis, Minati De, Simon S. Du, Martin Ester, Ankit Garg, Anna Gál, Cho-Jui Hsieh, Wei Hu, Bo Hu, Prateek Jain, Ziheng Jiang, Rajesh Jayaram, Chi Jin, Haotian Jiang, Daniel Kane, Tsunehiko Kameda, Weihao Kong, Rasmus Kyng, Ka Yui Lee, Yin Tat Lee, Yingyu Liang, Yibo Lin, David Liau, Jerry Li, Meng Li, Xingguo Li, Yuanzhi Li, Daogao Liu, Kyle Luh, Dana Moshkovitz, Vasileios Nakos, Michael Orshansky, Eric Price, Aviad Rubinstein, Milan Rubinstein, Ilya P. Razenshteyn, Ankit Singh Rawat, Sasanka Roy, Victor Reis, Xiaorui Sun, Aaron Schild, Aaron Sidford, Nikhil Srivastava, Wen Sun, Vladyslav Sokol, Seyed Abbas Sadat, Saeed Seddighin, Ruoqi Shen, Clifford Stein, Ewin Tang, Richard T. Vaughan, Santosh S. Vempala, Ye Wang, Mengdi Wang, Ruosong Wang, Zhengyu Wang, Tsui-Wei Weng, David P. Woodruff, Lin F. Yang, Xin Yang, Ger Yang, Xinyang Yi, Huacheng Yu, Yi Zhang, Qiuyi Zhang, Huan Zhang, Jiong Zhang, Hongyang Zhang, Ruohan Zhang, Ruizhe Zhang, Kai Zhong, Peilin Zhong, Yuke Zhu.

Useful Discussions I want to thank the researchers who had done super useful discussions with me, and they probably even didn't notice our conversation lead to a paper finally. More surprisingly, perhaps most of the researchers mentioned below couldn't remember they've ever talked to me. I'd like to thank Udit Agarwal, Alexandr Andoni, Josh Alman, Zeyuan Allen-Zhu, Amir Abboud, Megasthenis Asteris, Scott Aaronson, Arturs Backurs, Saugata Basu, Boaz Barak, Jarosław Błasiok, Saugata Basu, Sebastien Bubeck, Peter L. Bartlett, Michael Borokhovich, Mitali Bafna, Paul Beame, Abhishek Bhowmick, Ainesh Bakshi, Eshan Chattopadhyay, Lijie Chen, Xue Chen, Kenneth Clarkson, Hongge Chen, Danqi Chen, Sitan Chen, Chi-ning Chou, Thomas Dillig, Isil Dillig, Alexandros G. Dimakis, Ethan Elenberg, Ronen Eldan, Yu Feng, Vitaly Feldman, Uriel Feige, Ronald Fagin, Rong Ge, Anna Gál, Ankit Garg, Mika Göös, Surbhi Goel, Badih Ghazi, Daniel Hsu, Changyong Hu, Yige Hu, Cho-Jui Hsieh, Wei Hu, Samuel Hopkins, William Hoza, Bernhard Haeupler, Russell Impagliazzo, Chi Jin, Prateek Jain, T.S. Jayram, Ravindran Kannan, Michael Kapralov, Anna Karlin, Rasmus Kyng, Daniel Kane, Janardhan Kulkarni, Murat Kocaoglu, Pritish Kamath, Mrinal Kumar, J. M. Landsberg, Qi Lei, Fu Li, Yixuan Li, Yin Tat Lee, Yibo Lin, Jason D. Lee, James Lee, Yuanzhi Li, Zhiyuan Li, Xin Li, Yingyu Liang, Kyle Luh, Meng Li, Wuxi Li, Daogao Liu, Zhixian Lei, David Liau, Kasper Green Larsen, Syed Mohammad Meesum, Ankur Moitra, Dana Moshkovitz, Cameron Musco, Christopher Musco, Raghu Meka, Jelani Nelson, Vasileios Nakos, Preetum Nakkiran, Richard Peng, Eric Price, Greg Plaxton, Daniel Perrucci, Dimitris Papailiopoulos, Govind Ramnarayan, Ilya Razenshteyn, Anup Rao, James Renegar, Aviad Rubinstein, Rocco Servedio, Tselil Schramm, Clifford Stein, Wen Sun, Madhu Sudan, Aaron Sidford, Aaron Schild, Nikhil Srivastava, Xiaorui Sun, Tianxiao Shen, Saeed Seddighin, Thomas Steinke, Karthikeyan Shanmugam, Xiaofei Shi, Ewin Tang, Elias

Tsigaridas, Rashish Tandon, Avishay Tal, Santosh S. Vempala, Salil Vadhan, Jan Vondrák, Yuhao Wan, Yining Wang, Zhengyu Wang, Zhaoran Wang, Xinyu Wang, Ye Wang, David P. Woodruff, Ryan R. Williams, John Wright, Omri Weinstein, Mary Wootters, Shanshan Wu, Xiaoxia Wu, Bo Xiong, Yuanzhong Xu, Huacheng Yu, Bei Yu, Huacheng Yu, Xin Yang, Lin F. Yang, Ger Yang, Huan Zhang, Hongyang Zhang, Yi Zhang, Jiong Zhang, Ruizhe Zhang, Kai Zhong, Yuke Zhu, Danyang Zhuo, and David Zuckerman for useful discussions.

Visiting My research has benefited enormously from a number of visits to research institutions over the past few years. I would like to thank all my hosts, with whom I have established invaluable friendships: David P. Woodruff at IBM Almaden, Jelani Nelson at Harvard University, Yin Tat Lee at the University of Washington, Zeyuan Allen-Zhu, Jerry Li, and Ilya Razenshteyn at MSR Redmond, Peter L. Bartlett, David P. Woodruff, and Santosh Vempala at Simons Institute at the University of California, Berkeley, Nikhil Srivastava at the University of California, Berkeley, Omri Weinstein, Alex Andoni and Peilin Zhong at Columbia University, and Sanjeev Arora at Princeton University.

I would like to thank all my office mates at the institutions that I have stayed in over the last few years: Pravesh Kothari during my first year at UT-Austin; Mika Göös and Ilya Razenshteyn at IBM in 2015; Cameron Musco, Badih Ghazi, and Xingguo Li at IBM in 2016; Chen Shao, Lin F. Yang, Peilin Zhong, Hongyang Zhang at IBM in 2017. I had a productive year during my visit to Harvard University in 2017 and 2018, where I shared the office with Aviad Rubinstein, Mika Göös, Kyle Luh, Tselil Schramm, Rasmus Kyng, Tobias Christiani, and Huacheng Yu. I enjoyed my leisure time with Josh Alman, Chi-Ning Chou, Tobias Christiani, Zhixian Lei, Zhengyu Wang and Huacheng Yu while I was at Harvard. I had a productive summer when I was interning MSR Redmond in 2018 while sharing the office with Mark Sellke, and Yuanzhi Li. During my visit to UC Berkeley in 2019 Fall, I shared an office with Lijie Chen, Gautam Kamath, Jerry Li, Samuel Hopkins, Ainesh Bakshi, Simon S. Du, Themis Gouleakis, Rajesh Jayaram, Ruosong Wang, Xiaoxia Wu, Xiaofei Shi, and Hongyang Zhang. I was struggling on my thesis while I was interning MSR Redmond in 2019 Summer while sharing the office with Ronen Eldan, Mark Sellke, Sitan Chen, Lixin Huang, Kevin Tian. I enjoyed my time at the University of Washington where I shared the

office with Xin Yang, Haotian Jiang, Swati Padmanabhan, Victor Reis, Ruoqi Shen, Ewin Tang, and Robbie Weber in 2018 and 2019. I enjoyed my leisure time with Lequn Chen, Zihou Gao, Ziheng Jiang, Weihao Kong, Jialin Li, Hanchuan Li, Daogao Liu, Xuhai Xu, Tianyi Zhou, and Danyang Zhuo while I was at the University of Washington. I thank my office mates Fu Li, Kai Zhong, Qi Lei, Jiong Zhang, and Ruizhe Zhang at UT-Austin for their support during the latter part of my Ph.D. career. I enjoy my leisure time with Ruizhe Zhang during the last a few days of my Ph.D. program at UT-Austin.

Traveling As a frequent traveler, I was homeless for the majority of my Ph.D. years. I would like to thank all the friends who have kindly provided me a place to stay: Feng Xiao at IBM; Xindi Hu and Aviad Rubinstein at Harvard; Xin Yang and Jerry Li during my visit to UW and MSR; and Lijie Chen, Themis Gouleakis, Chi Jin, Gautam Kamath, and Santosh Vempala who shared their house with me while I was visiting UC Berkeley.

Over my entire Ph.D., I don't know how to drive. My life would be very inconvenient if I don't know the following friends who had given me a ride many times. I want to thank for Beidi Chen, Qiren Chen, Lequn Chen, Yu Feng, Chi Jin, Weihao Kong, Meng Li, Xingguo Li, Yuanzhi Li , Yibo Lin, Jialin Li, Jinsong Liu, Aviad Rubinstein, Ilya Razenshteyn, Ruoqi Shen, Aaron Sidford, Xinyu Wang, Ye Wang, David P. Woodruff, Yun Wu, Biying Xu, Feng Xiao, Xin Yang, Lin F. Yang, Bei Yu, Zhuoran Zhao, Ruohan Zhang, Kai Zhong, Danyang Zhuo.

RA and TA Over the past few years, I have received fundings from many generous professors, including Alexandros Dimakis, Inderjit Dhillon, Adam Klivans, Rasmus Kyng, Yin Tat Lee and Eric Price.

Over the past few years, I have been doing TA so many times. I'd like to thank Rasmus Kyng and Bill Young for working with at Harvard and UT-Austin.

Undergraduate The decision to pursue a Ph.D. is already a brave one for me. I really want to thank for my undergraduate advisors Richard Vaughan, Tsunehiko Kameda, Binay K. Bhattacharya, Ke Wang, Martin Ester, Ze-Nian Li, Hao Zhang (at Simon Fraser University) for kindly training and guiding a young researcher. I would like to thank for my undergraduate friends Song Chen, Tiaoxiang Gao, Junsong Hu, Wen Sun, Chi Jin, Yatao Wang, Mingzhou Yang, Huan Zhang, Zhuoran Zhao, Yuke Zhu who encouraged me to pursue Ph.D.

Struggling Time Over the entire Ph.D. time, I have been thinking about quitting the Ph.D. program seriously thousands of times. I really want to thank all the friends who had suggested me not to give up. I had a very struggling time during my first year at Austin. I truly appreciate Adam Klivans and Pravesh Kothari's support without which I might have quitted Ph.D. I really like to thank Alexandros G. Dimakis, Anna Gál, and Ankit Singh Rawat for helping me publishing the first theory paper during my Ph.D. This was extremely important to me, as it gave me the confidence to continue my Ph.D. research.

During the second year, I met my advisor Eric. I want to thank him for giving me a set of toys (Fox, etc.). Those inspire my research for many years. I finally collected six before graduation.

In the summer of my second year, I was an intern at IBM Almaden. This was the first time that I did research outside my home institution. I would like to thank my intern advisor David Woodruff for his help on many things, especially on giving me the first stock in my life. When I was planning to graduate, that stock is five times than before. Since then, I started to collaborate with David heavily, and he became my pseudo-advisor.

While I was at the University of Washington, I was struggling with many things. I want to thank Yin Tat Lee for chatting with me about many non-research kinds of stuff, sharing so many funny stories with me, and giving many bits of help in my life.

Even during the last year of my Ph.D., I was still considering quitting the Ph.D. due to a variety of reasons. I really appreciate the support from so many professors (Scott Aaronson, Greg Plaxton, Adam Klivans, Eric Price, David P. Woodruff) and friends (Zeyuan Allen-Zhu, Josh Alman, Lijie Chen, Gautam Kamath Rasmus Kyng, Yin Tat Lee, Xingguo

Li, Jerry Li, Ilya Razenshteyn, Aviad Rubinstein, Ruosong Wang, Zhengyu Wang, Lin Yang, Xin Yang, Peilin Zhong) who convinced me to finish the Ph.D. program.

??? Friends I wanted to thank Lijie Chen, Zhengyu Wang, and Peilin Zhong for their enourmous help on my research. Their contributions range from proposing new research ideas to paper proofreading. Many times they kindly declined the authorship they deserved. I am so grateful for their help and friendship that I could not find a proper category for them. This is why I put "???" above.

I wanted to thank Ziheng Jiang for his generous help at the University of Washington, without which I would not be able to write this thesis.

I really wanted to thank Billy (Vasileios) and Zhengyu for writing my only student papers with me.

At the end of the third year, I started to get interested in Machine Learning and Deep Learning. I would like to thank my friend Kai Zhong for introducing this new field for me.

Thesis I want to thank Zeyuan Allen-Zhu and Yin Tat Lee for the suggestion of the title of the thesis. I want to thank Jerry Li for choosing the final title. I want to thank Jerry Li (Sana Minatozaki) for his generous help on the abstract, introduction, and the open problem section of the thesis. I want to thank Lijie Chen for his help on acknowledgment. I want to thank Ruoqi Shen for her generous advice on the abstract of the thesis. I appreciate Zhengyu Wang's generous help on the acknowledgment, abstract, introduction and open problem section of the thesis. I want to thank Yin Tat Lee, Victor Reis, Xiaorui Sun, Xin Yang, Peilin Zhong for their generous help on the open problem section.

Defense and Graduation I want to thank Ruizhe Zhang for his generous help during my defense day. I want to thank all my committees and Vijaya Ramachandran for coming to my defense at UT-Austin. I want to thank Yin Tat Lee and Xin Yang for creating two Skype call lives of my defense. One is at MSR Redmond, and the other is at the University of Washington. I want to thank Weihao Kong, Jialin Li, Daogao Liu, Swati Padmanabhan, Ruoqi Shen, Xin Yang, and Danyang Zhuo for joining my defense remotely. I want to thank Beidi Chen, Lixin Huang, Gautam Kamath, Yin Tat Lee, Jerry Li, Chen Luo, Aaron Sidford, and Sam Wong for attending my defense remotely.

I want to thank Katie Dahm (who is the CS Graduate Program Coordinator at The University of Texas at Austin) for giving all kinds of help for letting me graduate on time.

To Junior Ph.D. Student To be honest, I never thought I was a successful Ph.D. student. At the end of my thesis defense, someone asked a question: "do you have any suggestions for junior students?". I am still not sure if I have a satisfactory answer to that question today. Instead, I wanted to write down how I do research, and what I feel when something happened, for the reference of future readers.

1. After every meeting, I will write down the notes as formal as possible via latex. Even if the idea proposed in the meeting is completely wrong, I still write down the details of all the calculations and mark why it doesn't work. To me, the definition of the research progress is not just solving the problem. Sometimes, ruling out some wrong directions also counts as remarkable progress.

2. For the first three months of my Ph.D., I almost spent all the time on solving one problem. But, it didn't go anywhere. I felt truly sad and wanted to quit the Ph.D. program. Then someone suggested me to go to some classes to learn more things and read more papers. I took the suggestion. Luckily, after that class, I got my first theory paper during my Ph.D. This gives me very strong confidence to continue my Ph.D.

3. After that first three months of bad experience, I usually spent more time reading papers than thinking about how to solve problems. I am reading ArXiv papers every day. Usually, once a conference released the accepted paper list, I will google every title of the paper and try to take a quick look.

4. I am in general happy to talk about research with anyone in any field. I am also open to working on any problems in any field. As long as my coauthors want to work on something with me, I am happy to work on it. As far as I remember, I never say "no" to

anyone or any problem.

To clarify, I am just sharing my experience with everyone. I am NOT suggesting anyone try to follow my way.

Parents Finally, it is time to say something for my parents.

Although I am neither a lousy Ph.D. student nor a stupid coauthor, I have to admit that I am a horrible son. Over my entire Ph.D. career, I have only met my parents twice for a total of one month. I still remember the shock that I had during our first meeting. I could barely recognize their faces, and they became so much older compared to the time I left them.

My parents do not know much about Computer Science or graduate school, and I was not patient enough to explain to them what was going on in my life. For all of these, I want to say "sorry" to my parents. I truly appreciate their support in my life. Mom and dad, I love you!

It is difficult to forget the pleasant time with my grandparents during my childhood. I felt really sorry that I did not give enough time to them as I grew older. That is the reason why I have mentioned all of my grandparents' names in this thesis.

We remark that the papers covered by this thesis are only about part of the author's gradschool-publications. Topics not covered in this thesis are deep learning theory [ZSJ+17, ZSD17, WZC+18, LSY19, SY19], recurrent neural network [ZLSD18], finding adversarial examples [WZC+18, ZCS+19], reinforcement learning [ZSB15, SS19], coding theory [DGRS15], unique games [BCS18], optimization [LPS19, vdBLSS19], learning mixture distributions [CLS20], multi-arm bandits [LPSY18], matrix completion [ZSJD18, BLS+19], Fourier transform with restricted samples [LSS19], regression [PSW17, DSSW18, DSWY19, DJS+19, SWY+19], Laplacian system [ASS19], low-rank approximation [LSW+19], EDA design [WLY+15], fast multipole method [ASS19], geometry algorithms [BBD+18, ASS19], robotics [ZS16], quantum algorithm [TS19] and discrepancy [RS19a].

The author also had done a few research when he was an undergraduate student. Since the author never wrote a undergraduate thesis, we like to list those papers here. The topics are robotics [SV12b, SSV12, SV13, SS14], graph and geometry algorithms [BKS12b, BKS12c, BKS14, BDK+14, BKS15b, BBD+16], data-mining [HSE12, SZ13].

Matrix Theory:
Optimization, Concentration, and Algorithms

Publication No. _____

Zhao Song, Ph.D.
The University of Texas at Austin, 2019

Supervisor: Eric Price

The matrix plays an essential role in many theoretical computer science and machine learning problems. In this thesis, we develop a better understanding of matrices with a view towards these applications. Our insights yield improvements for a number of old, well-studied algorithmic problems.

In this thesis, we study matrices from three perspectives. We first consider their role in *optimization*. We study a number of matrix optimization problems, and propose new solvers and results for linear programs, empirical risk minimization, ordinary differential equations, deep neural networks. We next consider how random matrices *concentrate*. Specifically, we generalize a number of scalar Chernoff-type concentration inequalities and the Spencer-type discrepancy theorems to matrices. Finally, we develop new *algorithms* for problems on matrices. These fall roughly into two sub-categories, namely matrix factorization problems and structured recovery problems. In the first category, we propose a number of new algorithms

for a variety of low-rank matrix factorization problems. In the second category, we give new algorithms for some recovery tasks with structured matrices. We design matrices and corresponding algorithms for compressed sensing tasks, and we give fast algorithms for the sparse Fourier transform problem, which can be thought of as a sparse recovery problem where one cannot freely choose the matrix. We now describe our contributions in more detail.

Linear programming is one of the fundamental problems in computer science. In both theory and practice, many problems can be solved via linear programming, and doing so often yields the best-known runtime. We present an algorithm that runs in the current matrix multiplication time, which breaks a thirty-year-old barrier. Furthermore, our technique can be generalized to speed up a large family of convex optimization problems, i.e., empirical risk minimization.

Sampling logconcave functions which arise in statistics and machine learning has been the subject of intensive study. This problem can be thought of as a special case of solving multivariate ordinary differential equations (ODEs). Under sufficiently strong smoothness conditions, discrete algorithms of Hamiltonian Monte Carlo (HMC) have runtime and number of function evaluations growing with the dimension. We give new algorithms that obtain a nearly linear implementation of HMC for a broad class of smooth, strongly logconcave densities, with the number of iterations (parallel depth) and gradient evaluations being polylogarithmic in the dimension (rather than polynomial, as in previous work).

Deep neural networks (DNNs) have demonstrated dominating performance in many fields; since AlexNet, networks used in practice are going wider and deeper. We prove why stochastic gradient descent (SGD) can find global minima on the training objective of DNNs in polynomial time. We only make two assumptions: the inputs are non-degenerate and

the network is over-parameterized. Furthermore, our results also hold for Recurrent Neural Networks (RNNs) which are multi-layer networks widely used in natural language processing. They are harder to analyze than feedforward neural networks, because the same recurrent unit is repeatedly applied across the entire time horizon.

The Chernoff bound for the concentration of scalar random variables is a fundamental tool in the analysis of randomized algorithms. Over the past decade, a matrix generalization of the Chernoff bound has also found widespread application, but this generalization is fairly restrictive. For a number of decades, it has been open whether one can remove some of these restrictions. We answer this question in the affirmative by giving a number of new matrix Chernoff bounds under more relaxed independence assumptions than before.

Spencer's theorem is a famous result in discrepancy theory, and it is an important open question how to generalize this result to the matrix setting. We make progress on this, and prove a matrix generalization of this result, in some restricted settings. Our result also generalizes the famous Kadison-Singer conjecture.

The classical low rank approximation problem is : given a matrix A, find a rank-k matrix B such that the Frobenius norm of $A-B$ is minimized. It can be solved in polynomial-time using, for instance, singular value decomposition. If one allows randomization and approximation, it can be solved in time proportional to the number of non-zero entries of A with high probability. We consider a number of natural generalizations of this important problem. We generalize the problem to consider a number of different norms, including weighted norms, entry-wise L1, and more general loss functions including Huber and Tukey loss. We also consider the natural tensor version of the problem. For all these settings, we give new state-of-the-art algorithms, including a number of new fixed parameter tractable

algorithms.

Compressed Sensing, or sparse recovery, is a powerful mathematical framework whose goal is to reconstruct an approximately sparse signal from linear measurements. We consider the extensively studied problem of L2/L2 compressed sensing. Our algorithm has faster decoding time and significantly smaller column sparsity, answering two open questions of prior work. Previous work on sublinear-time compressed sensing employed an iterative procedure, recovering the heavy coordinates in phases. We completely depart from that framework, and give the first sublinear-time algorithm which achieves the optimal number of measurements without iterating.

The Fourier transform is ubiquitous in computer science, mathematics, and beyond. In recent years, a number of works have studied methods for computing the Fourier transform in sublinear time if the output is sparse. We consider two important settings in which this occurs: namely, the sparse high-dimensional setting, and the sparse continuous setting. In the high dimensional setting, we consider the extensively studied problem of computing a k-sparse approximation to the d-dimensional Fourier transform of a length n signal. Our algorithm achieves a nearly optimal sample complexity and runs in time comparable to the Fast Fourier Transform. All previous algorithms proceed either via the Restricted Isometry Property or via filter functions. Our approach totally departs from the aforementioned techniques, and we believe is a new approach to the sparse Fourier transform problem.

While many of the works on sparse Fourier transforms have focused on the discrete setting, in many applications the input signal is continuous and naive discretization significantly worsens the sparsity level. Assuming the frequency gap is known, we present an algorithm for robustly computing sparse Fourier transforms in the continuous setting. Know-

ing the frequency gap is necessary for robustly identifying individual frequencies. However, was unknown whether interpolating the signal also requires a frequency gap. We resolve this problem by giving an algorithm which shows that such a gap not necessary for estimating the signal.

Chapter 1

Introduction

1.1 Introduction

Many important questions in computer science can be formulated as problems on matrices. Having a better understanding of the matrix is crucial for devising fast algorithms for many fundamental problems, including a majority of the 10 most important algorithms of the 20th century [Cip00]. Examples of this include linear programming, Metropolis algorithm for Monte Carlo, matrix/tensor factorization, low-rank approximation, Fourier transforms, etc. In this thesis, we make progress on a number of long-standing open problems related to this areas. Along the way, we propose a number of new techniques which be could be useful in the future. We first summarize several core ideas, new insights, and new techniques related to the matrix. These techniques will eventually lead to fast algorithms. Later on in the introduction, we go to the details of each category.

- **Sketching.** A powerful technique we will use in many places throughout this thesis is sketching. Given a matrix $A \in \mathbb{R}^{n \times d}$, our goal is to produce a concise representation of A to summarize informationa about A without using A directly. This is typically done by choosing a "small" sketching matrix S, and replacing A with SA. We say SA is a sketch of A. There are many previously studied choices for S, depending on the specific problem instance, including random Gaussian matrices, subsampled

randomized Hadamard matrices, and Count-Sketch matrices. By using SA, which is typically much smaller than A, we are able to speed up a number of algorithms.

This idea is often called "sketch and solve" in numerical linear algebra. Suppose that, for a given problem, we can produce a solver, which we wish to speed up. Oftentimes, we can apply a sketching matrix to reduce the dimensionality/freedom/size of the original problem, and then run the original solver on this smaller problem, and obtain a faster algorithm. Some classical examples are ℓ_2 norm linear regression and Frobenius norm low-rank approximation. A number of results in this thesis use much more complicated versions of these sketching techniques, such as "guess and sketch" and "sketch and iterate," to achieve similar speed-ups in other problem settings. Many results in this thesis modify the classical iterating algorithms more decently with a better understanding of hashing-trick, sampling, and concentration techniques.

- **Sampling.** Given a matrix $A \in \mathbb{R}^{n \times d}$, our goal is to obtain a concise representation of A by sampling some rows of A and reweighting them. Let $D \in \mathbb{R}^{n \times n}$ denote a sparse diagonal matrix. Then DA can be viewed as a sampled version of A. The goal of this is similar to sketching, as the goal is to produce a smaller representation of A, so that our algorithms run faster. In our context, the main difference between sketching and sampling is that in sketching, each row of SA is a linear combination of rows in A, and whereas when we sample, each row of DA is a row of A with reasonable rescaling factor. There are several well-known examples, e.g. importance sampling, leverage scores sampling, and Lewis weights sampling.

  – By sampling (in conjunction with some other ideas), we are able improve the

runtime for solving some convex problems, e.g. linear programs [CLS19]. We propose an algorithm that solves linear programs in the current matrix multiplication time. Our result breaks a thirty-year-old barrier.

- Sampling can also be used to solve some non-convex problems. We give a nearly optimal matrix CUR decomposition [SWZ17, SWZ19b] algorithm. We also extend the definition of matrix CUR problem to tensor CURT problem [SWZ19b] and provide a nearly optimal algorithm.
- Sampling can be used to speed up the iterating algorithm for orthogonal tensor decomposition [SWZ16]. This leads to a sublinear time finally.

- **Matrix Maintainance.** Given a matrix A and a sequence of T matrices $W^1, W^2, \cdots, W^T$, our goal is to approximately maintain $f(A, W^t)$ over all the iterations. Formally speaking, whenever we receives W^t, we want to generate $g(A, W^t)$ such that $g(A, W^t) \approx f(A, W^t)$. The objective is to do so faster than simply calculating $f(A, W^t)$ independently for each $t = 1, \ldots, T$, by leveraging some structure in the sequence of update matrices.

  - In [LSZ19], we propose a technique for doing this, which we call "iterate and sketch", when f takes the form of a projection. Specifically, we consider functions f of the form

    $$f(A, W) = \sqrt{W} A^\top (A W A^\top)^{-1} A \sqrt{W}.$$

    When using the central path method to solve linear programs, in each iteration we need to multiply $f(A, W^t)$ by some vector. However, since the updates W^t are

very structured, we don't need to compute this from scratch. By instead cleverly maintaining the sequence of updates, we are able to decrease the running time of the solver. Note that this idea is very different from "sketch and solve" described in the early paragraph. The main difference between "sketch and solve" and "iterate and sketch" is, the former just uses the original solver as a black-box, whereas the latter changes the original solver and uses a different sketching matrix over each iteration of the solver. There are other examples in the thesis can be thought of as "iterate and sketch", e.g. [CLS19, SWZ16].

- **Matrix Concentration.** The Chernoff bound for the concentration of scalar random variables is a fundamental and ubiquitous tool in the analysis of randomized algorithms. One common form of the bound is the following: given a list of independent random variables $x_1, \cdots, x_k \in [0, 1]$ with mean μ, then

$$\Pr\left[\left|\frac{1}{k}\sum_{i=1}^{k} x_i - \mu\right| > \epsilon\right] \leq 2\exp(-\Omega(k\epsilon^2)).$$

There is a natural generalization of this to matrices. Namely, if $X_1, \cdots, X_k$ are independent $n \times n$ complex Hermitian random matrices with $\|X_i\| \leq 1$ and mean μ, then the following is true:

$$\Pr\left[\left\|\frac{1}{k}\sum_{i=1}^{k} X_i - \mu\right\| > \epsilon\right] \leq 2n\exp(-\Omega(k\epsilon^2)).$$

Over the past decade, the matrix generalization of the Chernoff bound has also found widespread application, but this generalization is fairly restrictive. In particular, this bound requires strong independence of the individual X_i. In contrast, in the scalar setting, it is known that often times one can get away with some weak dependences

between the summands. For a number of decades, it has been open whether one can remove some of these restrictions in the matrix setting as well.

  - In the scalar setting, it is well-known that if the random variables follow the dependence structure of a random walk on a graph, then the random variables still obey a Chernoff-style bound. It was conjectured by Wigderson and Xiao that a similar result holds in the matrix setting. In [GLSS18], we resolve this conjecture in the affirmative. Formally speaking, let $v_1, \cdots, v_k$ denote a random walk on expander graph G, let f denote a mapping $f : V \to \mathbb{R}^{n\times n}$ with $\|f(v)\| \leq 1$, $\forall v \in V$, then $\sum_{i=1}^{k} f(v_i)$ follows matrix Chernoff bound.
  - We show a matrix Chernoff bound for random spanning trees [KS18]. Such a result was conjectured by Batson, Spielman, Srivastava and Teng [BSST13]. Formally speaking, let $A_1, \cdots, A_k \in \mathbb{R}^{n\times n}$ denote a list of matrices where each of them corresponds to a random spanning tree. We show that $k = O(\log^2 n)$ suffices to imply that $\sum_{i=1}^{k} A_i$ gives spectral sparsifier for graph G.

- **Sketch and Guess.** The "sketch and guess" is the following, surprisingly powerful, paradigm: to solve matrix (or tensor) factorization problem, first demonstrate that the optimal solution may be represented as a concise sketch with fewer degrees of freedom, and then simply "guess" this sketch by exhaustively searching over all possible sketches. Since we have reduced the degrees of freedom, this exhaustive search can be done relatively efficiently. For instance, consider the problem of low-rank factorization. Given a matrix $A \in \mathbb{R}^{n\times n}$, our goal is to find two matrices $U \in \mathbb{R}^{n\times k}$ and $V \in \mathbb{R}^{k\times n}$ so that $\|UV - A\|_F$ is minimized. The idea is to write a polynomial system with a small

number of variables and constraints, abd low degree, and then run a polynomial system solver on this small polynomial system. For example, in order to solve $\min \|UV - A\|_F^2$, we can create $2nk$ variable (one for every entry of U and V), and minimize the resulting degree-4 polynomial system. The polynomial system solver has exponential dependence on the number of variables, and thus has runtime $2^{O(nk)}$. The trick to reduce the number of variables is choosing two sketching matrices S (a fat one, it has size $O(k) \times n$) and R (a tall one, it has size $n \times O(k)$), then focusing on $\min_{X,Y} \|ASXYRA - A\|_F^2$. To solve this problem, we can create $O(k^2)$ variables to minimize a degree-4 polynomial system, resulting in a runtime that, while exponential in k^2, is polynomial in n. Of course, for this specific problem, this technique is overkill, as we can solve this problem in time which is polynomial in both n and k via SVD. However, in situations where the problem we are trying to solve is NP-hard, this technique (and extensions thereof) can provide a nearly optimal approximation algorithms.

- We first propose the "guess a sketch" idea in [RSW16]. The combination of guessing and sketching can be used to get FPT-type algorithms for several matrix/tensor factorization problems [SWZ17, SWZ19b].
- For the entry-wise L1 norm, we propose "sketch and relax" idea in [SWZ17]. We want to solve $\min \|UV - A\|_1$. To write a polynomial, we need to create variables for U, V and also n^2 sign variables. To reduce the number of variables, we use L1 embedding matrix to reduce the dimension from n to $r = \text{poly}(k)$ and then relax the problem to Frobenius by losing some factors in the approximation ratio.

Eventually, we just need to solve

$$\min_{X,Y} \|T_1 ASXYRAT_2 - T_1 AT_2\|_1.$$

Since the number of rows of T_1 and $T_2^\top$ is small, thus, we only need to create small number of sign variables, and as a result we obtain a faster runtime.

– For the tensor case, we propose "sketch and rotate" idea in [SWZ19b]. We want to solve $\min \|U \otimes V \otimes W - A\|_F^2$. Slightly different from matrix case, we can create $3nk$ variables to minimize a degree-6 polynomial system. Applying the sketching trick again, we can write

$$\min_{X,Y,Z} \|A_1 SX \otimes A_2 RY \otimes A_3 TZ - A\|_F^2$$

where $A_1, A_2, A_3 \in \mathbb{R}^{n \times n^2}$ are the three possible flattening of tensor A and S, R, T are random sketching matrices.

- **Iterating and Concentration.** Deep neural networks (DNNs) have demonstrated dominating performance in many fields; since AlexNet, networks used in practice are going wider and deeper. We want to give some explanation about why stochastic gradient descent (SGD) can find global minima on the training objective of DNNs and Recurrent Neural Networks (RNNs). In previous paragraphs, we have discussed several techniques for improving convex, non-convex, and NP-hard problems. Unfortunately, the theory of deep learning cannot benefit from those "sketch and solve", "sketch and iterate", and "sketch and guess" techniques.

  – One view of the over-parameterization theory of DNNs [AZLS19] is, $\|\phi(Wx)\|_2$ has a good concentration when x is some fixed unit vector, W is random Gaussian matrix, and $\phi(t) = \max\{t, 0\}$ is the ReLU activation function. Technically

speaking, if we normalize W properly, $\|\phi(Wx)\| \approx (1+\epsilon)\|x\|_2$ with very high probability. In each of iteration of SGD, we update $W \leftarrow W + \Delta W$. There, we need to argue such concentration-type result for different Ws in each iteration. We call it "iterate and concentrate". A variation of this idea appears in [LSZ19] (not involved ReLU), where we use subsampled randomized Hadamard matrix to show concentration over each iteration.

  - RNNs are multi-layer networks widely used in natural language processing. They are harder to analyze than feedforward neural networks, because the same recurrent unit is repeatedly applied across the entire time horizon. By doing a more careful randomness decomposition (in conjunction with other ideas, e.g., concentrations, Gram–Schmidt process), we can show the provable guarantees of RNNs [AZLS18].

- **Hashing.** For a given vector $x \in \mathbb{C}^n$ and a parameter k, we consider the problem where we observe $y = \Phi x$, and our goal is to figure out a $O(k)$-sparse approximation to x. There are two situations in which this problem is often considered. In one setting, we can design the matrix Φ. In this case, we want Φ to implement some hashing-based function. The major things to minimize are, the number of rows of Φ, the column sparsity of Φ (encoding time), and decoding time [GI10]. Alternatively, in some other settings, we cannot design the matrix Φ. Typically, in this setting, Φ is a discrete Fourier matrix, and the problem is referred to as the sparse Fourier transform problem. In this case, we want to smartly take some samples from Φx, and those samples are able to do a hashing job. The major things to minimize are sample complexity and decoding time.

The sparse Fourier transform also can be defined in the continuous setting. This problem can be thought of as the mathematical abstraction of supperresolution problems [Moi15], the development of which was awarded the 2014 Nobel Prize in Chemistry. Intuitively, in the discrete setting we are working with a matrix Φ of finite size, but in the continuous setting, we need to understand the "infinite matrix" Φ, which is more formally a linear operator over functions. However, by generalizing intuitions from the finite setting, many of the ideas can be transferred over to this infinite setting. In the continuous setting, there is one more important parameter to consider, in addition to the ones mentioned above. Namely, we should try to minimize the duration of the signal our algorithm needs to observe.

- The setting where we can design Φ is often called the *compressed sensing* problem [Don06, CRT06b]. We give a new construction of Φ and the corresponding algorithm that improves the classical L2/L2 compressed sensing task [NS19].
- We give a new iterating algorithm for the d-dimensional discrete sparse Fourier transform with nearly optimal sample complexity [NSW19a].
- In the continuous setting, in [PS15] we propose an algorithm for the robust sparse Fourier transform under the assumption of a frequency gap. The sample complexity is linear in k and logarithmic in the signal-to-noise ratio and the frequency resolution. Previous results with similar sample complexities could not tolerate an infinitesimal amount of i.i.d. Gaussian noise, and even algorithms with higher sample complexities increased the noise by a polynomial factor. We also give new results for how precisely the individual frequencies of the signal can be recovered.

– The previously mentioned work of [PS15] relies on recovering the frequencies, and as a result, requires a dependence on the frequency gap. However, if all we care about is reconstructing a k-sparse signal which is close to the original, but which potentially uses different frequencies, such a gap is not necessary. In [CKPS16], we demonstrate an algorithm for the robust sparse Fourier transform that does not require any dependence on the frequency gap. In some ways, both [PS15] and [CKPS16] can be thought of generalizations of the aforementioned hashing techniques to the continuous setting.

1.2 Optimization

Linear programming is one of the key problems in computer science. In both theory and practice, many problems can be reformulated as linear programs to take advantage of fast algorithms. For an arbitrary linear program $\min_{Ax=b,x\geq 0} c^\top x$ with n variables and d constraints[1], the fastest algorithm takes $O^*(\sqrt{d}\cdot \text{nnz}(A) + d^{2.5})$[2] where $\text{nnz}(A)$ is the number of non-zeros in A [LS14, LS15].

For the generic case $d = \Omega(n)$ we focus in this thesis, the current fastest runtime is dominated by $O^*(n^{2.5})$. This runtime has not been improved since the result by Vaidya on 1989 [Vai87, Vai89b]. The $n^{2.5}$ bound originated from two factors: the cost per iteration n^2 and the number of iterations $\sqrt{n}$. The n^2 cost per iteration looks optimal because this is the cost to compute Ax for a dense A. Therefore, many efforts [Kar84, Ren88, NN89, Vai89a,

[1] Throughout this thesis, we assume there is no redundant constraints and hence $n \geq d$. Note that papers in different communities uses different symbols to denote the number of variables and constraints in a linear program.

[2] We use O^* to hide $n^{o(1)}$ and $\log^{O(1)}(1/\delta)$ factors and $\widetilde{O}$ to hide $\log^{O(1)}(n/\delta)$ factors.

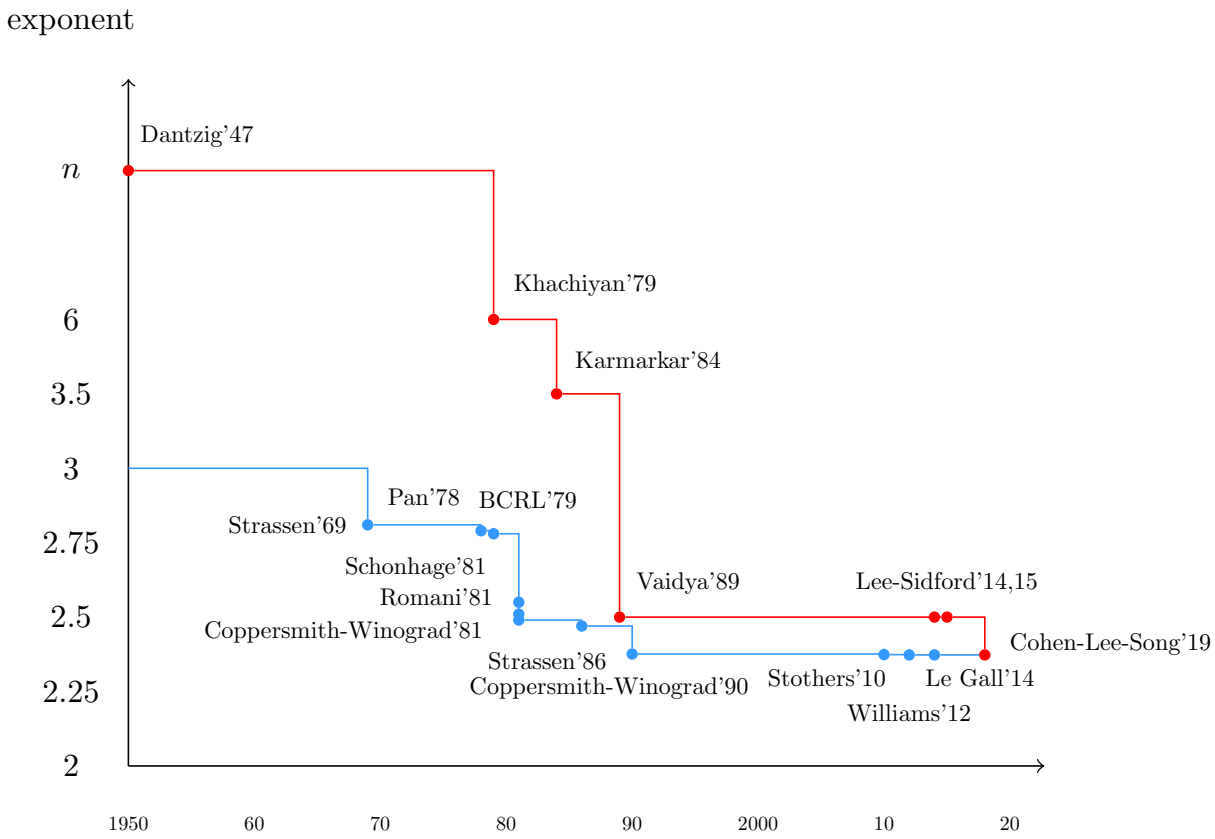

Figure 1.1: Linear Programming is Chasing Matrix Multiplication

LS14] have been focused on decreasing the number of iterations while maintaining the cost per iteration. As for many important linear programs (and convex programs), the number of iterations has been decreased, including maximum flow [Mad13, Mad16], minimum cost flow [CMSV17], geometric median [CLM+16], matrix scaling and balancing [CMTV17], and ℓ_p regression [BCLL18]. Unfortunately, beating $\sqrt{n}$ iterations (or $\sqrt{d}$ when $d \ll n$) for the general case remains one of the biggest open problems in optimization.

Avoiding this open problem, this thesis develops a stochastic central path method that has a runtime of $O^*(n^\omega + n^{2.5-\alpha/2} + n^{2+1/6})$, where ω is the exponent of matrix multiplication

and α is the dual exponent of matrix multiplication[3]. For the current value of $\omega \sim 2.38$ and $\alpha \sim 0.31$, the runtime is simply $O^*(n^\omega)$. This achieves the natural barrier for solving linear programs because linear system is a special case of linear program and that the currently fastest way to solve general linear systems involves matrix multiplication. Despite the exact approach used in [CW87, Wil12, DS13, LG14] cannot give a bound on ω better than 2.3078 [AFLG15] and all known approaches cannot achieve the bound $\omega = 2$ [AW18b], it is still possible that $\omega = 2.01$ using all known approaches. Therefore, we believe improving the additive $2 + 1/6$ term remains an interesting open problem.

Our method is a stochastic version of the short step central path method. This short step method takes $O^*(\sqrt{n})$ steps and each step decreases $x_i s_i$ by a $1 - 1/\sqrt{n}$ factor for all i where s is the dual variable [Ren88] (See the definition of s in (2.1)). This results in $O^*(\sqrt{n}) \times n = O^*(n^{1.5})$ coordinate updates. Our method takes the same number of step but only updates $\widetilde{O}(\sqrt{n})$ coordinates each step. Therefore, we only update $O^*(n)$ coordinates in total, which is nearly optimal.

Our framework is efficient enough to take a much smaller step while maintaining the same running time. For the current value of $\omega \sim 2.38$, we show how to obtain the same runtime of $O^*(n^\omega)$ by taking $O^*(n)$ steps and $\widetilde{O}(1)$ coordinates update per steps. This is because the complexity of each step decreases proportionally when the step size decreases. Beyond the cost per iteration, we remark that our algorithm is one of the very few central path algorithms [PRT02, Mad13, Mad16] that does not maintain $x_i s_i$ close to some ideal vector in ℓ_2 norm. We are hopeful that our stochastic method and our proof will be useful

[3]The dual exponent of matrix multiplication α is the supremum among all $a \geq 0$ such that it takes $n^{2+o(1)}$ time to multiply an $n \times n$ matrix by an $n \times n^a$ matrix.

Table 1.1: Let ω denote the exponent of the current matrix multiplication. "Iters" denotes the "number of iterations". "Cost/Iter" denotes the "cost per iteration". LP has n variables, $d = n$ constraints, and can be encoded in L input bits. We consider the case where A is a dense full rank matrix. We remark that all of results have difference when $\mathrm{rank}(A)$ is low rank, $\mathrm{nnz}(A)$ is sparse and $n \not\approx d$. However, when $d = n$, $\mathrm{rank}(A) = n$ and $\mathrm{nnz}(A) = n^2$, the running time remains to be $O(n^{2.5})$ for three decades.

for future research on interior point methods. In particular, it would be interesting to see how this can be combined with techniques in [Cla95, LS14] to get a faster algorithm for linear programs with $d \ll n$.

Besides the applications to linear programs, some of our techniques are probably useful for studying other important problems in convex optimization. In particular, our framework should be naturally extendable to a larger class of convex programs.

Empirical Risk Minimization Empirical Risk Minimization (ERM) problem is a fundamental question in statistical machine learning. There are a huge number of papers that have considered this topic [Nes83, Vap92, PJ92, Nes04, BBM05, BB08, NJLS09, MB11, FGRW12, LRSB12, JZ13, Vap13, SSZ13, DB14, DBLJ14, FGKS15, DB16, SLC+17, ZYJ17, ZX17, ZWX+17, GSS17, MS17, NS17, AKK+17, Csi18, JLGJ18] as almost all convex optimization

machine learning can be phrased in the ERM framework [SSBD14, Vap92]. While the statistical convergence properties and generalization bounds for ERM are well-understood, a general runtime bound for general ERM is not known although fast runtime bounds do exist for specific instances [AKPS19].

Examples of applications of ERM include linear regression, LASSO [Tib96], elastic net [ZH05], logistic regression [Cox58, HJLS13], support vector machines [CV95], ℓ_p regression [Cla05, DDH+09, BCLL18, AKPS19], quantile regression [Koe00, KH01, Koe05], AdaBoost [FS97], kernel regression [Nad64, Wat64], and mean-field variational inference [XJR02].

The classical Empirical Risk Minimization problem is defined as

$$\min_x \sum_{i=1}^m f_i(a_i^\top x + b_i)$$

where $f_i : \mathbb{R} \to \mathbb{R}$ is a convex function, $a_i \in \mathbb{R}^d$, and $b_i \in \mathbb{R}$, $\forall i \in [m]$. Note that this formulation also captures most standard forms of regularization as well.

Letting $y_i = a_i^\top x + b_i$, and $z_i = f_i(a_i^\top x + b_i)$ allows us to rewrite the original problem in the following sense,

$$\begin{aligned} \min_{x,y,z} \quad & \sum_{i=1}^m z_i \\ \text{s.t.} \quad & Ax + b = y \\ & (y_i, z_i) \in K_i = \{(y_i, z_i) : f_i(y_i) \le z_i\}, \forall i \in [m] \end{aligned} \tag{1.1}$$

We can consider a more general version where dimension of K_i can be arbitrary, e.g. n_i. Therefore, we come to study the general n-variable form

$$\min_{x \in \prod_{i=1}^m K_i, Ax=b} c^\top x$$

where $\sum_{i=1}^{m} n_i = n$. We give a result for solving the general model.

First-order algorithms for ERM are well-studied and a long series of accelerated stochastic gradient descent algorithms have been developed and optimized [Nes98, JZ13, XZ14, SSZ14, FGKS15, LMH15, MLF15, AY16, RHS+16, SS16, AH16, SLRB17, MS17, LMH17, LJCJ17, All17b, All17a, All18b, All18a]. However, these rates depend polynomially on the Lipschitz constant of ∇f_i and in order to achieve a $\log(1/\epsilon)$ dependence, the runtime will also have to depend on the strong convexity of the $\sum_i f_i$. In this thesis, we want to focus on algorithms that depend logarithmically on diameter/smoothness/strong convexity constants, as well as the error parameter ϵ. Note that gradient descent and a direct application of Newton's method do not belong to these class of algorithms, but for example, interior point method and ellipsoid method does.

Therefore, in order to achieve high-accuracy solutions for non-smooth and non strongly convex case, most convex optimization problems will rely on second-order methods, often under the general interior point method (IPM) or some sort of iterative refinement framework. So, we note that our algorithm is thus optimal in this general setting since second-order methods require at least n^ω runtime for general matrix inversion.

Our algorithm applies the interior point method framework to solve ERM. The most general interior point methods require $O(\sqrt{n})$-iterations of linear system solves [Nes98], requiring a naive runtime bound of $O(n^{\omega+1/2})$. Using the inverse maintenance technique [Vai89b, CLS19], one can improve the running time for LP to $O(n^\omega)$. This essentially implies that almost all convex optimization problems can be solved, up to subpolynomial factors, as fast as linear regression or matrix inversion!

The specific case of ℓ_2 regression can be solved in $O(n^\omega)$ time since the solution is explicitly given by solving a linear system. In the more general case of ℓ_p regression, [BCLL18] proposed a $\widetilde{O}_p(n^{|1/2-1/p|})$-iteration iterative solver with a naive $O(n^\omega)$ system solve at each step. Recently, [AKPS19] improved the runtime to $\widetilde{O}_p(n^{\max(\omega,7/3)})$, which is current matrix multiplication time as $\omega > 7/3$. However, both these results depend exponentially on p and fail to be impressive for large p. Otherwise, we are unaware of other ERM formulations that have have general runtime bounds for obtaining high-accuracy solutions.

Recently several works [AW18a, AW18b, Alm19] try to show the limitation of current known techniques for improving matrix multiplication time. Alman and Vassilevska Williams [AW18b] proved limitations of using the Galactic method applied to many tensors of interest (including Coppersmith-Winograd tensors [CW87]). More recently, Alman [Alm19] proved that by applying the Universal method on those tensors, we cannot hope to achieve any running time better than $n^{2.168}$ which is already above our $n^{2+1/6}$.

Algorithmic Theory of ODEs The complexity of sampling a high-dimensional density of the form $e^{-f(x)}$ where f is a convex function is a fundamental problem with many applications [LS90, LS92, LS93, LV06a, LV06b, Dal17, DK17, DRD18, DCWY18]. The focus of this part is to give very fast, i.e., nearly linear time algorithms, for a large subclass of such densities. A motivating and important case is the loss function for logistic regression, widely used in machine learning applications [Ber44, Paa00, NJ02, HJLS13, Bou14]:

$$\sum_{i=1}^{n} \phi_i(a_i^\top x)$$

where ϕ_i are convex functions; a popular choice is $\phi(t) = \log(1 + e^{-t})$. Sampling according to e^{-f} for this choice of f corresponds to sampling models according to their KL-divergence,

a natural and effective choice for classification problems [HJLS13].

A general approach to sampling is by an ergodic Markov chain whose stationary distribution is designed to have the desired density. Traditionally, this is done via a Metropolis filter, which accepts a proposed (random) next step y from the current point x with probability $\min\{1, \frac{f(y)}{f(x)}\}$. While very general, one downside of this approach is the possibility of high rejection probabilities, which typically force local steps to be very small. Nevertheless, for arbitrary logconcave functions (including nonsmooth ones), this approach has the current best guarantees [LV06b].

Another family of algorithms is derived from an underlying *continuous* stochastic process with the desired stationary density. A classic example of such a continuous process is Brownian motion. To sample a convex body for example, one could use Brownian motion with a boundary reflection condition. This is written as the stochastic equation:

$$\mathrm{d}X_t = \mathrm{d}W_t$$

with reflection at the boundary of the domain, and dW_t being infinitesimal Brownian motion. To sample from the density proportional to $e^{-f(x)}$, one can use the stochastic differential equation,

$$\mathrm{d}X_t = -\nabla f(X_t)\mathrm{d}t + \sqrt{2}\mathrm{d}W_t.$$

By the classical Fokker-Planck equation, under mild assumptions on f, the stationary density of this process is proportional to $e^{-f(x)}$.

How can we turn these continuous processes into algorithms? One approach is to take small rather than infinitesimal steps, and this leads to the Langevin dynamics, of which there are multiple flavors [Dal17, DK17, ZLC17, RRT17, DRD18, CCBJ18, CCAY+18, CFM+18].

Table 1.2: Summary of results, d is the dimension, κ is the condition number of $\nabla^2 f$. "Iters" denotes "the number of iterations / parallel depth". "Gra/Iter" denotes the "the number of gradients per iteration". We use the parallel depth of the algorithm as the number of iterations. We suppress polylogarithmic terms and dependence on the error parameter. Ball walk/hit-and-run apply to general logconcave distributions, the rest assume strongly logconcave with Lipschitz gradient and possibly more. "B./H." denotes "Ball Walk/Hit-and-run". "DL" denotes "Damped Langevin". In all previous work, for simplicity, we report the most favorable bounds by making various assumptions such as $\kappa \ll d$.

Starting with Dalalyan [Dal17], it has been established that these dynamics converge in polynomial (in dimension) time for strongly logconcave functions, with the underdamped version converging in $O(\sqrt{d})$ iterations (and polynomial dependences on appropriate condition numbers) [CCBJ18]. The dependence on dimension seems unavoidable in the discretized algorithm, even though the continuous process has no such dependence.

Hamiltonian Monte Carlo. HMC is a random process that maintains a position x and velocity pair v. To sample according to e^{-f}, we define a Hamiltonian $H(x, v) = f(x) + \frac{1}{2}\|v\|^2$.

At each step v is chosen randomly from $N(0, I)$ and x is updated using the following Ordinary Differential Equation (ODE) for a some fixed time interval.

$$\frac{\mathrm{d}x(t)}{\mathrm{d}t} = v(t), \quad \frac{\mathrm{d}v(t)}{\mathrm{d}t} = -\nabla f(x(t)). \tag{1.2}$$

This process has the particularly nice property that it conserves the value of H, and as a result there is no need to apply a Metropolis filter. HMC has been studied in many works [MS17, MV18, LV18]. Mangoubi and Smith [MS17] gave the following guarantee for strongly logconcave densities.

Note that Eq. (1.2) is a special case of the following first order ODE

$$\frac{\mathrm{d}}{\mathrm{d}t}x(t) = F(x(t), t), x(0) = v$$

where $F : \mathbb{R}^{d+1} \to \mathbb{R}^d$, $x(t) \in \mathbb{R}^d$ and $v \in \mathbb{R}^d$.

Moreover, we can write the k-th order ODE in the following way

$$\frac{\mathrm{d}^k}{\mathrm{d}t^k}x(t) = F(\frac{\mathrm{d}^{k-1}}{\mathrm{d}t^{k-1}}x(t), \cdots, x(t), t)$$
$$\frac{\mathrm{d}^i}{\mathrm{d}t^i}x(0) = v_i, \forall i \in \{k-1, \cdots, 1, 0\}.$$

where $F : \mathbb{R}^{kd+1} \to \mathbb{R}^d$, $x(t) \in \mathbb{R}^d$, and $v_0, v_1, \cdots, v_{k-1} \in \mathbb{R}^d$.

To solve HMC such special case ODE efficiently, it requires a better understanding of the ODE system. We analyze the collocation method for solving ODEs [Ise09]. This method is classical in numerical analysis.

We present the multivariate high-oder ODE guarantee. This generalizes and improves on the guarantee from [LV17]. Note that our result is a general result about solving ODE

efficiently, independent of the application to sampling. The only assumptions needed are that the ODE function is Lipschitz and that the solution is close to the span of small number of basis of functions. These natural assumptions suffice to get around the worst-case complexity lower bounds for solving such general ODEs [KF82, Ko83, Ko10, Kaw10, KC12].

Deep Neural Networks Neural networks have demonstrated a great success in numerous machine-learning tasks [KSH12, GMH13, LHP+15, AAA+16, HZRS16, SHM+16, SSS+17]. One of the empirical findings is that neural networks, trained by first-order methods from random initialization, have a remarkable ability to fit training data [ZBH+17].

From an *expressibility* perspective, this may not be surprising since modern neural networks are often over-parameterized: they have much more parameters than the number of training samples. There certainly *exist* parameter choices with zero training error as long as data is non-degenerate.

Yet, from an optimization perspective, the fact that randomly-initialized first-order methods can find global minima on the training data is *quite non-trivial*: neural networks are often equipped with the ReLU activation, making the training objective not only non-convex, but even non-smooth. Even the general convergence for finding approximate critical points of a non-convex, non-smooth function is not fully-understood [BLO05] and appears to be a challenging question on its own. This is in direct contrast to practice, in which ReLU networks trained by stochastic gradient descent (SGD) from random initialization *almost never* suffer from non-smoothness or non-convexity, and can avoid local minima for a variety of network architectures (see [GVS15]). A theoretical justification was missing to explain this phenomenon.

There are quite a few papers trying to understand the success of neural networks from optimization perspective. Many of them focus on the case when the inputs are random Gaussian, and work only for two-layer neural networks [BG17, Son17, Tia17, LY17, DLT+18, GLM17, PRSZ18, ZSJ+17, ZSD17]. [LL18] show that for a two-layer network with ReLU activation, SGD finds nearly-global optimal (say, 99% classification accuracy) solutions on the training data, as long as the network is *over-parameterized*, meaning that the number of neurons is polynomially large comparing to the input size. Moreover, if the data is sufficiently structured (say, coming from mixtures of separable distributions), this accuracy extends also to *test data*. As a separate note, over-parameterization is suggested as the possible key to avoid bad local minima by [SS18] even for two-layer networks.

There are also results that go beyond two-layer networks with limitations. Some consider deep *linear* neural networks without any activation functions [HM17, ACGH18, BHL18, Kaw16]. [Dal17] studies multi-layer neural networks but essentially only with respect to the *convex* task of training the last layer.[4] [SC16] show that under over-parameterization and under random input perturbation, there is bad local minima for multi-layer neural networks. [JGH18] derive global convergence using neural tangent kernel for *infinite-width* neural networks.

In this thesis, we study the following fundamental questions

Can DNN be trained close to zero training error efficiently under mild assumptions?

If so, can the running time depend only polynomially *in the network depth and input size?*

[4] [Dal17] works in a parameter regime where the weight changes of all layers except the last one make negligible contribution to the final output.

Motivation In 2012, AlexNet was born with 5 convolutional layers [KSH12]. The later VGG network uses 19 layers [SSZ14], and GoogleNet uses 22 layers [SLJ+15]. In practice, we cannot go deeper by naively stacking layers together, due to the so-called vanishing/exploding gradient problem. To deal with this issue, networks with residual links (ResNet) were proposed with the capability of handling at least 152 layers [HZRS16]. Compared with practical networks that go much deeper, existing theory has been mostly around two-layer (thus one-hidden-layer) neural networks, even just for the training process alone. Thus,

Can we theoretically justify how the training process has worked for multi-layer neural networks?

In this thesis, we extend the over-parameterization theory to *multi-layer* neural networks.

Recurrent Neural Networks Among different architectures of neural networks, one of the *least* theoretically-understood structure is the recurrent one [Elm90]. A recurrent neural network recurrently applies the same network unit to a sequence of input tokens, such as a sequence of words in a language sentence. RNN is particularly useful when there are long-term, non-linear interactions between input tokens in the same sequence. These networks are widely used in practice for natural language processing, language generation, machine translation, speech recognition, video and music processing, and many other tasks [MKB+10, MKB+11, SSN12, KB13, SSB14, SVL14, CVMBB14, CGCB14]. On the theory side, while there are some attempts to show that an RNN is more expressive than a feedforward neural network [KNO18], when and how an RNN can be efficiently learned has little theoretical explanation.

In practice, RNN is usually trained by simple local-search algorithms such as SGD. However, unlike shallow networks, the training process of RNN often runs into the trouble of vanishing or exploding gradient [SMH11]. That is, the value of the gradient becomes exponentially small or large in the time horizon, even when the training objective is still constant. [5]

In practice, one of the popular ways to resolve this is by the long short term memory (LSTM) structure [HS97]. However, one can also use rectified linear units (ReLUs) as activation functions to avoid vanishing or exploding gradient [SBS+17]. In fact, one of the earliest adoptions of ReLUs was on applications of RNNs for this purpose twenty years ago [Hah98, SA96].

Since the RNN structure was proposed, a large number of variations have been designed over past decades. For a more detailed survey, we refer the readers to [SBS+17].

In this thesis, we study the following general question

- *Can ReLU provably stabilize the training process and avoid vanishing/exploding gradient?*
- *Can RNN be trained close to zero training error* efficiently *under mild assumptions?*

Remark 1.2.1. When there is no activation function, RNN is known as *linear dynamical system*. Hardt, Ma and Recht [HMR18] first proved the convergence of finding global minima for

[5] Intuitively, an RNN recurrently applies the same network unit for L times if the input sequence is of length L. When this unit has "operator norm" larger than one or smaller than one, the final output can possibly exponentially explode or vanish in L. More importantly, when one back propagates through time —which intuitively corresponds to applying the reverse unit multiple times— the gradient can also vanish or explode. Controlling the operator norm of a non-linear operator can be quite challenging.

such linear dynamical systems. Followups in this line of research include [HSZ17, HLS+18].

1.3 Concentration

The study of concentration of sums of random variables dates back to Central Limit Theorems, and hence de Moivre and Laplace [Tij], while modern concentration bounds for sums of random variables were perhaps first established by Bernstein [Ber24], and a popular variant now known as Chernoff bounds was introduced by Rubin and published by Chernoff [Che52].

Concentration of measure for matrix-valued random variables is the phenomenon that many matrix valued distributions are to close their mean with high probability, closeness usually being measured by spectral norm. Modern quantitative bounds of the form often used in theoretical computer science were derived by Rudelson [Rud99], while Ahlswede and Winter [AW02] established a useful matrix-version of the Laplace transform that plays a central role in scalar concentration results such as those of Bernstein. [AW02] combined this with the Golden-Thompson trace inequality to prove matrix concentration results. Tropp refined this approach, and by replacing the use of Golden-Thompson with deep a theorem on concavity of certain trace functions due to Lieb, Tropp was able to recover strong versions of a wide range of scalar concentration results, including matrix Chernoff bounds, Azuma and Freedman's inequalities for matrix martingales [Tro12].

Matrix concentration results have had an enormous range of applications in computer science, and are ubiquitous throughout spectral graph theory [ST04, SS11, CKP+17], sketching [Coh16a], approximation algorithms [HSSS16], numerical linear algebra, quantum information theory, and deep learning [ZSJ+17, ZSD17, SY19]. Most applications are based on results for independent random matrices, but more flexible bounds, such as Tropp's Matrix Freedman Inquality [Tro11a], have been used to greatly simplify algorithms, e.g.

for solving Laplacian linear equations [KS16] and for semi-streaming graph sparsification [AG09, KPPS17]. Matrix concentration results are also closely related to other popular tools sampling tools, such as Karger's techniques for generating sparse graphs that approximately preserve the cuts of denser graphs [BK96].

We formally state the natural generalization of the Chernoff bound appeared in the works of Rudelson [Rud99], Ahlswede-Winter [AW02], and Tropp [Tro12]. They showed that a similar concentration phenomenon is true for *matrix-valued* random variables. In particular, if $X_1, \ldots, X_k$ are independent $d \times d$ complex Hermitian random matrices with $\|X_i\| \leq 1$, then the following is true:

$$\Pr\left[\left\|\frac{1}{k}\sum_{i=1}^{k} X_i - \mathbb{E}[X]\right\| > \epsilon\right] \leq 2d \cdot \exp(-\Omega(k\epsilon^2)). \tag{1.3}$$

The only difference between this and the usual Chernoff bound is the factor of d in front of the deviation probability; to see that it is necessary, notice that the diagonal case simply corresponds to a direct sum of d arbitrarily correlated instances of the scalar Chernoff bound, so by the union bound the probability should be d times as large in the worst case. This so called "Matrix Chernoff Bound".

Expander Walk An important generalization of this bound was achieved by Gillman [Gil98] (with refinements later by [Lez98, Kah97, LP04, WX05, Hea08, Wag08, CLLM12, RR17]), who significantly relaxed the independence assumption to Markov dependence. In particular, suppose G is a regular graph with vertex set $V = [n]$, $X : V \to \mathbb{C}$ is a bounded function, and $v_1, \ldots, v_k$ is a stationary random walk[6] of length k on G. Then, even though

[6]That is the first vertex v_1 is chosen uniformly at random – which is the stationary distribution of the graph G.

the random variables $X(v_i)$ are in not independent (except when G is the complete graph with self loops), it is shown that:

$$\Pr\left[\left|\frac{1}{k}\sum_{i=1}^{k} X(v_i) - \mathbb{E}[X]\right| > \epsilon\right] \leq 2 \cdot \exp(-\Omega((1-\lambda)k\epsilon^2)), \tag{1.4}$$

where $1-\lambda$ is the spectral gap of the transition matrix of the random walk. The gain here is that sampling a stationary random walk of length k on a constant degree graph with constant spectral gap requires $\log(n) + O(k)$ random bits, which is much less than the $k\log(n)$ bits required to produce k independent samples. Since such graphs can be explicitly constructed, this leads to a generic "derandomization" of the Chernoff bound, which has had several important applications (see [WX05] for a detailed discussion). In particular, it leads to the following randomness efficient sampler for scalar-valued functions ([Gil98]) using known strongly explicit constructions of expander graphs [RVW00, LPS88]:

Theorem 1.3.1 ([Gil98])**.** *For any $\epsilon > 0$ and $k \geq 1$, there is a $\mathrm{poly}(r)$-time computable sampler $\sigma : \{0,1\}^r \to [n]^k$, where $r = \log(n) + O(k)$ s.t. for all functions $f : [n] \to [-1,1]$ satisfying $\mathbb{E}\, f = 0$, we have that*

$$\Pr_{w \in_R \{0,1\}^r}\left[\left|\frac{1}{k}\sum_{i=1}^{k} f(\sigma(w)_i)\right| \geq \epsilon\right] \leq 2\exp\left(-\Omega\left(\epsilon^2 k\right)\right).$$

In many applications of interest k is about $\log(n)$, and going from $O(\log^2(n))$ to $O(\log(n))$ random bits leads to a complete derandomization by cycling over all seeds $w \in \{0,1\}^r$.

It is natural to wonder whether there is a common generalization of (1.4) and (1.3), i.e., a "Matrix Expander Chernoff Bound". Such a result was conjectured by Wigderson and

Xiao in [WX06]. In this thesis, we prove the Wigderson and Xiao conjecture. In order to prove that conjecture, we also propose a new Golden-Thompson inequality. The original Golden-Thompson inequality only holds for two matrices [Gol65, Tho65]. Our new Golden-Thompson inequality holds for multiple matrices.

Strongly Rayleigh and Matrix Chernoff for Random Spanning Trees Negative dependence of random variables is an appealing property that intuition suggests should help with concentration of measure. Notions of negative dependence can be formalized in many ways. Roughly speaking, these notions characterize distributions where where some event occurring ensures that other events of interest become less likely. A simple example is the distribution of a sequence of coin flips, conditioned on the total number of heads in the outcome. In this distribution, conditioning on some coin coming out heads makes all other coins less likely to come out heads. Unfortunately, negative dependence phenomena are not as robust as positive association which can be established from local conditions using the powerful FKG theorem [FKG71].

Strongly Rayleigh distributions were introduced recently by Borcea, Brändén, and Liggett [BBL09] as a class of negatively dependent distributions of binary-valued random variables with many useful properties. Strongly Rayleigh distributions satisfy useful negative dependence properties, and retain these properties under natural conditioning operations. Strongly Rayleigh distributions also satisfy a powerful stability property under conditioning known as *Stochastic Covering* [PP14], which is useful for analyzing them through martingale techniques. A measure on $\{0,1\}^n$ is said to be Strongly Rayleigh if its generating polynomial is real stable [BBL09]. There are many interesting examples of Strongly Rayleigh distribu-

tions [PP14]: The example mentioned earlier of heads of independent coin flips conditional on the total number of heads in the outcome; symmetric exclusion processes; determinental point processes and determinental measures on a boolean lattice. An example of particular interest to us is the edges of uniform or weighted random spanning trees, which form a Strongly Rayleigh distribution.

We prove a Matrix Chernoff bound for the case of k-homogeneous Strongly Rayleigh distributions. Our bound is slightly weaker than the bound for independent variables. We give lower bounds that show our bounds are close to tight in some regimes, but importantly, our lower bounds do not establish separation from the behaviour of indepedent random matrices, leaving open the question of whether the true bound should match the independent case in all regimes – which seems plausible.

We use our bound to show new concentration results related to random spanning trees of graphs. Random spanning trees are one among the most well-studied probabilistic objects in graph theory, going back to the work of Kirchoff [Kir47] in 1847, who gave formula relating the number of spanning trees in a graph to the determinant of the Laplacian of the same graph.

Algorithms for sampling of random spanning trees have been studied extensively, [Gue83, Bro89, Ald90, Kul90, Wil96, CMN96, KM09, MST15, HX16, DKP$^+$17, DPPR17, Sch18], and a random spanning tree can now be sampled in almost linear time [Sch18]. There is also a long line [BK96, ST11, SS11, BSS12, Zou12, LS17, LS18] of research about generating graph spectral sparsifier as fast as possible. However, the connection between those two objects is open for decades. We answer the question positively by providing the following result

Theorem 1.3.2. *Given as input a weighted graph G with n vertices and a parameter $\epsilon > 0$, let $T_1, T_2, \cdots, T_t$ denote t independent inverse leverage score weighted random spanning trees, if we choose $t = O(\epsilon^{-2} \log^2 n)$ then with probability $1 - 1/\operatorname{poly}(n)$,*

$$(1-\epsilon)L_G \preceq \frac{1}{t}\sum_{i=1}^{t} L_{T_i} \preceq (1+\epsilon)L_G.$$

In addition, we also show $t = \Omega(\epsilon^{-2} \log n)$ is necessary.

Discrepancy Discrepancy theory is an area of combinatorics that studies how well continuous objects can be approximated by discrete ones. It lies at the heart of numerous problems in mathematics and computer science [Cha00]. Although closely tied to probability theory, direct randomized approaches rarely yield the best bounds. In a classical formulation in discrepancy theory, we have n sets on n elements, and would like to two-color the elements so that each set has roughly the same number of elements of each color. Using a simple random coloring, it is an easy consequence of Chernoff's bound that there exists a coloring such that the discrepancy in all n sets is $O(\sqrt{n \log n})$ [AS16]. However, in a celebrated result, Spencer showed that in fact there is a coloring with discrepancy at most $6\sqrt{n}$ [Spe85].

Recently, there has been significant success in generalizing Chernoff [Che52], Hoeffding, Bernstein, and Bennett-type concentration bounds for scalar random variables to matrix-valued random variables [Rud99, AW02, Tro12]. Consider the following matrix concentration bound, which is a direct consequence of a matrix Hoeffding bound.

Theorem 1.3.3 ([Tro12])**.** *Let $\xi_i \in \{\pm 1\}$ be independent, symmetric random signs and $A_1, \ldots, A_n \in \mathbb{C}^{m \times m}$ be positive semi-definite matrices. Suppose $\max_{i \in [n]} \|A_i\| \leq \epsilon$ and*

$\|\sum_{i=1}^n A_i\| \leq 1$. *Then,*

$$\Pr\left[\left\|\sum_{i=1}^n \xi_i A_i\right\| \geq t\sqrt{\epsilon}\right] \leq 2m\exp(-t^2/2).$$

A consequence of this theorem is that with high probability

$$\left\|\sum_{i=1}^n \xi_i A_i\right\| = O(\sqrt{\log m})\sqrt{\epsilon}. \tag{1.5}$$

The Kadison-Singer theorem of [MSS15b] is essentially equivalent to the following statement (which can readily be derived from the bipartition statement in [MSS15b]).

Theorem 1.3.4 (Kadison-Singer [MSS15b])**.** *Let* $u_1, \ldots, u_n \in \mathbb{C}^m$ *and suppose* $\max_{i\in[n]} \|u_i u_i^*\| \leq \epsilon$ *and* $\sum_{i=1}^n u_i u_i^* = I$*. Then, there exists signs* $\xi_i \in \{\pm 1\}$ *s.t.*

$$\left\|\sum_{i=1}^n \epsilon_i u_i u_i^*\right\| \leq O(\sqrt{\epsilon}).$$

Thus, for rank 1 matrices the theorem improves on the norm bound in Equation (1.5), by a factor $\sqrt{\log m}$, in a manner analogous to the improvement of Spencer's theorem over the bound based on the scalar Chernoff bound.

For random signings of matrices one can establish bounds in some cases that are much stronger than Theorem 1.3.3.

Theorem 1.3.5 ([Tro12])**.** *Let* $\xi_i \in \{\pm 1\}$ *be independent random signs, and let* $A_1, \ldots, A_n \in \mathbb{C}^{m\times m}$ *be Hermitian matrices. Let* $\sigma^2 = \|\sum_{i=1}^n \mathbb{V}[\xi_i]A_i^2\|$*. Then,*

$$\Pr\left[\left\|\sum_{i=1}^n \mathbb{E}[\xi_i]A_i - \sum_{i=1}^n \xi_i A_i\right\| \geq t\cdot\sigma\right] \leq 2m\exp(-t^2/2).$$

From this theorem we deduce that with high probability

$$\left\| \sum_{i=1}^{n} \mathbb{E}[\xi_i] A_i - \sum_{i=1}^{n} \xi_i A_i \right\| = O(\sqrt{\log m})\sigma. \tag{1.6}$$

Of course, this implies that there exists a choice of signs $\epsilon_1, \ldots, \epsilon_n \in \{\pm 1\}$ such that

$$\left\| \sum_{i=1}^{n} \mathbb{E}[\xi_i] A_i - \sum_{i=1}^{n} \epsilon_i A_i \right\| = O(\sqrt{\log m})\sigma.$$

For rank-1 matrices, we want to show there exists a choice of signs with a stronger guarantee. Formally speaking, we can prove the following result.

Theorem 1.3.6. *Consider any independent scalar random variables $\xi_1, \ldots, \xi_n$ with finite support. Let $u_1, \ldots, u_n \in \mathbb{C}^m$ and*

$$\sigma^2 = \left\| \sum_{i=1}^{n} \mathbb{V}[\xi_i](u_i u_i^*)^2 \right\|.$$

Then there exists a choice of outcomes $\epsilon_1, \ldots, \epsilon_n$ in the support of $\xi_1, \ldots, \xi_n$

$$\left\| \sum_{i=1}^{n} \mathbb{E}[\xi_i] u_i u_i^* - \sum_{i=1}^{n} \epsilon_i u_i u_i^* \right\| \leq O(\sigma).$$

1.4 Compressed Sensing and Sparse Fourier Transform

Compressed Sensing, or sparse recovery, is a powerful mathematical framework the goal of which is to reconstruct an approximately k-sparse vector $x \in \mathbb{R}^n$ from linear measurements $y = \Phi x$, where $\Phi \in \mathbb{R}^{m \times n}$. The most important goal is to reduce the number of measurements m needed to approximate the vector x, avoiding the linear dependence on n. In discrete signal processing, where this framework was initiated [CRT06b, Don06], the core principle that the sparsity of a signal can be exploited to recover it using much fewer samples than the Shannon-Nyquist Theorem. We refer to the matrix Φ as the sketching or sensing matrix, and $y = \Phi x$ as the sketch of vector x.

Sparse recovery is the primary task of interest in a number of applications, such as image processing [TLW+06, LDP07a, DDT+08], design pooling schemes for biological tests [ECG+09, DWG+13], pattern matching [CEPR07], combinatorial group testing [SAZ09, ESAZ09, KBG+10], localizing sources in sensor networks [ZBSG05, ZPB06], as well as neuroscience [GS12]. Furthermore, not surprisingly, tracking heavy hitters in data streams, also known as frequent items, can be captured by the sparse recovery framework [Mut05a, CH09, KSZC03, Ind07]. In practice, streaming algorithms for detecting heavy hitters have been used to find popular destination addresses and heavy bandwidth users by AT&T [CJK+04] or answer "iceberg queries" in databases [FSGM+99].

Sparse recovery attracts researchers from different communities, from both theoret-

ical and practical perspective. During the last ten years, hundreds of papers have been published by theoretical computer scientists, applied mathematicians and electrical engineers that specialize in compressed sensing. While numerous algorithms using space linear in the universe size n are known, [Don06, CRT06b, IR08a, NT09a, BIR08a, BD09a, SV16] to name a few, our goal is to obtain algorithms that are sublinear, something that is crucial in many applications.

The desirable quantities we want to optimize may vary depending on the application. For example, in network management, x_i could denote the total number of packets with destination i passing through a network router. In such an application, storing the sketching matrix explicitly is typically not a tenable solution, since this would lead to an enormous space consumption; the number of possible IP addresses is 2^{32}. Moreover, both the query and the update time should be very fast, in order to avoid congestion on the network. Incremental updates to x come rapidly, and the changes to the sketch should also be implemented very fast; we note that in this case, even poly-logarithmic factors might be prohibitive. Interested readers can refer to [KSZC03, EV03] for more information about streaming algorithms for network management applications.

"The goal of that research is to obtain encoding and recovery schemes with good compression rate (i.e., short sketch lengths) as well as good algorithmic properties (i.e., low encoding, update and recovery times)." – *Anna Gilbert and Piotr Indyk* [GI10]

In this thesis, we consider the extensively studied problem of L2/L2 compressed sensing. The main contribution of our work is an improvement over [GLPS10] with faster decoding time and significantly smaller column sparsity, answering two open questions of the aforementioned work.

Year	Reference	Measurements	Decoding Time	Encoding Time
2006	[Don06, CRT06b]	$k \log(n/k)$	LP	$k \log(n/k)$
2006	[CCF02, CM06]	$\epsilon^{-2} k \log n$	$\epsilon^{-1} n \log n$	$\log n$
2008	[NT09a]	$k \log(n/k)$	$nk \log(n/k)$	$\log(n/k)$

Table 1.3: (A list of ℓ_2/ℓ_2-sparse recovery results). We ignore the "O" for simplicity. LP denotes the time of solving Linear Programs [CLS19], and the state-of-the-art algorithm takes n^ω time where ω is the exponent of matrix multiplication. The results in [Don06, CRT06b, NT09a] do not explicitly state the ℓ_2/ℓ_2 guarantee, but their approach obtains it by an application of the Johnson-Lindenstrauss Lemma; they also cannot facilitate $\epsilon < 1$, obtaining thus only a 2-approximation. The c in previous work is a sufficiently large constant, not explicitly stated, which is defined by probabilistically picking an error-correcting code of short length and iterating over all codewords. We estimate $c \geq 4$. We note that our runtime is (almost) achieved.

Previous work on sublinear-time compressed sensing employed an iterative procedure, recovering the heavy coordinates in phases. We completely depart from that framework, and give the first sublinear-time L2/L2 scheme which achieves the optimal number of measurements without iterating; this new approach is the key step to our progress. Towards that, we satisfy the L2/L2 guarantee by exploiting the heaviness of coordinates in a way that was not exploited in previous work. Via our techniques we obtain improved results for various sparse recovery tasks, and indicate possible further applications to problems in the field, to which the aforementioned iterative procedure creates significant obstructions.

High-dimensional Discrete Fourier Transform Probably the most important subtopic of compressed sensing/sparse recovery is the sparse Fourier transform, where one desires to

reconstruct a k-sparse vector from Fourier measurements. In other words, measurements are not allowed to be generic, but have to belong to the so-called Fourier ensemble. In Optics imaging [Goo05, Voe11] and Magnetic resonance imaging (MRI) [ASSN08], the physics [Rey89] of the underlying device restricts us to the Fourier ensemble, where the sparse Fourier problem becomes highly relevant. In fact, one of the initial motivations of Candes, Romberg and Tao came out due to the aforementioned applications. The number of samples plays a crucial role: they determine the amount of radiation a patient receives in CT scans, and taking fewer samples can reduce the amount of time the patient needs to stay in the machine. The framework has found its way in practical life-changing applications. Software includes the Compressed Sensing GRAB-VIBE, CS SPACE, CS SEMAC and CS TOF by Siemens [Sie], as well as Compressed Sense by Phillips [Phi]. Its incorporation in the MRI technology allows faster acquisition rates, depiction of dynamic processes or moving organs, as well as acceleration of MRI scanning up to a factor of 40. On the webpage of SIEMENS Healthineers, for example, one can see the following, as well as numerous similar statements.

This allows bringing the advantages of Compressed Sensing GRASP-VIBE *to daily clinical routine.*

- *Perform push-button, free-breathing liver dynamics.*
- *Overcome timing challenges in dynamic imaging and respiratory artifacts.*
- *Expand the patient population eligible for abdominal* MRI.

The Fourier transform is in fact ubiquitous: image processing, audio processing, telecommunications, seismology, polynomial multiplication, Subset Sum and other text-

Table 1.4: $n = p^d$. E.k denotes the "Exactly k-sparse" setting, which is a noiseless setting. "Gua" denotes "Guarantee". We ignore the O for simplicity. The ℓ_∞/ℓ_2 is the strongest possible guarantee, with ℓ_2/ℓ_2 coming second, ℓ_2/ℓ_1 third and exactly k-sparse being the less strong. We note that [CT06, RV08, CGV13, Bou14, HR16] obtain a uniform guarantee, i.e. with $1 - 1/\text{poly}(n)$ they allow reconstruction of all vectors; ℓ_∞/ℓ_2 and ℓ_2/ℓ_2 are impossible in the uniform case [CDD09]. We also note that [RV08, CGV13, Bou14, HR16] give improved analysis of the Restricted Isometry property; the algorithm is suggested and analyzed (modulo the RIP property) in [BD08]. The work in [HIKP12a] does not explicitly state the extension to the d-dimensional case, but can easily be inferred from the arguments. [HIKP12a, IK14, Kap16, KVZ19] work when the universe size in each dimension are powers of 2. We also assume that the signal-to-noise ratio is bounded by a polynomial of n, which is a standard assumption in the sparse Fourier transform literature [HIKP12a, IK14, Kap16, Kap17, LN19].

book algorithms are a few of the examples where the Fast Fourier Transform finds applications. The Fast Fourier Transform by Cooley and Tukey [CT65] runs in $O(n \log n)$ time, and has far-reaching applications in all of the aforementioned cases. It is thus expected that algorithms which exploit sparsity assumptions about the input, and can outperform FFT in applications are of high practical value. Generally, the two most important parameters one

would like to optimize are the sample complexity, i.e. the numbers needed to obtain from the time domain, as well as time needed to approximate the Fourier Transform.

Two different lines of research exist for the problem: the one focuses solely on sample complexity, while the other tries to achieve sublinear time while keeping the sample complexity as low as possible. The first line of research operates via the renowned Restricted Isometry Property (RIP), which proceeds by taking random samples and solving a linear/convex program, or an iterative thresholding procedure [CT06, DDTS06, TG07, BD08, DM08, RV08, BD09b, BD09a, NT09b, NV09, GK09, BD10, NV10, Fou11, Bou14, HR16]. The analysis of the algorithms is performed in the following way, in two steps. The first step ensures that, after sampling an appropriate number of points from the time domain, the inverse DFT matrix restricted on the rows indexed by those points acts as a near isometry on the space of k-sparse vectors. All of the state of the art results [CT06, RV08, Bou14, HR16] employ chaining arguments to make the analysis of this sampling procedure as tight as possible. The second part is how to exploit the aforementioned near-isometry property to find the best k-sparse approximation to the signal. There the approaches either follow an iterative procedure which gradually denoise the signal [BD08, NT09b, NV09], or perform ℓ_1 minimization [CT06], a method that promotes sparsity of solutions.

The second line of research tries to implement arbitrary linear measurements via sampling Fourier coefficients [GL89, Man92, KM93, GGI+02, AGS03, GMS05, Iwe08, Iwe10, HIKP12a, HIKP12b, LWC13, Iwe13, PR14, IKP14, IK14, Kap16, Kap17, CI17, BZI17, MZIC17, LN19] and use sparse functions (in the time domain) which behave like bandpass filters in the frequency domain. The seminal work of Kapralov [Kap17] achieves $O(k \log n)$ samples and running time that is some log factors away from the sample complexity. This

would be the end of the story, apart from the fact that this algorithm does not scale well with dimension, since it has an exponential dependence on d. Indeed, in many applications, one is interested in higher dimensions, rather than the one-dimensional case. The main reason[7] why this curse of dimensionality appears is due to the lack of dimension-independent ways to construct functions that approximate the ℓ_∞ ball and are sufficiently sparse in the time domain. A very nice work of Kapralov, Velingker and Zandieh [KVZ19] tries to remedy that by combining the standard execution of FFT with careful aliasing, but their algorithm works in a noiseless setting, and has a polynomial, rather than linear, dependence on k; the running time is polynomial in $k, \log n$ and the exponential dependence is avoided. It is an important and challenging question whether a robust and more efficient algorithm can be found.

We note that in many applications, such as MRI or computed tomography (CT), the main focus is the sample complexity; the algorithms that have found their way to industry are, to the best of our knowledge, not concerned with sublinear running time, but with the number of measurements, which determine the acquisition time, or in CT the radiation dose the patient receives.

In this work, we consider the extensively studied problem of computing a k-sparse approximation to the d-dimensional Fourier transform of a length n signal. Our algorithm uses $O(k \log k \log n)$ samples, is dimension-free, operates for any universe size, and achieves the strongest ℓ_∞/ℓ_2 guarantee, while running in time comparable to the Fast Fourier Transform. All previous algorithms proceed either via the Restricted Isometry Property or via

[7]But not the only one: pseudorandom permutations for sparse FT in high dimensions also incur an exponential loss, and it is not known whether this can be avoided.

Table 1.5: Reconstructing the signal in the continuous setting. Let η denote the frequency gap. The first three results requires a frequency gap, and the last result doesn't require a frequency gap. We reconstruct an $x'(t)$ such that $\frac{1}{T}\int_0^T |x'(t) - x(t)|^2 \mathrm{d}t \leq \alpha \cdot \frac{1}{T}\int_0^T |g(t)|^2 \mathrm{d}t$, where α is the Approx. Ratio.

filter functions. Our approach totally departs from the aforementioned techniques, and we believe it is a fresh look to the sparse Fourier transform problem.

Continuous Fourier Transform In many situations, much of the reason for using Fourier transforms is because the transformed signal is *sparse*—i.e., the energy is concentrated in a small set of k locations. In such situations, one could hope for a dependency that depends nearly linearly on k rather than n. Moreover, one may be able to find these frequencies while only sampling the signal for some period of time. This idea has led to a number of results on *sparse Fourier transforms*, including [GGI+02, GMS05, HIKP12a, IK14], that can achieve $O(k \log(n/k) \log n)$ running time and $O(k \log(n/k))$ sample complexity (although not quite both at the same time) in a robust setting.

These works apply to the discrete Fourier transform, but lots of signals including audio or radio originally come from a continuous domain. The standard way to convert a continuous Fourier transform into a discrete one is to apply a window function then subsample. Unfortunately, doing so "smears out" the frequencies, blowing up the sparsity. Thus,

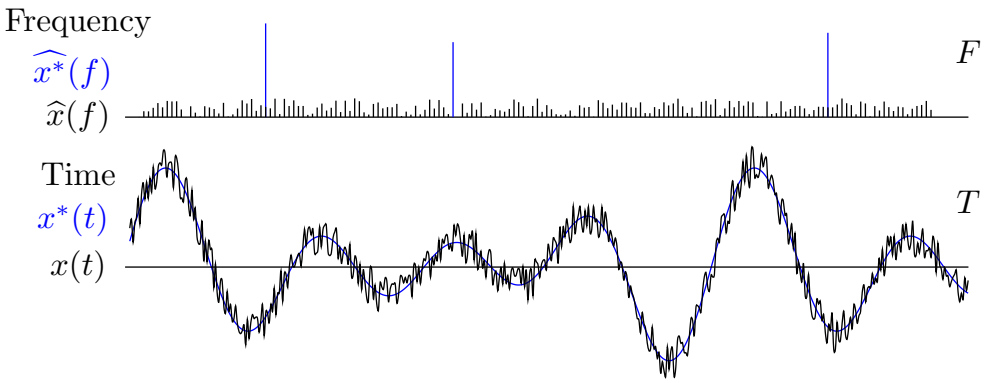

Figure 1.2: Sampling Model. x^* is a perfect signal. We are only allowed to samples from x which is a signal that has noise.

one can hope for significant efficiency gains by directly solving the sparse Fourier transform problem in the continuous setting. This has led researchers to adapt techniques from the discrete setting to the continuous both in theory [BCG+12, TBSR13, CF14, DB13] and in practice [SAH+13]. However, these results are not robust to noise: if the signal is sampled with a tiny amount of Gaussian noise or decays very slightly over time, no method has been known for computing a sparse Fourier transform in the continuous setting with sample complexity linear in k and logarithmic in other factors. That is what we present in this paper.

Formally, a vector $x^*(t)$ has a k-sparse Fourier transform if it can be written as

$$x^*(t) = \sum_{i=1}^{k} v_i e^{2\pi \mathbf{i} f_i t}$$

for some *tones* $\{(v_i, f_i)\}$. We consider the problem where we can sample some signal

$$x(t) = x^*(t) + g(t)$$

at any t we choose in some interval $[0, T]$, where $x^*(t)$ has a k-sparse Fourier transform and

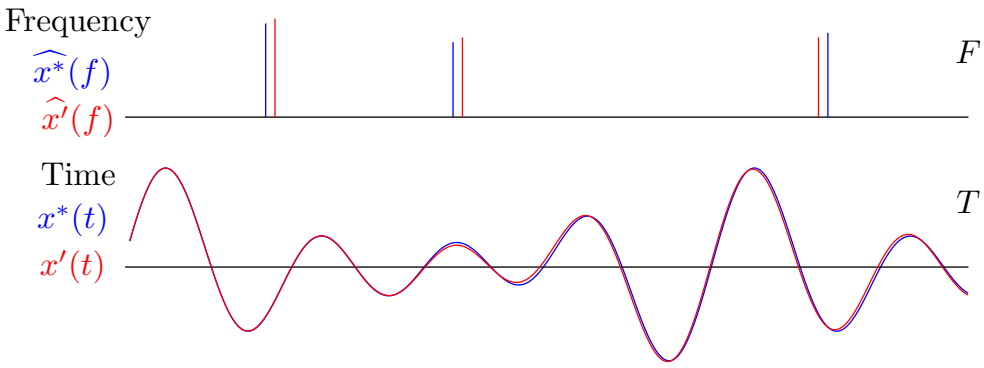

Figure 1.3: Recovered signal. Our goal is to output signal x' such that x' is close to x^*.

$g(t)$ is arbitrary noise. As long as g is "small enough," one would like to recover a good approximation to x (or to x^*, or to $\{(v_i, f_i)\}$) using relatively few samples $t \in [0, T]$ and fast running time. Our algorithm achieves several results of this form, but a simple one is an ℓ_2/ℓ_2 guarantee: we reconstruct an $x'(t)$ with k-sparse Fourier transform such that

$$\frac{1}{T}\int_0^T |x'(t) - x(t)|^2 \mathrm{d}t \lesssim \frac{1}{T}\int_0^T |g(t)|^2 \mathrm{d}t$$

using a number of samples that is k times logarithmic factors[8]. To the best of our knowledge, this is the first algorithm achieving such a constant factor approximation with a sample complexity sublinear in T and the signal-to-noise ratio.

Our algorithm also gives fairly precise estimates of the individual tones (v_i, f_i) of the signal x^*. To demonstrate what factors are important, it is helpful to think about a concrete setting. Let us consider sound from a simplified model of a piano.

Thought experiment: piano tuning In a simplified model of a piano, we have keys corresponding to frequencies over some range $[-F, F]$. The noise $g(t)$ comes from ambient

[8]We use $f \lesssim g$ to denote that $f \leq Cg$ for some universal constant C.

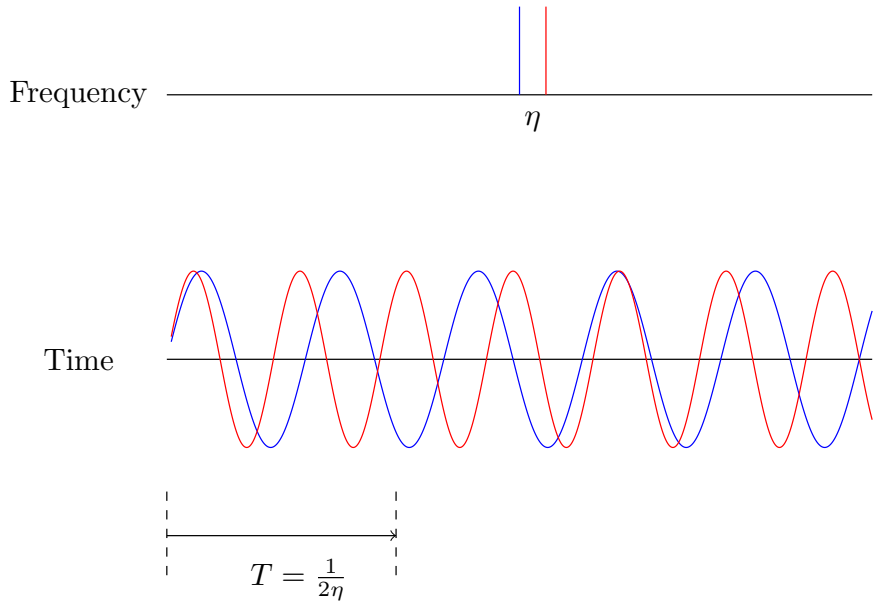

Figure 1.4: Thought Experiments

noise and the signals not being pure tones (because, for example, the notes might decay slowly over time). For concrete numbers, a modern piano has 88 keys spaced from about 27.5 Hz to $F = 4200$Hz. The space between keys ranges from a few Hz to a few hundred Hz, but most chords will have an $\eta = 30$Hz or more gap between the frequencies being played. One typically would like to tune the keys to within about $\pm\nu = 1$Hz. And piano music typically has k around 5.

Now, suppose you would like to build a piano tuner that can listen to a chord and tell you what notes are played and how they are tuned. For such a system, how long must we wait for the tuner to identify the frequencies? How many samples must the tuner take? And how robust is it to the noise?

If you have a constant signal-to-noise ratio, you need to sample for a time T of at

least order $1/\nu = 1$ second in order to get 1Hz precision—frequencies within 1Hz of each other will behave very similarly over small fractions of a second, which noise can make indistinguishable. You also need at least $\Omega(k \log(\frac{F}{k\nu})) \approx 50$ samples, because the support of the signal contains that many bits of information and you only get a constant number per measurement (at constant SNR). At higher signal-to-noise ratios ρ, these results extend to $\Omega(\frac{1}{\nu\rho})$ duration and $\Omega(k \log_\rho(\frac{F}{k\nu}))$ samples. But as the signal-to-noise ratio gets very high, there is another constraint on the duration: for $T < \frac{1}{\eta} \approx 33$ milliseconds the different frequencies start becoming hard to distinguish, which causes the robustness to degrade exponentially in k [Moi15] (though the lower bound there only directly applies to a somewhat restricted version of our setting).

This suggests the form of a result: with a duration $T > \frac{1}{\eta}$, one can hope to recover the frequencies to within $\frac{1}{\rho T}$ using $O(k \log_\rho(\frac{FT}{k}))$ samples. We give an algorithm that is within logarithmic factors of this ideal: with a duration $T > \frac{O(\log(k/\delta))}{\eta}$, we recover the frequencies to within $O(\frac{1}{\rho T})$ using $O(k \log_\rho(FT) \cdot \log(k/\delta) \cdot \log k)$ samples, where ρ and $1/\delta$ are (roughly speaking) the minimum and maximum signal-to-noise ratios that you can tolerate, respectively.

Instead of trying to tune the piano by recovering the frequencies precisely, one may simply wish to record the sound for future playback with relatively few samples. Our algorithm works for this as well: the combination $x'(t)$ of our recovered frequencies satisfies

$$\frac{1}{T}\int_0^T |x'(t) - x(t)|^2 \mathrm{d}t \lesssim \frac{1}{T}\int_0^T |g(t)|^2 \mathrm{d}t.$$

Continuous Fourier Transform without Frequency Gap In an interpolation problem, one can observe $x(t) = x^*(t) + g(t)$, where $x^*(t)$ is a structured signal and $g(t)$ denotes noise,

at points t_i of one's choice in some interval $[0, T]$. The goal is to recover an estimate $\widetilde{x}$ of x^* (or of x). Because we can sample over a particular interval, we would like our approximation to be good on that interval, so for any function $y(t)$ we define

$$\|y\|_T^2 = \frac{1}{T}\int_0^T |y(t)|^2 \mathrm{d}t.$$

to be the ℓ_2 error on the sample interval. For some parameters C and δ, we would then like to get

$$\|\widetilde{x} - x^*\|_T \leq C\,\|g\|_T + \delta\,\|x^*\|_T \tag{1.7}$$

while minimizing the number of samples and running time. Typically, we would like C to be $O(1)$ and to have δ be very small (either zero, or exponentially small). Note that, if we do not care about changing C by $O(1)$, then by the triangle inequality it doesn't matter whether we want to estimate x^* or x (i.e. we could replace the LHS of (1.7) by $\|\widetilde{x} - x\|_T$).

Of course, to solve an interpolation problem one also needs x^* to have structure. One common form of structure is that x^* have a sparse Fourier representation. We say that a function x^* is k-Fourier-sparse if it can be expressed as a sum of k complex exponentials:

$$x^*(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}.$$

for some $v_j \in \mathbb{C}$ and $f_j \in [-F, F]$, where F is the "bandlimit". Given F, T, and k, how many samples must we take for the interpolation (1.7)?

If we ignore sparsity and just use the bandlimit, then Nyquist sampling and Shannon-Whittaker interpolation uses $FT + 1/\delta$ samples to achieve (1.7). Alternatively, in the absence of noise, x^* can be found from $O(k)$ samples by a variety of methods, including Prony's

method from 1795 or Reed-Solomon syndrome decoding [Mas69], but these methods are not robust to noise.

If the signal is periodic with period T—i.e., the frequencies are multiples of $1/T$—then we can use sparse discrete Fourier transform methods, which take $O(k \log^c(FT/\delta))$ time and samples (e.g. [GGI+02, HIKP12a, IKP14]). If the frequencies are not multiples of $1/T$ (are "off the grid"), then the discrete approximation is only k/δ sparse, making the interpolation less efficient; and even this requires that the frequencies be well separated.

A variety of algorithms have been designed to recover off-grid frequencies directly, but they require the minimum gap among the frequencies to be above some threshold. With frequency gap at least $1/T$, we can achieve a k^c approximation factor using $O(FT)$ samples [Moi15], and with gap above $O(\log^2 k)/T$ we can get a constant approximation using $O(k \log^c(FT/\delta))$ samples and time [PS15].

Having a dependence on the frequency gap is natural. If two frequencies are very close together—significantly below $1/T$—then the corresponding complex exponentials will be close on $[0, T]$, and hard to distinguish in the presence of noise. In fact, from a lower bound in [Moi15], below $1/T$ frequency gap one cannot recover the frequencies in the presence of noise as small as $2^{-\Omega(k)}$. The lower bound proceeds by constructing two signals using significantly different frequencies that are exponentially close over $[0, T]$.

But if two signals are so close, do we need to distinguish them? Such a lower bound doesn't apply to the interpolation problem, it just says that you can't solve it by finding the frequencies. Our question becomes: can we benefit from Fourier sparsity in a regime where we can't recover the individual frequencies?

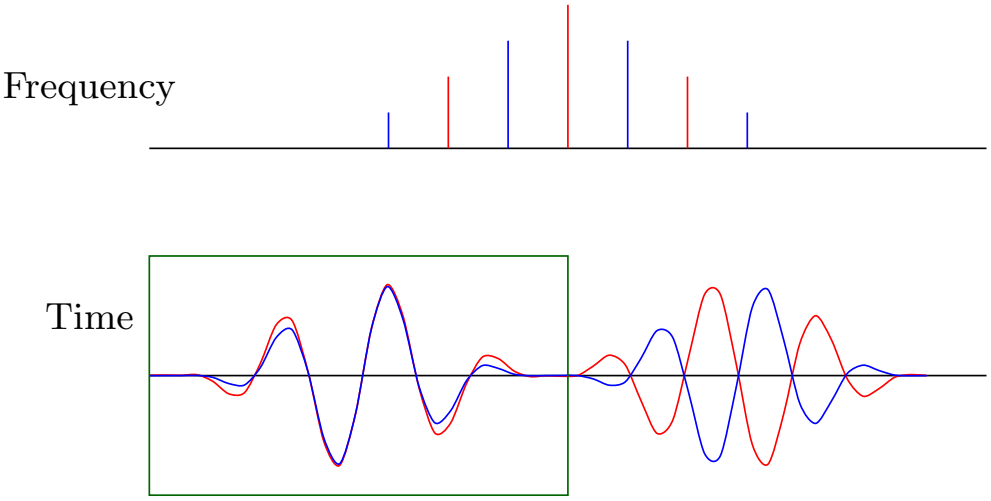

Figure 1.5: Moitra's lower bound [Moi15]. $\forall \epsilon > 0$, if sample duration $T < \frac{(1-\epsilon)}{\eta}$, then $\exists$ two k-Fourier-sparse signals: $x(t)$ and $x'(t)$, each has η frequency gap. To tell them apart, need noise $\leq 2^{-\Omega(\epsilon k)}$. This example only implies that frequency recovery requires frequency gap, but what if we just want to interpolate signal?

We answer in the affirmative, giving an algorithm for the interpolation using $O(\mathrm{poly}(k \log(FT/\delta))$ samples.

1.5 Factorization

Low rank approximation is arguably one of the most well-studied problems in randomized numerical linear algebra, with diverse applications to clustering [DFK+04, FSS13, LBKW14, CEM+15], data mining [AFK+01], distance matrix completion [Cha12], information retrieval [PRTV00], learning mixtures of distributions [AM05, KSV08], recommendation systems [DKR02], and web search [AFKM01, Kle99]. In practice one often has a low rank matrix which has been corrupted with noise of bounded norm, and low rank approximation allows one to approximately recover the original matrix. Low rank approximation may also help explain a dataset, revealing low dimensional structure in high dimensional data. Given a low rank approximation, one can store a matrix and compute a matrix-vector product much more efficiently by storing the corresponding factorization. It can also be used as a preprocessing step in applications, that is, by first projecting data onto a lower-dimensional

subspace one preserves important properties of the input, but can now run subsequent algorithms in the lower-dimensional space. For example, it has been proposed to reduce the data dimension in Non-Negative Matrix Factorization [LS00] (more on this below), and Latent Dirichlet Allocation (LDA) [BNJ01].

The basic low rank approximation problem is: given an $n \times n$ matrix A, find a matrix $\widehat{A}$ of rank at most k for which $\|A - \widehat{A}\|_F$ is minimized, where for a matrix B, $\|B\|_F = \left(\sum_{i,j} B_{i,j}^2\right)^{1/2}$ is its Frobenius norm. This formulation intuitively corresponds to the matrix $\widehat{A}$ capturing as much of the variance of A as possible. It is well-known that the optimal solution is given by A_k, which if $U\Sigma V^\top$ is the singular value decomposition (SVD) of A, where U and V are orthogonal matrices and Σ is a non-negative diagonal matrix with $\Sigma_{1,1} \geq \Sigma_{2,2} \geq \cdots \geq \Sigma_{n,n}$, then $A_k = U\Sigma_k V^\top$, where Σ_k agrees with Σ on its first k diagonal entries and is 0 otherwise. Although the SVD is computable in polynomial time, it is often acceptable to output a matrix $\widehat{A}$ for which $\|A - \widehat{A}\|_F \leq (1+\epsilon)\|A - A_k\|_F$ with high probability. In the latter case, much more efficient algorithms are known, and it is possible to compute such an $\widehat{A}$ in $\mathrm{nnz}(A) + n \cdot \mathrm{poly}(k/\epsilon)$ time, where $\mathrm{nnz}(A)$ denotes the number of non-zero entries of A [CW13, MM13, NN13a]. We note that for typical applications k and $1/\epsilon$ are assumed to be much smaller than n, e.g., in [Har14] they are treated as absolute constants.

Weighted Despite the large body of work on low rank approximation, the *weighted* case is not well understood. In this case one is given an $n \times n$ matrix A and an $n \times n$ matrix W

with $W_{i,j} \geq 0$, and one seeks to solve:

$$\min_{\text{rank-}k \text{ matrices } \widehat{A}} \|W \circ (A - \widehat{A})\|_F^2 = \min_{\text{rank-}k \text{ matrices } \widehat{A}} \sum_{i,j} W_{i,j}^2 (A_{i,j} - \widehat{A}_{i,j})^2.$$

The classical low rank approximation is a special case in which $W_{i,j} = 1$ for all i and j. However, in general there may not be a good reason to weight all elements of the approximation error $A - \widehat{A}$ equally, especially if one is given prior knowledge about the distribution of the errors. For example, suppose the columns of A each come from a low-dimensional subspace but one of the columns is then shifted by a fixed large vector so that its mean is different. One may first want to recenter the data by subtracting off the mean from each of the columns. While this is possible without weighted low rank approximation, suppose instead that each of the columns of A comes from a perturbation of columns in a low dimensional subspace but one of the columns has a much larger variance. Then if all weights were equal, it would be enough for $\widehat{A}$ to fit this one single large variance column, which fails to capture the entire low-dimensional subspace. One way of fixing this is to reweight each entry of A by the inverse of its variance. This is a common technique used in gene expression analysis, where the error model for microarray measurements provides entry-specific noise estimates, or when entries of A represent aggregates of many samples such as in word co-occurrence matrices and non-uniform weights are needed to appropriately capture any differences in the sample sizes; see [SJ03] for a discussion, and also the Wikipedia entry on weighted low rank approximation for a brief introduction.

While the extension of low rank approximation to the weighted case goes back to work of Young in 1940 [You40], its complexity is not well-understood, partly because the weighted case does not admit a solution via the SVD and may have many local minima [SJ03]. Early

work by Shpak [Shp90] looked at gradient-based approaches while Lu et al. [LPW97, LA03] looked at alternating minimization methods. These were significantly sped up in practice by the work of Srebro and Jaakkola [SJ03], with success in various applications such as color image restoration [MES08], though there are no provable time bounds and in the worst case the running times could be exponential or worse. In fact, weighted low rank approximation is known to be NP-hard to approximate up to a $(1 \pm 1/\operatorname{poly}(n))$ factor [GG11]. We note that this also follows from the fact that matrix completion, arguably one of the most important special cases of weighted low rank approximation in which case all weights are 0 or 1, which we discuss more below, is also known to be NP-hard [Pee96, HMRW14]. Typically, though, assumptions such as incoherence and randomly sampled entries allow one to circumvent this hardness [CR09, LLR16]. There is some debate as to whether these assumptions are valid, for instance in [SW15] an argument is made why randomly missing entries may not hold for real-world datasets.

Many natural questions are left open from previous work. In particular one question as we see it is the following:

For which weight matrices W is the problem tractable? More generally, is it possible to identify a natural parameter of W and to obtain parameterized complexity bounds in terms of that parameter?

Entry-wise L1 norm Two well-studied problems in numerical linear algebra are regression and low rank approximation. In regression, one is given an $n \times d$ matrix A, and an $n \times 1$ vector b, and one seeks an $x \in \mathbb{R}^d$ which minimizes $\|Ax - b\|$ under some norm. For example, for least squares regression one minimizes $\|Ax - b\|_2$. In low rank approximation, one is

given an $n \times d$ matrix A, and one seeks a rank-k matrix $\widehat{A}$ which minimizes $\|A - \widehat{A}\|$ under some norm. For example, in Frobenius norm low rank approximation, one minimizes $\|A - \widehat{A}\|_F = \left(\sum_{i,j}(A_{i,j} - \widehat{A}_{i,j})^2\right)^{1/2}$. Algorithms for regression are often used as subroutines for low rank approximation. Indeed, one of the main insights of [DMM06c, DMM06b, Sar06, DMM08, CW09] was to use results for generalized least squares regression for Frobenius norm low rank approximation. Algorithms for ℓ_1-regression, in which one minimizes $\|Ax - b\|_1 = \sum_i |(Ax)_i - b_i|$, were also used [BD13, SW11] to fit a set of points to a hyperplane, which is a special case of entrywise ℓ_1-low rank approximation, the more general problem being to find a rank-k matrix $\widehat{A}$ minimizing $\sum_{i,j} |A_{i,j} - \widehat{A}_{i,j}|$.

Randomization and approximation were introduced to significantly speed up algorithms for these problems, resulting in algorithms achieving relative error approximation with high probability. Such algorithms are based on sketching and sampling techniques; we refer to [Woo14b] for a survey. For least squares regression, a sequence of work [Sar06, CW13, MM13, NN13a, LMP13, BDN15, Coh16a] shows how to achieve algorithms running in $\text{nnz}(A) + \text{poly}(d)$ time. For Frobenius norm low rank approximation, using the advances for regression this resulted in $\text{nnz}(A) + (n + d)\,\text{poly}(k)$ time algorithms. For ℓ_1-regression, sketching and sampling-based methods [Cla05, SW11, CDMI+13, CW13, MM13, LMP13, WZ13, CW15b, CP15] led to an $\text{nnz}(A) + \text{poly}(d)$ time algorithm.

Just like Frobenius norm low rank approximation is the analogue of least squares regression, entrywise ℓ_1-low rank approximation is the analogue of ℓ_1-regression. Despite this analogy, *no non-trivial upper bounds with provable guarantees* are known for ℓ_1-low rank approximation. Unlike Frobenius norm low rank approximation, which can be solved exactly using the singular value decomposition, no such algorithm or closed-form solution is known

for ℓ_1-low rank approximation. Moreover, the problem was recently shown to be NP-hard [GV15]. A major open question is whether there exist approximation algorithms, sketching-based or otherwise, for ℓ_1-low rank approximation. Indeed, the question of obtaining betters algorithms was posed in section 6 of [GV15], in [Exc13], and as the second part of open question 2 in [Woo14b], among other places. The earlier question of NP-hardness was posed in Section 1.4 of [KV09], for which the question of obtaining approximation algorithms is a natural followup. The goal of our work is to answer this question.

We now formally define the ℓ_1-low rank approximation problem: we are given an $n \times d$ matrix A and approximation factor $\alpha \geq 1$, and we would like, with large constant probability, to output a rank-k matrix $\widehat{A}$ for which

$$\|A - \widehat{A}\|_1 \leq \alpha \cdot \min_{\text{rank-}k \text{ matrices } A'} \|A - A'\|_1,$$

where for an $n \times d$ matrix C, we let $\|C\|_1 = \sum_{i=1}^{n} \sum_{j=1}^{d} |C_{i,j}|$. This notion of low rank approximation has been proposed as a more robust alternative to Frobenius norm low rank approximation [KK03, KK05, KLC+15, Kwa08, ZLS+12, BJ12, BD13, BDB13, MXZZ13, MKP13, MKP14, MKCP16, PK16], and is sometimes referred to as ℓ_1-matrix factorization or robust PCA. ℓ_1-low rank approximation gives improved results over Frobenius norm low rank approximation since outliers are less exaggerated, as one does not square their contribution in the objective. The outlier values are often erroneous values that are far away from the nominal data, appear only a few times in the data matrix, and would not appear again under normal system operation. These works also argue ℓ_1-low rank approximation can better handle missing data, is appropriate in noise models for which the noise is not Gaussian, e.g., it produces the maximum likelihood estimator for Laplacian noise [Gao08, KAC+08, VT01], and can be used in image processing to prevent image occlusion [YZD12].

To see that ℓ_1-low rank approximation and Frobenius norm low rank approximation can give very different results, consider the $n \times n$ matrix $A = \left[\begin{smallmatrix} n & 0 \\ 0 & B \end{smallmatrix}\right]$, where B is *any* $(n-1) \times (n-1)$ matrix with $\|B\|_F < n$. The best rank-1 approximation with Frobenius norm error is given by $\widehat{A} = n \cdot e_1 e_1^\top$, where e_1 is the first standard unit vector. Here $\widehat{A}$ ignores all but the first row and column of A, which may be undesirable in the case that this row and column represent an outlier. Note $\|A - \widehat{A}\|_1 = \|B\|_1$. If, for example, B is the all 1s matrix, then $\widehat{A} = [0, 0; 0, B]$ is a rank-1 approximation for which $\|A - \widehat{A}\|_1 = n$, and therefore this solution is a much better solution to the ℓ_1-low rank approximation problem than $n \cdot e_1 e_1^\top$, for which $\|A - n \cdot e_1 e_1^\top\|_1 = (n-1)^2$.

Despite the advantages of ℓ_1-low rank approximation, its main disadvantage is its computationally intractability. It is not rotationally invariant and most tools for Frobenius low rank approximation do not apply. To the best of our knowledge, all previous works only provide heuristics. Using that for an $n \times d$ matrix C, $\|C\|_F \leq \|C\|_1 \leq \sqrt{nd}\|C\|_F$, a Frobenius norm low rank approximation gives a $\sqrt{nd}$ approximation for ℓ_1-low rank approximation. A bit better is to use algorithms for low rank approximation with respect to the sum of distances, i.e., to find a rank-k matrix $\widehat{A}$ minimizing $\|A - \widehat{A}\|_{1,2}$, where for an $n \times d$ matrix C, $\|C\|_{1,2} = \sum_{i=1}^n \|C_i\|_2$, where C_i is the i-th row of C. A sequence of work [DV07, FMSW10, FL11, SV12a, CW15a] shows how to obtain an $O(1)$-approximation to this problem in $\mathrm{nnz}(A) + (n+d)\,\mathrm{poly}(k) + \exp(k)$ time, and using that $\|C\|_{1,2} \leq \|C\|_1 \leq \sqrt{d}\|C\|_{1,2}$ results in an $O(\sqrt{d})$-approximation.

Zero-one Law To understand the role of the Frobenius norm in the algorithms above, we recall a standard motivation for this error measure. Suppose one has n data points in

a k-dimensional subspace of $\mathbb{R}^d$, where $k \ll d$. We can write these points as the rows of an $n \times d$ matrix A^* which has rank k. The matrix A^* is often called the *ground truth matrix*. In a number of settings, due to measurement noise or other kinds of noise, we only observe the matrix $A = A^* + \Delta$, where each entry of the *noise matrix* $\Delta \in \mathbb{R}^{n \times n}$ is an i.i.d. random variable from a certain mean-zero noise distribution $\mathcal{D}$. One method for approximately recovering A^* from A is maximum likelihood estimation. Here one tries to find a matrix B maximizing the log-likelihood: $\max_{\text{rank-}k\ B} \sum_{i,j} \log p(A_{i,j} - B_{i,j})$, where $p(\cdot)$ is the probability density function of the underlying noise distribution $\mathcal{D}$. For example, when the noise distribution is Gaussian with mean zero and variance σ^2, denoted by $N(0, \sigma^2)$, then the optimization problem is $\max_{\text{rank-}k\ B} \sum_{i,j} \left(\log(1/\sqrt{2\pi\sigma^2}) - (A_{i,j} - B_{i,j})^2/(2\sigma^2) \right)$, which is equivalent to solving the Frobenius norm loss low rank approximation problem defined above.

The Frobenius norm loss, while having nice statistical properties for Gaussian noise, is well-known to be sensitive to outliers. Applying the same maximum likelihood framework above to other kinds of noise distributions results in minimizing other kinds of loss functions. In general, if the density function of the underlying noise $\mathcal{D}$ is $p(z) = c \cdot e^{-g(z)}$, where c is a normalization constant, then the maximum likelihood estimation problem for this noise distribution becomes the following generalized entry-wise loss low rank approximation problem: $\min_{\text{rank-}k\ B} \sum_{i,j} g(A_{i,j} - B_{i,j}) = \min_{\text{rank-}k\ B} \|A - B\|_g$, which is a central topic of recent work on *generalized low-rank models* [UHZ+16]. For example, when the noise is Laplacian, the entrywise ℓ_1 loss is the maximum likelihood estimation, which is also robust to sparse outliers. A natural setting is when the noise is a mixture of small Gaussian noise and sparse outliers; this noise distribution is referred to as the *Huber density*. In this case

the Huber loss function gives the maximum likelihood estimate [UHZ+16], where the Huber function [Hub64] is defined to be: $g(x) = x^2/(2\tau)$ if $|x| < \tau/2$, and $g(x) = |x| - \tau/2$ if $|x| \geq \tau$. Another nice property of the Huber error measure is that it is differentiable everywhere, unlike the ℓ_1-norm, yet still enjoys the robustness properties as one moves away from the origin, making it less sensitive to outliers than the ℓ_2-norm. There are many other kinds of loss functions, known as M-estimators [Zha97], which are widely used as loss functions in robust statistics [HRRS11].

Although several specific cases have been studied, such as entry-wise ℓ_p loss [CLMW11, SWZ17, CGK+17a, BKW17, BBB+19a], weighted entry-wise ℓ_2 loss [RSW16], and cascaded $\ell_p(\ell_2)$ loss [DVTV09, CW15a], the landscape of general entry-wise loss functions remains elusive. There are no results known for any loss function which is not scale-invariant, much less any kind of characterization of which loss functions admit efficient algorithms. This is despite the importance of these loss functions; we refer the reader to [UHZ+16] for a survey of generalized low rank models. This motivates the main question in our work:

Question 1.5.1 (General Loss Functions)**.** *For a given approximation factor $\alpha > 1$, which functions g allow for efficient low-rank approximation algorithms? Formally, given an $n \times d$ matrix A, can we find a* rank-k *matrix B for which $\|A - B\|_g \leq \alpha \min_{\text{rank}-k\ B'} \|A - B'\|_g$, where for a matrix C, $\|C\|_g = \sum_{i \in [n], j \in [d]} g(C_{i,j})$? What if we also allow B to have rank* $\text{poly}(k \log n)$*?*

For Question 1.5.1, one has $g(x) = |x|^p$ for p-norms, and note the Huber loss function also fits into this framework. Allowing B to have slightly larger rank than k, namely, $\text{poly}(k \log n)$, is often sufficient for applications as it still allows for the space savings and

computational gains outlined above. These are referred to as bicriteria approximations and are the focus of our work.

Tensor Tensors are often more useful than matrices for capturing higher order relations in data. Computing low rank factorizations of approximations of tensors is the primary task of interest in a number of applications, such as in psychology[Kro83], chemometrics [Paa00, SBG04], neuroscience [AAB+07, KB09, CLK+15], computational biology [CV15, SC15], natural language processing [CYYM14, LZBJ14, LZMB15, BNR+15], computer vision [VT02, WA03, SH05, HPS05, HD08, AFdLGTL09, PLY10, LFC+16, CLZ17], computer graphics [VT04, WWS+05, Vas09], security [AÇKY05, ACY06, KB06], cryptography [FS99, Sch12, KYFD15, SHW+16] data mining [KS08, RST10, KABO10, Mør11], machine learning applications such as learning hidden Markov models, reinforcement learning, community detection, multi-armed bandit, ranking models, neural network, Gaussian mixture models and Latent Dirichlet allocation [MR05, AFH+12, HK13, ALB13, ABSV14, AGH+14, AGHK14, BCV14, JO14a, GHK15, PBLJ15, JSA15, ALA16, AGMR16, ZSJ+17], programming languages [RTP16], signal processing [Wes94, DLDM98, Com09, CMDL+15], and other applications [YCS11, LMWY13, OS14, ZCZJ14, STLS14, YCS16, RNSS16].

Despite the success for matrices, the situation for order-q tensors for $q > 2$ is much less understood. There are a number of works based on alternating minimization [CC70, Har70, FMPS13, FT15, ZG01, BS15] gradient descent or Newton methods [ES09, ZG01], methods based on the Higher-order SVD (HOSVD) [LMV00a] which provably incur $\Omega(\sqrt{n})$-inapproximability for Frobenius norm error [LMV00b], the power method or orthogonal iteration method [LMV00b], additive error guarantees in terms of the flattened (unfolded)

tensor rather than the original tensor [MMD08], tensor trains [Ose11], the tree Tucker decomposition [OT09], or methods specialized to orthogonal tensors [KM11, AGH+14, MHG15, WTSA15, WA16, SWZ16]. There are also a number of works on the problem of tensor completion, that is, recovering a low rank tensor from missing entries [WM01, AKDM10, TSHK11, LMWY13, MHWG14, JO14b, BM16]. There is also another line of work using the sum of squares (SOS) technique to study tensor problems [BKS15a, GM15, HSS15, HSSS16, MSS16, PS17, SS17], other recent work on tensor PCA [All12b, All12a, RM14, JMZ15, ADGM16, ZX17], and work applying smoothed analysis to tensor decomposition [BCMV14]. Several previous works also consider more robust norms than the Frobenius norm for tensors, e.g., the R_1 norm (ℓ_1-ℓ_2-ℓ_2 norm in our work) [HD08], ℓ_1-PCA [PLY10], entry-wise ℓ_1 regularization [GGH14], M-estimator loss [YFS16], weighted approximation [Paa97, TK11, LRHG13], tensor-CUR [OST08, MMD08, CC10, FMMN11, FT15], or robust tensor PCA [GQ14, LFC+16, CLZ17].

Some of the above works, such as ones based on the tensor power method or alternating minimization, require incoherence or orthogonality assumptions. Others, such as those based on the simultaneous SVD, require an assumption on the minimum singular value. See the monograph of Moitra [Moi14a] for further discussion. Unlike the situation for matrices, there is no work for tensors that is able to achieve the following natural relative error guarantee: given a q-th order tensor $A \in \mathbb{R}^{n^{\otimes q}}$ and an arbitrary accuracy parameter $\epsilon > 0$, output a rank-k tensor B for which

$$\|A - B\|_F^2 \leq (1+\epsilon)\,\mathrm{OPT}, \tag{1.8}$$

where $\mathrm{OPT} = \inf_{\text{rank-}k\ B'} \|A - B'\|_F^2$, and where recall the rank of a tensor B is the minimal integer k for which B can be expressed as $\sum_{i=1}^{k} U_1^i \otimes U_2^i \otimes \cdots \otimes U_q^i$. General speaking, a q-th

order tensor can have rank at most n^{q-1}. A third order tensor, for example, has rank which is an integer in $\{0, 1, 2, \ldots, n^2\}$.

For notational simplicity, we will start by assuming third order tensors with all dimensions of equal size, but we extend all of our main theorems below to tensors of any constant order $q > 3$ and dimensions of different sizes.

The first caveat regarding (1.8) for tensors is that an optimal rank-k solution may not even exist! This is a well-known problem for tensors (see, e.g., [KHL89, Paa00, KDS08, Ste06, Ste08] and more details in section 4 of [DSL08]), for which for any rank-k tensor B, there always exists another rank-k tensor B' for which $\|A - B'\|_F^2 < \|A - B\|_F^2$. If OPT $= 0$, then in this case for any rank-k tensor B, necessarily $\|A - B\|_F^2 > 0$, and so (1.8) cannot be satisfied. This fact was known to algebraic geometers as early as the 19th century, which they refer to as the fact that the locus of r-th secant planes to a Segre variety may not define a (closed) algebraic variety [DSL08, Lan12]. It is also known as the phenomenon underlying the concept of *border rank*[9][Bin80, Bin86, BCS97, Knu98, Lan06]. In this case it is natural to allow the algorithm to output an arbitrarily small $\gamma > 0$ amount of additive error. Note that unlike several additive error algorithms for matrices, the additive error here can in fact be an arbitrarily small positive function of n. If, however, OPT > 0, then for any $\epsilon > 0$, there exists a rank-k tensor B for which $\|A - B\|_F^2 \leq (1 + \epsilon)$ OPT, and in this case we should still require the algorithm to output a relative-error solution. If an optimal rank-k solution B exists, then as for matrices, it is natural to require the algorithm to output a relative-error solution.

[9] https://en.wikipedia.org/wiki/Tensor_rank_decomposition#Border_rank

Besides the above definitional issue, a central reason that (1.8) has not been achieved is that computing the rank of a third order tensor is well-known to be NP-hard [Hås90, HL13]. Thus, if one had such a polynomial time procedure for solving the problem above, one could determine the rank of A by running the procedure on each $k \in \{0, 1, 2, \ldots, n^2\}$, and check for the first value of k for which $\|A - B\|_F^2 = 0$, thus determining the rank of A. However, it is unclear if approximating the tensor rank is hard. This question will also be answered in this work.

1.6 More Algorithms

Regression Sketching has emerged as a powerful technique for speeding up problems in numerical linear algebra, such as regression. In the overconstrained regression problem, one is given an $n \times d$ matrix A, with $n \gg d$, as well as an $n \times 1$ vector b, and one wants to find a vector $\widehat{x}$ so as to minimize the residual error $\|Ax - b\|_2$. Using the sketch and solve paradigm, one first computes $S \cdot A$ and $S \cdot b$ for a randomly chosen matrix S, then outputs $x' = (SA)^\dagger Sb$ so as to minimize $\|SAx' - Sb\|_2$.

The sketch-and-solve paradigm gives a bound on $\|x' - x^*\|_2$ when A is well-conditioned. One of result cares about $\|x' - x^*\|_\infty$, we call it ℓ_∞ regression problem. We also studied regression problem under general norms (i.e. symmetric norm regression $\min \|Ax - b\|_{\text{symmetric norm}}$) and general structure (i.e. tensor regression $\min_x \|(A_1 \otimes A_2)x - b\|$).

Clustering We consider the k-means clustering problem in the dynamic streaming setting, where points from a discrete Euclidean space $\{1, 2, \ldots, \Delta\}^d$ can be dynamically inserted to or deleted from the dataset. For this problem, we provide a one-pass coreset construction algorithm using space $\widetilde{O}(k \cdot \mathrm{poly}(d, \log \Delta))$, where k is the target number of centers. To our knowledge, this is the first dynamic geometric data stream algorithm for k-means using space polynomial in dimension and nearly optimal (linear) in k.

LCS Binary String Given a pair of n-character strings, the problems of computing their Longest Common Subsequence and Edit Distance have been extensively studied for decades. For exact algorithms, LCS and Edit Distance (with character insertions and deletions) are equivalent; the state of the art running time is (almost) quadratic in n, and this is tight under plausible fine-grained complexity assumptions. But for approximation algorithms the picture is different: there is a long line of works with improved approximation factors for Edit Distance, but for LCS (with binary strings) only a trivial 1/2-approximation was known. In this work we give a reduction from approximate LCS to approximate Edit Distance, yielding the first efficient $(1/2 + \epsilon)$-approximation algorithm for LCS for some constant $\epsilon > 0$.

LCS Longest common subsequence (LCS) is a classic and central problem in combinatorial optimization. While LCS admits a quadratic time solution, recent evidence suggests that solving the problem may be impossible in truly subquadratic time. A special case of LCS wherein each character appears at most once in every string is equivalent to the longest increasing subsequence problem (LIS) which can be solved in quasilinear time. In this work, we present novel algorithms for approximating LCS in truly subquadratic time and LIS in truly sublinear time. Our approximation factors depend on the ratio of the optimal solution size over the input size. We denote this ratio by λ and obtain the following results for LCS and LIS without any prior knowledge of λ.

- A truly subquadratic time algorithm for LCS with approximation factor $O(\lambda^3)$.
- A truly sublinear time algorithm for LIS with approximation factor $O(\lambda^3)$.

Triangle inequality was recently used by Boroujeni *et al.* [BEG+18] and Chakraborty

et al. [CDG+18] to present new approximation algorithms for edit distance. Our techniques for LCS extend the notion of triangle inequality to non-metric settings.

Map-Reduce Many modern parallel systems, such as MapReduce, Hadoop and Spark, can be modeled well by the MPC model. The MPC model captures well coarse-grained computation on large data — data is distributed to processors, each of which has a sublinear (in the input data) amount of memory and we alternate between rounds of computation and rounds of communication, where each machine can communicate an amount of data as large as the size of its memory. This model is stronger than the classical PRAM model, and it is an intriguing question to design algorithms whose running time is smaller than in the PRAM model.

One fundamental graph problem is connectivity. On an undirected graph with n nodes and m edges, $O(\log n)$ round connectivity algorithms have been known for over 35 years. However, no algorithms with better complexity bounds were known. In this work, we give **fully scalable, faster algorithms for the connectivity problem**, by parameterizing the time complexity as a function of the *diameter* of the graph. Our main result is a $O(\log D \log \log_{m/n} n)$ time connectivity algorithm for diameter-D graphs, using $\Theta(m)$ total memory. If our algorithm can use more memory, it can terminate in fewer rounds, and there is no lower bound on the memory per processor.

We extend our results to related graph problems such as spanning forest, finding a DFS sequence, exact/approximate minimum spanning forest, and bottleneck spanning forest. We also show that achieving similar bounds for reachability in *directed graphs* would imply faster boolean matrix multiplication algorithms.

We introduce several new algorithmic ideas. We describe a general technique called *double exponential speed problem size reduction* which roughly means that if we can use total memory N to reduce a problem from size n to n/k, for $k = (N/n)^{\Theta(1)}$ in one phase, then we can solve the problem in $O(\log \log_{N/n} n)$ phases. In order to achieve this fast reduction for graph connectivity, we use a multistep algorithm. One key step is a carefully constructed truncated broadcasting scheme where each node broadcasts neighbor sets to its neighbors in a way that limits the size of the resulting neighbor sets. Another key step is *random leader contraction*, where we choose a smaller set of leaders than many previous works do.

Optimization

Chapter 2

Linear Programs

This chapter shows how to solve linear programs of the form $\min_{Ax=b,x\geq 0} c^\top x$ with n variables in time

$$O^*((n^\omega + n^{2.5-\alpha/2} + n^{2+1/6}) \log(n/\delta))$$

where ω is the exponent of matrix multiplication, α is the dual exponent of matrix multiplication, and δ is the relative accuracy. For the current value of $\omega \sim 2.37$ and $\alpha \sim 0.31$, our algorithm takes $O^*(n^\omega \log(n/\delta))$ time. When $\omega = 2$, our algorithm takes $O^*(n^{2+1/6} \log(n/\delta))$ time.

Our algorithm utilizes several new concepts that we believe may be of independent interest:

- We define a stochastic central path method.
- We show how to maintain a projection matrix $\sqrt{W}A^\top (AWA^\top)^{-1} A\sqrt{W}$ in sub-quadratic time under ℓ_2 multiplicative changes in the diagonal matrix W.

2.1 Introduction

Linear programming is one of the key problems in computer science. In both theory and practice, many problems can be reformulated as linear programs to take advantage of fast algorithms. For an arbitrary linear program $\min_{Ax=b,x\geq 0} c^\top x$ with n variables and d constraints[1], the fastest algorithm takes $O^*(\sqrt{d}\cdot \mathrm{nnz}(A)+d^{2.5})$[2] where $\mathrm{nnz}(A)$ is the number of non-zeros in A [LS14, LS15].

For the generic case $d=\Omega(n)$ we focus in this paper, the current fastest runtime is dominated by $O^*(n^{2.5})$. This runtime has not been improved since the result by Vaidya on 1989 [Vai87, Vai89b]. The $n^{2.5}$ bound originated from two factors: the cost per iteration n^2 and the number of iterations $\sqrt{n}$. The n^2 cost per iteration looks optimal because this is the cost to compute Ax for a dense A. Therefore, many efforts [Kar84, Ren88, NN89, Vai89a, LS14] have been focused on decreasing the number of iterations while maintaining the cost per iteration. As for many important linear programs (and convex programs), the number of iterations has been decreased, including maximum flow [Mad13, Mad16], minimum cost flow [CMSV17], geometric median [CLM+16], matrix scaling and balancing [CMTV17], and ℓ_p regression [BCLL18]. Unfortunately, beating $\sqrt{n}$ iterations (or $\sqrt{d}$ when $d\ll n$) for the general case remains one of the biggest open problems in optimization.

Avoiding this open problem, we develop a stochastic central path method that has a runtime of $O^*(n^\omega+n^{2.5-\alpha/2}+n^{2+1/6})$, where ω is the exponent of matrix multiplication

[1] Throughout this paper, we assume there is no redundant constraints and hence $n\geq d$. Note that papers in different communities uses different symbols to denote the number of variables and constraints in a linear program.

[2] We use O^* to hide $n^{o(1)}$ and $\log^{O(1)}(1/\delta)$ factors and $\widetilde{O}$ to hide $\log^{O(1)}(n/\delta)$ factors.

and α is the dual exponent of matrix multiplication[3]. For the current value of $\omega \sim 2.38$ and $\alpha \sim 0.31$, the runtime is simply $O^*(n^\omega)$. This achieves the natural barrier for solving linear programs because linear system is a special case of linear program and that the currently fastest way to solve general linear systems involves matrix multiplication. Despite the exact approach used in [CW87, Wil12, DS13, LG14] cannot give a bound on ω better than 2.3078 [AFLG15] and all known approaches cannot achieve the bound $\omega = 2$ [AW18b], it is still possible that $\omega = 2.01$ using all known approaches. Therefore, we believe improving the additive $2 + 1/6$ term remains an interesting open problem.

Our method is a stochastic version of the short step central path method. This short step method takes $O^*(\sqrt{n})$ steps and each step decreases $x_i s_i$ by a $1 - 1/\sqrt{n}$ factor for all i where s is the dual variable [Ren88] (See the definition of s in (2.1)). This results in $O^*(\sqrt{n}) \times n = O^*(n^{1.5})$ coordinate updates. Our method takes the same number of step but only updates $\widetilde{O}(\sqrt{n})$ coordinates each step. Therefore, we only update $O^*(n)$ coordinates in total, which is nearly optimal.

Our framework is efficient enough to take a much smaller step while maintaining the same running time. For the current value of $\omega \sim 2.38$, we show how to obtain the same runtime of $O^*(n^\omega)$ by taking $O^*(n)$ steps and $\widetilde{O}(1)$ coordinates update per steps. This is because the complexity of each step decreases proportionally when the step size decreases. Beyond the cost per iteration, we remark that our algorithm is one of the very few central path algorithms [PRT02, Mad13, Mad16] that does not maintain $x_i s_i$ close to some ideal vector in ℓ_2 norm. We are hopeful that our stochastic method and our proof will be useful

[3]The dual exponent of matrix multiplication α is the supremum among all $a \geq 0$ such that it takes $n^{2+o(1)}$ time to multiply an $n \times n$ matrix by an $n \times n^a$ matrix.

for future research on interior point methods. In particular, it would be interesting to see how this can be combined with techniques in [Cla95, LS14] to get a faster algorithm for linear programs with $d \ll n$.

Besides the applications to linear programs, some of our techniques are probably useful for studying other important problems in convex optimization. In particular, our framework should be naturally extendable to a larger class of convex programs.

2.1.1 Related Work

Interior point method has a long history, for more detailed surveys, we refer the readers to [Wri97, Ye97, Ren01, RTV05, Meg12, Ter13]. This paper in part inspired by the use of data-structure in Laplacian solvers [ST04, KMP10, KMP11, CKM+11, KOSZ13, CKM+14, KLP+16, KS16, CKK+18, KPSZ18], in particular the cycle update in [KOSZ13].

2.2 Results and Techniques

Theorem 2.2.1 (Main result)**.** *Given a linear program* $\min_{Ax=b,x\geq 0} c^\top x$ *with no redundant constraints. Assume that the polytope has diameter* R *in* ℓ_1 *norm, namely, for any* $x \geq 0$ *with* $Ax = b$*, we have* $\|x\|_1 \leq R$*.*

Then, for any $0 < \delta \leq 1$, $\textsc{Main}(A, b, c, \delta)$ *outputs* $x \geq 0$ *such that*

$$c^\top x \leq \min_{Ax=b,x\geq 0} c^\top x + \delta \cdot \|c\|_\infty R \quad \text{and} \quad \|Ax - b\|_1 \leq \delta \cdot \left(R \sum_{i,j} |A_{i,j}| + \|b\|_1 \right)$$

in expected time

$$\left(n^{\omega+o(1)} + n^{2.5-\alpha/2+o(1)} + n^{2+1/6+o(1)}\right) \cdot \log(\frac{n}{\delta})$$

where ω *is the exponent of matrix multiplication,* α *is the dual exponent of matrix multiplication.*

For the current value of $\omega \sim 2.38$ *and* $\alpha \sim 0.31$*, the expected time is simply* $n^{\omega+o(1)} \log(\frac{n}{\delta})$.

Remark 2.2.1. See [Ren88] and [LS13, Sec E, F] on the discussion on converting an approximation solution to an exact solution. For integral A, b, c, it suffices to pick $\delta = 2^{-O(L)}$ to get an exact solution where $L = \log(1 + d_{\max} + \|c\|_\infty + \|b\|_\infty)$ is the bit complexity and $d_{\max}$ is the largest absolute value of the determinant of a square sub-matrix of A. For many combinatorial problems, $L = O(\log(n + \|b\|_\infty + \|c\|_\infty))$.

In this paper, we assume all floating point calculations are done exactly for simplicity. In general, the algorithm can be carried out with $O(L)$ bits of accuracy. This is necessary because each coordinate in the solution could require as much as $\Omega(L)$ bits to represent. See [Ren88] for some discussions on the numerical stability of the interior point methods.

If $T(n)$ is the current cost of matrix multiplication and inversion with $T(n) \sim n^{2.38}$, our runtime is simply $O(T(n) \log n \log(\frac{n}{\delta}))$. The $\log(\frac{n}{\delta})$ comes from iteration count and the $\log n$ factor comes from the doubling trick ($|y_{\pi(1.5r)}| \geq (1 - 1/\log n)|y_{\pi(r)}|$) in the projection maintenance section. We left the problem of obtaining $O(T(n) \log(\frac{n}{\delta}))$ as an open problem.

Finally, we note that our runtime holds for any square and rectangular matrix multiplication algorithm as long as $\omega \leq 3 - \alpha$ (See Lemma 2.6.3) For example, Strassen algorithm together with a simple rectangular multiplication algorithm gives a runtime of roughly $n^{2.807}$.

2.2.1 Central Path Method

Our algorithm relies on two new ingredients: stochastic central path and projection maintenance. The central path method consider the linear programs

$$\min_{Ax=b, x\geq 0} c^\top x \quad \text{(primal)} \quad \text{and} \quad \max_{A^\top y \leq c} b^\top y \quad \text{(dual)}$$

with $A \in \mathbb{R}^{d\times n}$. Any solution of the linear program satisfies the following optimality conditions:

$$\begin{aligned} x_i s_i &= 0 \text{ for all } i, \\ Ax &= b, \\ A^\top y + s &= c, \\ x_i, s_i &\geq 0 \text{ for all } i. \end{aligned} \tag{2.1}$$

We call (x, s, y) feasible if it satisfies the last three equations above. For any feasible (x, s, y), the duality gap is $\sum_i x_i s_i$. The central path method find a solution of the linear program by following the central path which uniformly decrease the duality gap. The central path $(x_t, s_t, y_t) \in \mathbb{R}^{n+n+d}$ is a path parameterized by t and defined by

$$\begin{aligned} x_{t,i} s_{t,i} &= t \text{ for all } i, \\ Ax_t &= b, \\ A^\top y_t + s_t &= c, \\ x_{t,i}, s_{t,i} &\geq 0 \text{ for all } i. \end{aligned} \tag{2.2}$$

It is known [YTM94] how to transform linear programs by adding $O(n)$ many variables and constraints so that:

- The optimal solution remains the same.
- The central path at $t = 1$ is near $(1_n, 1_n, 0_d)$ where 1_n and 0_d are all 1 and all 0 vectors with lengths n and d.
- It is easy to convert an approximate solution of the transformed program to the original one.

For completeness, a theoretical version of such result is included in Lemma 3.8.2. This result shows that it suffices to move gradually (x_1, s_1, y_1) to (x_t, s_t, y_t) for small enough t.

2.2.1.1 Short Step Central Path Method

The short step central path method maintains $x_i s_i = \mu_i$ for some vector μ such that

$$\sum_i (\mu_i - t)^2 = O(t^2) \quad \text{for some scalar } t > 0. \tag{2.3}$$

Since the duality gap is $\sum_i \mu_i$, it suffices to find x and s satisfying the above equation with small enough t. There are many variants of central path methods. We will focus on the version that decreases t and takes a step of μ at the same time. The purpose of moving μ is to maintain the invariant (2.3) and the purpose of decreasing t is decrease the duality gap, which is roughly nt. One natural way to maintain the invariant (2.3) is to do a gradient descent step on the energy $\sum_i (\mu_i - t)^2$ defined in (2.3), namely, moving μ to $\mu - h(\mu - t)$ with step size h[4]. Compared to other versions, we only take one step instead of multiple steps to move μ closer to the central path t per update of t.

[4]The classical view of central path method is to take a Newton step on the system (2.2), which turns out to be same as taking a gradient step on the energy defined in (2.3). However, our main algorithm will choose a different energy and this gradient descent view is crucial for designing our algorithm.

More generally, say we want to move from μ to $\mu + \delta_\mu$, we approximate the term $(x + \delta_x)_i(s + \delta_s)_i$ by $x_i s_i + x_i \delta_{s,i} + s_i \delta_{x,i}$ and obtain the following system:

$$\begin{aligned} X\delta_s + S\delta_x &= \delta_\mu, \\ A\delta_x &= 0, \\ A^\top \delta_y + \delta_s &= 0, \end{aligned} \tag{2.4}$$

where $X = \mathrm{diag}(x)$ and $S = \mathrm{diag}(s)$. This equation is the linear approximation of the original goal (moving from μ to $\mu + \delta_\mu$), and that the step is explicitly given by the formula

$$\delta_x = \frac{X}{\sqrt{XS}}(I - P)\frac{1}{\sqrt{XS}}\delta_\mu \text{ and } \delta_s = \frac{S}{\sqrt{XS}}P\frac{1}{\sqrt{XS}}\delta_\mu, \tag{2.5}$$

where $P = \sqrt{\frac{X}{S}}A^\top \left(A\frac{X}{S}A^\top\right)^{-1} A\sqrt{\frac{X}{S}}$ is an orthogonal projection and the formulas $\frac{X}{\sqrt{XS}}, \frac{X}{S}, \cdots$ are the diagonal matrices of the corresponding vectors.

In turns out that one can decrease t by $1 - \frac{1}{\sqrt{n}}$ multiplicative factor every iteration while maintain the invariant (2.3). This requires $\widetilde{O}(\sqrt{n})$ iterations to converge. Combining this with the inverse maintenance technique [Vai87], this gives a total runtime of $n^{2.5}$. More precisely, the algorithm maintains the invariant $\sum_i (\mu_i - t)^2 = O(t^2)$ by making steps bring μ_i closer to t while taking steps to decrease μ_i uniformly. The progress of the whole algorithm is measured by t because the duality gap is bounded by nt.

2.2.1.2 Stochastic Central Path Method

This part discuss how to modify the short step central path to decrease the cost per iteration to roughly $n^{\omega - \frac{1}{2}}$. Since our goal is to implement a central path method in sub-quadratic time per iteration, we even do not have the budget to compute Ax every

iterations. Therefore, instead of maintaining $\left(A\frac{X}{S}A^\top\right)^{-1}$ shown in previous papers, we will study the problem of maintaining a projection matrix $P = \sqrt{\frac{X}{S}}A^\top\left(A\frac{X}{S}A^\top\right)^{-1}A\sqrt{\frac{X}{S}}$ due to the formula of δ_x and δ_s (2.5).

However, even if the projection matrix P is given explicitly for free, it is difficult to multiply the dense projection matrix with a dense vector δ_μ in time $o(n^2)$. To avoid moving along a dense δ_μ, we move along an $O(k)$ sparse direction $\widetilde{\delta}_\mu$ defined by

$$\widetilde{\delta}_{\mu,i} = \begin{cases} \delta_{\mu,i}/p_i, & \text{with probability } p_i \stackrel{\text{def}}{=} k \cdot \left(\frac{\delta_{\mu,i}^2}{\sum_l \delta_{\mu,l}^2} + \frac{1}{n}\right); \\ 0, & \text{else.} \end{cases} \tag{2.6}$$

The sparse direction is defined so that we are moving in the same direction in expectation ($\mathbb{E}[\widetilde{\delta}_{\mu,i}] = \delta_{\mu,i}$) and that the direction has as small variance as possible ($\mathbb{E}[\widetilde{\delta}_{\mu,i}^2] \leq \frac{\sum_i \delta_{\mu,i}^2}{k}$). If the projection matrix is given explicitly, we can apply the projection matrix on $\widetilde{\delta}_\mu$ in time $O(nk)$. This paper picks $k \sim \sqrt{n}$ and the sum of the cost of projection vector multiplications in the whole algorithm is about $nk^2 = n^2$.

During the whole algorithm, we maintain a projection matrix

$$\overline{P} = \sqrt{\frac{\overline{X}}{\overline{S}}}A^\top\left(A\frac{\overline{X}}{\overline{S}}A^\top\right)^{-1}A\sqrt{\frac{\overline{X}}{\overline{S}}}$$

for vectors $\overline{x}$ and $\overline{s}$ such that $\overline{x}_i$ and $\overline{s}_i$ are multiplicative approximations of x_i and s_i respectively for all i. Since we maintain the projection at a nearby point $(\overline{x}, \overline{s})$, our stochastic step $x \leftarrow x + \widetilde{\delta}_x$, $s \leftarrow s + \widetilde{\delta}_s$ and $y \leftarrow y + \widetilde{\delta}_y$ are defined by

$$\begin{aligned} \overline{X}\widetilde{\delta}_s + \overline{S}\widetilde{\delta}_x &= \widetilde{\delta}_\mu, \\ A\widetilde{\delta}_x &= 0, \\ A^\top\widetilde{\delta}_y + \widetilde{\delta}_s &= 0, \end{aligned} \tag{2.7}$$

which is different from (2.4) on both sides of the first equation. Note that this system use $\overline{X}$ and $\overline{S}$ because we have only maintained this projection matrix. The main goal of Section 2.4 is to show $\overline{X} = \Theta(X)$ and $\overline{S} = \Theta(S)$ is good enough for our interior point method. Similar to (2.5), Lemma 2.4.2 shows that

$$\widetilde{\delta}_x = \frac{\overline{X}}{\sqrt{\overline{X}\overline{S}}}(I - \overline{P})\frac{1}{\sqrt{\overline{X}\overline{S}}}\widetilde{\delta}_\mu \text{ and } \widetilde{\delta}_s = \frac{\overline{S}}{\sqrt{\overline{X}\overline{S}}}\overline{P}\frac{1}{\sqrt{\overline{X}\overline{S}}}\widetilde{\delta}_\mu. \tag{2.8}$$

The previously fastest algorithm involves maintaining the matrix inverse $(A\frac{X}{S}A^\top)^{-1}$ using subspace embedding techniques [Sar06, CW13, NN13a] and leverage score sampling [SS11]. In this paper, we maintain the projection directly using lazy update.

The key departure from the central path we present is that we can only maintain

$$0.9t \leq \mu_i = x_i s_i \leq 1.1t \quad \text{for some } t > 0$$

instead of μ close to t in ℓ_2 norm. We will further explain the proof in Section 2.4.1.

2.2.2 Projection Maintenance via Lazy Update

The projection matrix we maintain is of the form $\sqrt{W}A^\top \left(AWA^\top\right)^{-1} A\sqrt{W}$ where $W = \mathrm{diag}(x/s)$. For intuition, we only explain how to maintain the matrix

$$M_w \stackrel{\mathrm{def}}{=} A^\top (AWA^\top)^{-1}A$$

for the short step central path step here. In this case, we have $\sum_i \left(\frac{w_i^{\mathrm{new}} - w_i}{w_i}\right)^2 = O(1)$ for each step. Given this, there are mainly two extreme cases, w changes uniformly on all coordinates and w changes only on a few coordinates.

If the changes $\left(\frac{w_i^{\mathrm{new}} - w_i}{w_i}\right)^2$ is uniformly across all the coordinates, then $w_i^{\mathrm{new}} = (1 \pm \frac{1}{\sqrt{n}})w_i$ for all i. Since it takes $\sqrt{n}$ steps to change all coordinates by a constant factor and we only need to maintain M_v for some $v_i = \Theta(w_i)$ for all i, we can update the matrix every $\sqrt{n}$ steps. Hence, the average cost per iteration of maintaining the projection matrix is $n^{\omega - \frac{1}{2}}$, which is exactly what we desired.

For the other extreme case that the "adversary" puts all of his ℓ_2 budget on few coordinates, only $\sqrt{n}$ coordinates are changed by a constant factor during all $\sqrt{n}$ iterations. In this case, instead of updating M_w every step, we can compute $M_w h$ online by the Woodbury matrix identity.

Fact 2.2.2 ([Woo50]). *The Woodbury matrix identity is*

$$(M + UCV)^{-1} = M^{-1} - M^{-1}U(C^{-1} + VM^{-1}U)^{-1}VM^{-1}.$$

Let $S \subset [n]$ denote the set of coordinates that is changed by more than a constant factor and $r = |S|$. Using the identity above, we have that

$$M_{w^{\mathrm{new}}} = M_w - (M_w)_S(\Delta_{S,S}^{-1} + (M_w)_{S,S})^{-1}((M_w)_S)^\top, \tag{2.9}$$

where $\Delta = \mathrm{diag}(w^{\mathrm{new}} - w)$, $(M_w)_S \in \mathbb{R}^{n \times r}$ is the r columns from S of M_w and $(M_w)_{S,S}, \Delta_{S,S} \in \mathbb{R}^{r \times r}$ are the r rows and columns from S of M_w and Δ.

As long as there are only few coordinates violating $v_i = \Theta(w_i)$, (2.9) can be applied online efficiently. In another case, we can use (2.9) instead to update the matrix M_w and the cost is dominated by multiplying a $n \times n$ matrix with a $n \times n^r$ matrix.

Theorem 2.2.3 (Rectangular matrix multiplication, [LGU18])**.** *Let the dual exponent of matrix multiplication α be the supremum among all $a \geq 0$ such that it takes $n^{2+o(1)}$ time to multiply an $n \times n$ matrix by an $n \times n^a$ matrix.*

Then, for any $n \geq r$, multiplying an $n \times r$ with an $r \times n$ matrix or $n \times n$ with $n \times r$ takes time

$$n^{2+o(1)} + r^{\frac{\omega-2}{1-\alpha}} n^{2-\frac{\alpha(\omega-2)}{1-\alpha}+o(1)}.$$

Furthermore, we have $\alpha > 0.31389$.

See Lemma 2.6.4 for the origin of the formula. Since the cost of multiplying $n \times n$ matrix by a $n \times 1$ matrix is same as the cost for $n \times n$ with $n \times n^{0.31}$, (2.9) should be used to update at least $n^{0.31}$ coordinates. In the extreme case only few w_i are changing, we only need to update the matrix $n^{\frac{1}{2}-0.31}$ times during the whole algorithm and each takes n^2 time, and hence the total cost is less than n^ω for the current value of $\omega \sim 2.37$.

In previous papers [Kar84, Vai89b, NN91, NN94, LS14, LS15], the matrix is updated in a fixed schedule independent of the input sequence w. This leads to sub-optimal bounds if used in this paper. We instead define a potential function to measure the distance between the approximate vector v and the target vector w. When there are less than n^α coordinates

of v that is far from w, we are lazy and do not update the matrix. We simply apply the Woodbury matrix identity online. When there are more than n^α coordinates, we update v by a certain greedy step. As in the extreme cases, the worst case of our algorithm is that the "adversary" puts his ℓ_2 budget across all coordinates uniformly and hence the worst case runtime is $n^{\omega-\frac{1}{2}}$ per iteration. We will further explain the potential in Section 2.5.1.

2.3 Notations

For notation convenience, we assume the number of variables $n \geq 10$ and there is no redundant constraints. In particular, this implies that the constraint matrix A is full rank and $n \geq d$.

For a positive integer n, let $[n]$ denote the set $\{1, 2, \cdots, n\}$.

For any function f, we define $\widetilde{O}(f)$ to be $f \cdot \log^{O(1)}(f)$. In addition to $O(\cdot)$ notation, for two functions f, g, we use the shorthand $f \lesssim g$ (resp. $\gtrsim$) to indicate that $f \leq Cg$ (resp. $\geq$) for some absolute constant C.

We use $\sinh x$ to denote $\frac{e^x - e^{-x}}{2}$ and $\cosh x$ to denote $\frac{e^x + e^{-x}}{2}$.

For vectors $a, b \in \mathbb{R}^n$ and accuracy parameter $\epsilon \in (0, 1)$, we use $a \approx_\epsilon b$ to denote that $(1 - \epsilon)b_i \leq a_i \leq (1 + \epsilon)b_i, \forall i \in [n]$. Similarly, for any scalar t, we use $a \approx_\epsilon t$ to denote that $(1 - \epsilon)t \leq a_i \leq (1 + \epsilon)t, \forall i \in [n]$.

For a vector $x \in \mathbb{R}^n$ and $s \in \mathbb{R}^n$, we use xs to denote a length n vector with the i-th coordinate $(xs)_i$ is $x_i \cdot s_i$. Similarly, we extend other scalar operations to vector coordinate-wise.

Given vectors $x, s \in \mathbb{R}^n$, we use X and S to denote the diagonal matrix of those two vectors. We use $\frac{X}{S}$ to denote the diagonal matrix given $(\frac{X}{S})_{i,i} = x_i/s_i$. Similarly, we extend other scalar operations to diagonal matrix diagonal-wise. Note that matrix $\sqrt{\frac{X}{S}} A^\top (A \frac{X}{S} A^\top)^{-1} A \sqrt{\frac{X}{S}}$ is an orthogonal projection matrix.

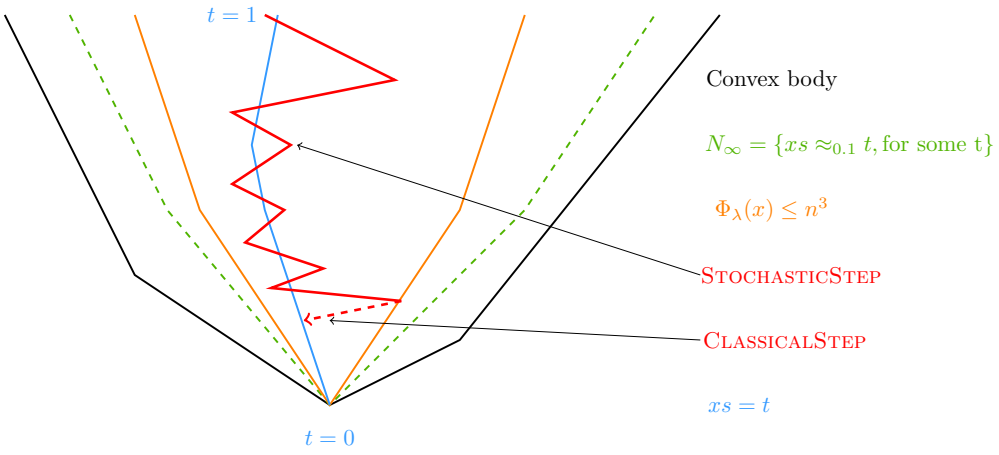

Figure 2.1: ClassicalStep happens with n^{-2} probability

2.4 Stochastic Central Path Method

2.4.1 Proof Outline

The short step central path method is defined using the approximation $(x+\delta_x)_i(s+\delta_s)_i \sim x_i s_i + x_i\delta_{s,i} + s_i\delta_{x,i}$. This approximate is only accurate if $\|X^{-1}\delta_x\|_\infty \le 1/2$ and $\|S^{-1}\delta_s\|_\infty \le 1/2$. For the δ_x step, we have

$$X^{-1}\delta_x = \frac{1}{\sqrt{XS}}(I-P)\frac{1}{\sqrt{XS}}\delta_\mu \sim \frac{1}{t}(I-P)\delta_\mu, \tag{2.10}$$

where we used $x_i s_i \sim t$ for all i.

If we know that $\|\delta_\mu\|_2 \le t/4$, then the ℓ_∞ norm can be bounded as follows:

$$\|X^{-1}\delta_x\|_\infty \le \|X^{-1}\delta_x\|_2 \lesssim \frac{1}{t}\|(I-P)\delta_\mu\|_2 \le \frac{1}{t}\|\delta_\mu\|_2 \le 1/2,$$

where we used that $I-P$ is an orthogonal projection matrix. This is the reason why a standard choice of $\delta_{\mu,i}$ is $-ct/\sqrt{n}$ for all i for some small constant c.

For the stochastic step, $\widetilde{\delta}_{\mu,i} \sim -\frac{t}{\sqrt{n}}\frac{n}{k}$ for roughly k coordinates where the term $\frac{n}{k}$ is used to preserve the expectation of the step. Therefore, the ℓ_2 norm of $\widetilde{\delta}_\mu$ is very large

Algorithm 2.1 Stochastic Step

procedure StochasticStep($\mathrm{mp}, x, s, \delta_\mu, k, \epsilon$) ▷ Lemma 2.4.2,2.4.3,2.4.7

  $w \leftarrow \frac{x}{s}$, $\widetilde{v} \leftarrow \mathrm{mp.Update}(w)$ ▷ Algorithm 2.3

  $\overline{x} \leftarrow x\sqrt{\frac{\widetilde{v}}{w}}$, $\overline{s} \leftarrow s\sqrt{\frac{w}{\widetilde{v}}}$ ▷ It guarantees that $\frac{\overline{x}}{\overline{s}} = \widetilde{v}$ and $\overline{xs} = xs$

  repeat

    Generate $\widetilde{\delta}_\mu$ such that ▷ Compute a sparse direction

    $$\widetilde{\delta}_{\mu,i} \leftarrow \begin{cases} \delta_{\mu,i}/p_i, & \text{with prob. } p_i = \min(1, k \cdot ((\delta_{\mu,i}^2 / \sum_{l=1}^n \delta_{\mu,l}^2) + 1/n)); \\ 0 & \text{else.} \end{cases}$$

    ▷ Compute an approximate step

    ▷ Find $(\widetilde{\delta}_x, \widetilde{\delta}_s, \widetilde{\delta}_y)$ such that these three equations hold

$$\begin{aligned} \overline{X}\widetilde{\delta}_s + \overline{S}\widetilde{\delta}_x &= \widetilde{\delta}_\mu, \\ A\widetilde{\delta}_x &= 0, \\ A^\top \widetilde{\delta}_y + \widetilde{\delta}_s &= 0. \end{aligned}$$

    $p_\mu \leftarrow \mathrm{mp.Query}(\frac{1}{\sqrt{\overline{X}\overline{S}}}\widetilde{\delta}_\mu)$ ▷ Algorithm 2.3

    $\widetilde{\delta}_s \leftarrow \frac{\overline{S}}{\sqrt{\overline{X}\overline{S}}} p_\mu$ ▷ According to (2.11)

    $\widetilde{\delta}_x \leftarrow \frac{1}{\overline{S}}\widetilde{\delta}_\mu - \frac{\overline{X}}{\sqrt{\overline{X}\overline{S}}} p_\mu$ ▷ According to (2.12)

  until $\|\overline{s}^{-1}\widetilde{\delta}_s\|_\infty \leq \frac{1}{100\log n}$ and $\|\overline{x}^{-1}\widetilde{\delta}_x\|_\infty \leq \frac{1}{100\log n}$

  return $(x + \widetilde{\delta}_x, s + \widetilde{\delta}_s)$

end procedure

($\|\widetilde{\delta}_\mu\|_2 \sim t\sqrt{\frac{n}{k}}$). After the projection, we have $\|X^{-1}\delta_x\|_2 \sim \frac{1}{t}\|(I-P)\delta_\mu\|_2 \sim \sqrt{\frac{n}{k}}$. Hence, the bound of $\|X^{-1}\delta_x\|_\infty$ using $\|X^{-1}\delta_x\|_2$ is too weak. To improve the bound, we use Chernoff bounds to estimate $\|X^{-1}\delta_x\|_\infty$.

Beside the ℓ_∞ norm bound, the proof sketch in (2.10) also requires using $x_i s_i \sim t$ for all i. The short step central path proof maintains an invariant that $\sum_i (x_i s_i - t)^2 = O(t^2)$. However, since our stochastic step has a stochastic noise with ℓ_2 norm as large as $t\sqrt{\frac{n}{k}}$, one cannot hope to maintain $x_i s_i$ close to t in ℓ_2 norm. Instead, we follow an idea in

Algorithm 2.2 Our Main Algorithm

[LS14, LSW15] and maintain the following potential

$$\sum_{i=1}^{n} \cosh\left(\lambda\left(\frac{x_i s_i}{t} - 1\right)\right) = n^{O(1)}$$

with $\lambda = \Theta(\log n)$. This potential is a variant of soft-max. Note that the potential bounded by $n^{O(1)}$ implies that $x_i s_i$ is a multiplicative approximation of t. To bound the potential, consider $r_i = \frac{x_i s_i}{t}$ and $\Phi(r)$ be the potential above. Then, we have that

$$\mathbb{E}[\Phi(r^{\text{new}})] \leq \Phi(r) + \langle \nabla\Phi(r), \mathbb{E}[r^{\text{new}} - r]\rangle + O(1)\,\mathbb{E}\,\|r^{\text{new}} - r\|^2_{\nabla^2\Phi(r)}.$$

The first order term can be bounded efficiently because $\mathbb{E}[r^{\text{new}} - r]$ is close to the short step central path step. The second term is a variance term which scales like $1/k$ due to the k independent coordinates. Therefore, the potential changed by $1/k \sim 1/\sqrt{n}$ factor each step. Hence, we can maintain it for roughly $\sqrt{n}$ steps.

To make sure the potential Φ is bounded during the whole algorithm, our step is the mixtures of two steps of the form $\delta_\mu \sim -\frac{t}{\sqrt{n}} - t\frac{\nabla\Phi}{\|\nabla\Phi\|_2}$. The first term is to decrease t and the second term is to decrease Φ.

Since the algorithm is randomized, there is a tiny probability that Φ is large. In that case, we switch to a short step central path method. See Figure 2.1, Algorithm 2.1, and Algorithm 3.6. The first part of the proof involves bounding every quantity listed in Table 2.1. In the second part, we are using these quantities to bound the expectation of Φ.

To decouple the proof in both parts, we will make the following assumption in first part. It will be verified in the second part.

Assumption 2.4.1. *Assume the following for the input of the procedure* StochasticStep *(see Algorithm 2.1):*

- $xs \approx_{0.1} t$ *with* $t > 0$.
- $mp.\textsc{Update}(w)$ *outputs* $\widetilde{v}$ *such that* $w \approx_{\epsilon_{mp}} \widetilde{v}$ *with* $\epsilon_{mp} \leq 1/40000$.
- $\|\delta_\mu\|_2 \leq \epsilon t$ *with* $0 < \epsilon < 1/(40000 \log n)$.
- $k \geq 1000\epsilon\sqrt{n}\log^2 n/\epsilon_{mp}$.

Quantity	Bound	Place
$\|\mathbb{E}[s^{-1}\widetilde{\delta}_s]\|_2, \|\mathbb{E}[x^{-1}\widetilde{\delta}_x]\|_2, \|\mathbb{E}[\mu^{-1}\widetilde{\delta}_\mu]\|_2$	$O(\epsilon)$	Part 1, Lemma 2.4.3
$\|\mathbb{E}[\mu^{-1}(\mu^{\mathrm{new}} - \mu - \widetilde{\delta}_\mu)]\|_2$	$O(\epsilon_{mp} \cdot \epsilon)$	Part 1, Lemma 2.4.7
$\|\mathbb{E}[\mu^{-1}(\mu^{\mathrm{new}} - \mu)]\|_2$	$O(\epsilon)$	Part 1, Lemma 2.4.7
$\mathbb{V}[s_i^{-1}\widetilde{\delta}_{s,i}], \mathbb{V}[x_i^{-1}\widetilde{\delta}_{x,i}], \mathbb{V}[\mu_i^{-1}\widetilde{\delta}_{\mu,i}]$	$O(\epsilon^2/k)$	Part 2, Lemma 2.4.3
$\mathbb{V}[\mu_i^{-1}\mu^{\mathrm{new}}]$	$O(\epsilon^2/k)$	Part 2, Lemma 2.4.7
$\|s^{-1}\widetilde{\delta}_s\|_\infty, \|x^{-1}\widetilde{\delta}_x\|_\infty, \|\mu^{-1}\widetilde{\delta}_\mu\|_\infty$	$O(1/\log n)$	Part 3, Lemma 2.4.3
$\|\mu^{-1}(\mu^{\mathrm{new}} - \mu)\|_\infty$	$O(1/\log n)$	Part 3, Lemma 2.4.7

Table 2.1: The bound of each quantity under Assumption 2.4.1. For intuition, think $\epsilon \sim \epsilon_{mp} \sim 1/10$ and $k \sim \sqrt{n}$.

2.4.2 Bounding each quantity of stochastic step

First, we give an explicit formula for our step, which will be used in all subsequent calculations.

Lemma 2.4.2. *The procedure* StochasticStep$(\mathrm{mp}, x, s, \delta_\mu, k, \epsilon)$ *(see Algorithm 2.1) finds a solution* $\widetilde{\delta}_x$, $\widetilde{\delta}_s \in \mathbb{R}^n$ *to* (2.7) *by the formula*

$$\widetilde{\delta}_x = \frac{\overline{X}}{\sqrt{\overline{X}\overline{S}}}(I - \overline{P})\frac{1}{\sqrt{\overline{X}\overline{S}}}\widetilde{\delta}_\mu \tag{2.11}$$

$$\widetilde{\delta}_s = \frac{\overline{S}}{\sqrt{\overline{X}\overline{S}}}\overline{P}\frac{1}{\sqrt{\overline{X}\overline{S}}}\widetilde{\delta}_\mu \tag{2.12}$$

with

$$\overline{P} = \sqrt{\frac{\overline{X}}{\overline{S}}}A^\top \left(A\frac{\overline{X}}{\overline{S}}A^\top\right)^{-1} A\sqrt{\frac{\overline{X}}{\overline{S}}}. \tag{2.13}$$

Proof. For the first equation of (2.7), we multiply $A\overline{S}^{-1}$ on both sides,

$$A\overline{S}^{-1}\overline{X}\widetilde{\delta}_s + A\widetilde{\delta}_x = A\overline{S}^{-1}\widetilde{\delta}_\mu.$$

Since the second equation gives $A\widetilde{\delta}_x = 0$, then we know that $A\overline{S}^{-1}\overline{X}\widetilde{\delta}_s = A\overline{S}^{-1}\widetilde{\delta}_\mu$.

Multiplying $A\overline{S}^{-1}\overline{X}$ on both sides of the third equation of (2.7), we have

$$-A\overline{S}^{-1}\overline{X}A^\top\widetilde{\delta}_y = A\overline{S}^{-1}\overline{X}\widetilde{\delta}_s = A\overline{S}^{-1}\widetilde{\delta}_\mu.$$

Thus,

$$\begin{aligned}
\widetilde{\delta}_y &= -(A\overline{S}^{-1}\overline{X}A^\top)^{-1}A\overline{S}^{-1}\widetilde{\delta}_\mu, \\
\widetilde{\delta}_s &= A^\top(A\overline{S}^{-1}\overline{X}A^\top)^{-1}A\overline{S}^{-1}\widetilde{\delta}_\mu, \\
\widetilde{\delta}_x &= \overline{S}^{-1}\widetilde{\delta}_\mu - \overline{S}^{-1}\overline{X}A^\top(A\overline{S}^{-1}\overline{X}A^\top)^{-1}A\overline{S}^{-1}\widetilde{\delta}_\mu.
\end{aligned}$$

Recall we define $\overline{P}$ as (2.13), then we have

$$\widetilde{\delta}_s = \frac{\overline{S}}{\sqrt{\overline{X}\overline{S}}}\cdot\sqrt{\frac{\overline{X}}{\overline{S}}}A^\top(A\frac{\overline{X}}{\overline{S}}A^\top)^{-1}\sqrt{\frac{\overline{X}}{\overline{S}}}\cdot\frac{1}{\sqrt{\overline{X}\overline{S}}}\widetilde{\delta}_\mu = \frac{\overline{S}}{\sqrt{\overline{X}\overline{S}}}\overline{P}\frac{1}{\sqrt{\overline{X}\overline{S}}}\widetilde{\delta}_\mu,$$

and

$$\widetilde{\delta}_x = \overline{S}^{-1}\widetilde{\delta}_\mu - \frac{\overline{X}}{\sqrt{\overline{X}\overline{S}}}\cdot\sqrt{\frac{\overline{X}}{\overline{S}}}A^\top(A\frac{\overline{X}}{\overline{S}}A^\top)^{-1}\sqrt{\frac{\overline{X}}{\overline{S}}}\cdot\frac{1}{\sqrt{\overline{X}\overline{S}}}\widetilde{\delta}_\mu = \frac{\overline{X}}{\sqrt{\overline{X}\overline{S}}}(I-\overline{P})\frac{1}{\sqrt{\overline{X}\overline{S}}}\widetilde{\delta}_\mu.$$

which are matching (2.11) and (2.12).

To see why the StochasticStep outputs $\widetilde{\delta}_x$, $\widetilde{\delta}_s$ satisfying (2.11) and (2.12), we note that

$$p_\mu = \sqrt{\widetilde{V}}A^\top\left(A\frac{\overline{X}}{\overline{S}}A^\top\right)^{-1}A\sqrt{\widetilde{V}}\frac{1}{\sqrt{\overline{X}\overline{S}}}\widetilde{\delta}_\mu = \overline{P}\frac{1}{\sqrt{\overline{X}\overline{S}}}\widetilde{\delta}_\mu$$

because of Theorem 2.5.1. □

Using the explicitly formula, we are ready to bound all quantities we needed in the following two subsubsections.

2.4.2.1 Bounding $\widetilde{\delta}_s$, $\widetilde{\delta}_x$ and $\widetilde{\delta}_\mu$

Lemma 2.4.3. *Under the Assumption 2.4.1, the two vectors $\widetilde{\delta}_x$ and $\widetilde{\delta}_s$ found by* StochasticStep *satisfy :*

1. $\|\mathbb{E}[\overline{s}^{-1}\widetilde{\delta}_s]\|_2 \leq 2\epsilon, \|\mathbb{E}[\overline{x}^{-1}\widetilde{\delta}_x]\|_2 \leq 2\epsilon, \|\mathbb{E}[s^{-1}\widetilde{\delta}_s]\|_2 \leq 2\epsilon, \|\mathbb{E}[x^{-1}\widetilde{\delta}_x]\|_2 \leq 2\epsilon, \|\mathbb{E}[\mu^{-1}\widetilde{\delta}_\mu]\|_2 \leq 4\epsilon$.

2. $\mathbb{V}[\frac{\widetilde{\delta}_{s,i}}{\overline{s}_i}] \leq \frac{2\epsilon^2}{k}, \mathbb{V}[\frac{\widetilde{\delta}_{x,i}}{\overline{x}_i}] \leq \frac{2\epsilon^2}{k}, \mathbb{V}[\frac{\widetilde{\delta}_{s,i}}{s_i}] \leq \frac{2\epsilon^2}{k}, \mathbb{V}[\frac{\widetilde{\delta}_{x,i}}{x_i}] \leq \frac{2\epsilon^2}{k}, \mathbb{V}[\frac{\widetilde{\delta}_{\mu,i}}{\mu_i}] \leq \frac{8\epsilon^2}{k}$.

3. $\|\overline{s}^{-1}\widetilde{\delta}_s\|_\infty \leq \frac{0.01}{\log n}, \|s^{-1}\widetilde{\delta}_s\|_\infty \leq \frac{0.02}{\log n}, \|\overline{x}^{-1}\widetilde{\delta}_x\|_\infty \leq \frac{0.01}{\log n}, \|x^{-1}\widetilde{\delta}_x\|_\infty \leq \frac{0.02}{\log n}, \|\mu^{-1}\widetilde{\delta}_\mu\|_\infty \leq \frac{0.02}{\log n}$.

Remark 2.4.1. For notational simplicity, the $\mathbb{E}$ and $\mathbb{V}$ in the proof are for the case without resampling (Line 12). Since the all the additional terms due to resampling are polynomially bounded and since we can set failure probability to an arbitrarily small inverse polynomial (see Claim 2.4.6), the proof does not change and the result remains the same.

Proof.

Claim 2.4.4 (Part 1, bounding the ℓ_2 norm of expectation)**.**

$$\|\mathbb{E}[\overline{s}^{-1}\widetilde{\delta}_s]\|_2 \leq 2\epsilon, \|\mathbb{E}[\overline{x}^{-1}\widetilde{\delta}_x]\|_2 \leq 2\epsilon, \|\mathbb{E}[s^{-1}\widetilde{\delta}_s]\|_2 \leq 2\epsilon, \|\mathbb{E}[x^{-1}\widetilde{\delta}_x]\|_2 \leq 2\epsilon, \|\mathbb{E}[\mu^{-1}\widetilde{\delta}_\mu]\|_2 \leq 4\epsilon.$$

Proof. For $\|\overline{s}^{-1}\widetilde{\delta}_s\|_\infty$, we consider the i-th coordinate of the vector

$$\overline{s}_i^{-1}\widetilde{\delta}_{s,i} = \frac{1}{\sqrt{\overline{x}_i\overline{s}_i}}\sum_{j=1}^{n}\overline{P}_{i,j}\frac{\widetilde{\delta}_{\mu,j}}{\sqrt{\overline{x}_j\overline{s}_j}}.$$

Then, we have

$$\mathbb{E}\left[\overline{s}_i^{-1}\widetilde{\delta}_{s,i}\right] = \frac{1}{\sqrt{\overline{x}_i\overline{s}_i}}\sum_{j=1}^{n}\overline{P}_{i,j}\frac{\mathbb{E}[\widetilde{\delta}_{\mu,j}]}{\sqrt{\overline{x}_j\overline{s}_j}} = \frac{1}{\sqrt{\overline{x}_i\overline{s}_i}}\sum_{j=1}^{n}\overline{P}_{i,j}\frac{\delta_{\mu,j}}{\sqrt{\overline{x}_j\overline{s}_j}}.$$

Since $xs \approx_{0.1} t$ and $\|\delta_\mu\| \leq \epsilon t$, we have $\|\frac{\delta_\mu}{\sqrt{xs}}\|_2 \leq \frac{1.1\epsilon t}{\sqrt{t}}$. Since $\overline{P}$ is an orthogonal projection matrix, we have $\|\overline{P}\frac{\delta_\mu}{\sqrt{\overline{xs}}}\|_2 \leq \|\frac{\delta_\mu}{\sqrt{\overline{xs}}}\|_2$. Putting all the above facts and $xs = \overline{xs}$, we can show

$$\begin{aligned}
\left\|\mathbb{E}[\overline{s}^{-1}\widetilde{\delta}_s]\right\|_2^2 &= \sum_{i=1}^n \left(\frac{1}{\sqrt{\overline{x}_i\overline{s}_i}}\sum_{j=1}^n \overline{P}_{i,j}\frac{\delta_{\mu,j}}{\sqrt{\overline{x}_j\overline{s}_j}}\right)^2 = \sum_{i=1}^n \frac{1}{\overline{x}_i\overline{s}_i}\left(\sum_{j=1}^n \overline{P}_{i,j}\frac{\delta_{\mu,j}}{\sqrt{\overline{x}_j\overline{s}_j}}\right)^2 \\
&\leq \frac{1}{0.9t}\sum_{i=1}^n \left(\sum_{j=1}^n \overline{P}_{i,j}\frac{\delta_{\mu,j}}{\sqrt{\overline{x}_j\overline{s}_j}}\right)^2 = \frac{1}{0.9t}\|\overline{P}\frac{\delta_\mu}{\sqrt{\overline{xs}}}\|_2^2 \\
&\leq \frac{1}{0.9t}\|\frac{\delta_\mu}{\sqrt{\overline{xs}}}\|_2^2 \leq \frac{(1.1)^2}{0.9t}\cdot\frac{(\epsilon t)^2}{t} \leq 1.4\epsilon^2,
\end{aligned}$$

which implies that

$$\left\|\mathbb{E}[\overline{s}^{-1}\widetilde{\delta}_s]\right\|_2 \leq 1.2\epsilon. \tag{2.14}$$

Notice that the proof for x is identical to the proof for s because $(I - \overline{P})$ is also a projection matrix. Since $\overline{s} \approx_{0.1} s$ and $\overline{x} \approx_{0.1} x$, then we can also prove the next two inequalities in the Claim statement.

Now, we are ready to bound $\|\mathbb{E}[\mu^{-1}\widetilde{\delta}_\mu]\|_2$

$$\|\mathbb{E}[\mu^{-1}\widetilde{\delta}_\mu]\|_2 = \|\mathbb{E}[\overline{s}^{-1}\overline{x}^{-1}(\overline{x}\widetilde{\delta}_s + \overline{s}\widetilde{\delta}_x)]\|_2 \leq \|\mathbb{E}[\overline{s}^{-1}\widetilde{\delta}_s]\|_2 + \|\mathbb{E}[\overline{x}^{-1}\widetilde{\delta}_x]\|_2 \leq 4\epsilon.$$

by using $\mu = xs = \overline{xs}$ and $\overline{x}\widetilde{\delta}_s + \overline{s}\widetilde{\delta}_x = \widetilde{\delta}_\mu$ from (2.7). □

Claim 2.4.5 (Part 2, bounding the variance per coordinate)**.**

$$\mathbb{V}[\overline{s}_i^{-1}\widetilde{\delta}_{s,i}] \leq \frac{2\epsilon^2}{k}, \mathbb{V}[\overline{x}_i^{-1}\widetilde{\delta}_{x,i}] \leq \frac{2\epsilon^2}{k}, \mathbb{V}[s_i^{-1}\widetilde{\delta}_{s,i}] \leq \frac{2\epsilon^2}{k}, \mathbb{V}[x_i^{-1}\widetilde{\delta}_{x,i}] \leq \frac{2\epsilon^2}{k}, \mathbb{V}[\mu_i^{-1}\widetilde{\delta}_{\mu,i}] \leq \frac{8\epsilon^2}{k}.$$

Proof. Consider the i-th coordinate of the vector

$$\overline{s}_i^{-1}\widetilde{\delta}_{s,i} = \frac{1}{\sqrt{\overline{x}_i\overline{s}_i}}\sum_{j=1}^n \overline{P}_{i,j}\frac{\widetilde{\delta}_{\mu,j}}{\sqrt{\overline{x}_j\overline{s}_j}}.$$

For variance of $\overline{s}_i^{-1}\widetilde{\delta}_{s,i}$, we have

$$\begin{aligned}
\mathbb{V}[\overline{s}_i^{-1}\widetilde{\delta}_{s,i}] &= \frac{1}{\overline{x}_i\overline{s}_i}\sum_{j=1}^n \frac{\overline{P}_{i,j}^2}{\overline{x}_j\overline{s}_j}\mathbb{V}[\widetilde{\delta}_{\mu,j}] && \text{by all } \widetilde{\delta}_{\mu,j} \text{ are independent} \\
&\leq \frac{1}{\overline{x}_i\overline{s}_i}\sum_{j=1}^n \frac{\overline{P}_{i,j}^2}{\overline{x}_j\overline{s}_j}\frac{1}{k}\frac{\delta_{\mu,j}^2}{\frac{\delta_{\mu,j}^2}{\sum_{l=1}^n \delta_{\mu,l}^2}+\frac{1}{n}} && \text{by (2.6)} \\
&\leq \frac{1}{\overline{x}_i\overline{s}_i}\sum_{j=1}^n \frac{\overline{P}_{i,j}^2}{\overline{x}_j\overline{s}_j}\frac{1}{k}\sum_{l=1}^n \delta_{\mu,l}^2 \\
&\leq \frac{1.3}{t^2}\sum_{j=1}^n \overline{P}_{i,j}^2\frac{1}{k}\sum_{l=1}^n \delta_{\mu,l}^2 \leq \frac{1.3\epsilon^2}{k}, && \text{by } \overline{x}_i\overline{s}_i = x_is_i \approx_{1/10} t
\end{aligned}$$

where we used that $\sum_{j=1}^n \overline{P}_{i,j}^2 = \overline{P}_{i,i} \leq 1$, $\|\delta_\mu\|_2 \leq \epsilon t$ at the end.

The proof for the other three inequalities in the Claim statement are identical to this one. We omit here.

For the variance of $\mu_i^{-1}\widetilde{\delta}_{\mu,i}$,

$$\begin{aligned}
\mathbb{V}[\mu_i^{-1}\widetilde{\delta}_{\mu,i}] =\ & \mathbb{V}[\overline{x}_i^{-1}\overline{s}_i^{-1}(\overline{x}_i\widetilde{\delta}_{s,i} + \overline{s}_i\widetilde{\delta}_{x,i})] \\
&\leq 2\,\mathbb{V}[\overline{x}_i^{-1}\overline{x}_i\overline{s}_i^{-1}\widetilde{\delta}_{s,i}] + 2\,\mathbb{V}[\overline{s}_i^{-1}\overline{s}_i\overline{x}_i^{-1}\widetilde{\delta}_{x,i}] \\
&= 2\,\mathbb{V}[\overline{s}_i^{-1}\widetilde{\delta}_{s,i}] + 2\,\mathbb{V}[\overline{x}_i^{-1}\widetilde{\delta}_{x,i}] \leq 8\epsilon^2/k.
\end{aligned}$$

where the first step follows by definition of $\mu = xs = \overline{x}\overline{s}$ and (2.7), the second step follows by triangle inequality and, the last step follows by $\mathbb{V}[\overline{s}_i^{-1}\widetilde{\delta}_{s,i}], \mathbb{V}[\overline{x}_i^{-1}\widetilde{\delta}_{x,i}] \leq 2\epsilon^2/k$ □

Claim 2.4.6 (Part 3, bounding the probability of success)**.** *Without resampling, the following holds with probability* $1 - 2n\exp(-\frac{0.003k}{\epsilon\sqrt{n}\log n})$.

$$\|\overline{s}^{-1}\widetilde{\delta}_s\|_\infty \leq \frac{0.01}{\log n}, \|s^{-1}\widetilde{\delta}_s\|_\infty \leq \frac{0.02}{\log n}, \|\overline{x}^{-1}\widetilde{\delta}_x\|_\infty \leq \frac{0.01}{\log n}, \|x^{-1}\widetilde{\delta}_x\|_\infty \leq \frac{0.02}{\log n}, \|\mu^{-1}\widetilde{\delta}_\mu\|_\infty \leq \frac{0.02}{\log n}.$$

With resampling, it always holds.

Proof. We can write $\overline{s}_i^{-1}\widetilde{\delta}_{s,i} - \mathbb{E}[\overline{s}_i^{-1}\widetilde{\delta}_{s,i}] = \sum_j Y_j$ where Y_j are independent random variables defined by

$$Y_j = \frac{1}{\sqrt{\overline{x}_i\overline{s}_i}}\overline{P}_{i,j}\frac{\widetilde{\delta}_{\mu,j}}{\sqrt{\overline{x}_j\overline{s}_j}} - \frac{1}{\sqrt{\overline{x}_i\overline{s}_i}}\overline{P}_{i,j}\frac{\delta_{\mu,j}}{\sqrt{\overline{x}_j\overline{s}_j}}.$$

We bound the sum using Bernstein inequality (Lemma A.1.2). Note that Y_j are mean 0 and that Claim 2.4.5 shows that $\sum_{j=1}^n \mathbb{E}[Y_j^2] = \mathbb{V}[\overline{s}_i^{-1}\widetilde{\delta}_{s,i}] \le \frac{2\epsilon^2}{k}$. We also need to give an upper bound for Y_j

$$\begin{aligned}
|Y_j| &= \left|\frac{1}{\sqrt{\overline{x}_i\overline{s}_i}}\overline{P}_{i,j}\left(\frac{\widetilde{\delta}_{\mu,j}-\delta_{\mu,j}}{\sqrt{\overline{x}_j\overline{s}_j}}\right)\right| \\
&\le \frac{1.2}{t}|\widetilde{\delta}_{\mu,j}-\delta_{\mu,j}| && \text{by } |\overline{P}_{i,j}| \le 1, x_i s_i \approx_{1/10} t \\
&\le \frac{1.2}{t}|\delta_{\mu,j}/p_j| && \text{by } \widetilde{\delta}_{\mu,j} \in [0, \delta_{\mu,j}/p_j] \\
&= \frac{1.2}{t}\frac{1}{k}\frac{1}{(\frac{\delta_{\mu,i}}{\sum_{l=1}^n \delta_{\mu,l}^2} + \frac{1}{n\delta_{\mu,i}})} && \text{by (2.6)} \\
&\le \frac{0.6}{t}\frac{1}{k}\left(n\sum_{l=1}^n \delta_{\mu,l}^2\right)^{1/2} && \text{by } a^2+b^2 \ge 2ab \\
&\le \frac{0.6\epsilon\sqrt{n}}{k} \stackrel{\text{def}}{=} M. && \text{by } \|\delta_\mu\|_2 \le \epsilon t
\end{aligned}$$

Now, we can apply Bernstein inequality (Lemma A.1.2)

$$\begin{aligned}
\Pr\left[\left|\sum_{j=1}^n Y_j\right| > b\right] &\le 2\exp\left(-\frac{b^2/2}{\sum_{j=1}^n \mathbb{E}[Y_j^2] + Mb/3}\right) \\
&\le 2\exp\left(-\frac{b^2/2}{2\epsilon^2/k + (0.6\epsilon\sqrt{n}/k)\cdot b/3}\right).
\end{aligned}$$

We choose $b = \frac{0.005}{\log n}$ and use $\epsilon \le \frac{1}{400\log n}$ and $n \ge 10$ to get

$$\Pr\left[\left|\sum_{j=1}^n Y_j\right| \ge \frac{0.05}{\log n}\right] \le 2\exp\left(-\frac{0.003k}{\epsilon\sqrt{n}\log n}\right).$$

Since $\|\mathbb{E}[\overline{s}_i^{-1}\widetilde{\delta}_{s,i}]\|_2 \le 2\epsilon \le \frac{0.005}{\log n}$, we have that $|\overline{s}_i^{-1}\widetilde{\delta}_{s,i}| \le \frac{0.01}{\log n}$ with probability $1 - 2\exp(-\frac{0.003k}{\epsilon\sqrt{n}\log n})$. Taking a union bound, we have that $\|\overline{s}^{-1}\widetilde{\delta}_s\|_\infty \le \frac{0.01}{\log n}$ with probability $1 - 2n\exp(-\frac{0.003k}{\epsilon\sqrt{n}\log n})$. Similarly, this holds for the other 3 terms.

Now, the last term follows by

$$|\mu_i^{-1}\widetilde{\delta}_{\mu,i}| = |\overline{x}_i^{-1}\overline{s}_i^{-1}(\overline{x}_i\widetilde{\delta}_{s,i} + \overline{s}_i\widetilde{\delta}_{x,i})| = |\overline{s}_i^{-1}\widetilde{\delta}_{s,i}| + |\overline{x}_i^{-1}\widetilde{\delta}_{x,i}| \le \frac{0.02}{\log n}.$$

□

□

2.4.2.2 Bounding $\mu^{\text{new}} - \mu$

Lemma 2.4.7. *Under the Assumption 2.4.1, the vector* $\mu_i^{\text{new}} \stackrel{\text{def}}{=} (x_i + \widetilde{\delta}_{x,i})(s_i + \widetilde{\delta}_{s,i})$ *satisfies*

1. $\|\mathbb{E}[\mu^{-1}(\mu^{\text{new}} - \mu - \widetilde{\delta}_\mu)]\|_2 \le 10\epsilon_{mp}\cdot\epsilon$ *and* $\|\mathbb{E}[\mu^{-1}(\mu^{\text{new}} - \mu)]\|_2 \le 5\epsilon$.
2. $\mathbb{V}[\mu_i^{-1}\mu_i^{\text{new}}] \le 50\epsilon^2/k$ *for all* i.
3. $\|\mu^{-1}(\mu^{\text{new}} - \mu)\|_\infty \le \frac{0.021}{\log n}$.

Claim 2.4.8 (Part 1 of Lemma 2.4.7)**.**

$$\|\mathbb{E}[\mu^{-1}(\mu^{\text{new}} - \mu - \widetilde{\delta}_\mu)]\|_2 \le 10\epsilon_{mp}\cdot\epsilon, \text{ and } \|\mathbb{E}[\mu^{-1}(\mu^{\text{new}} - \mu)]\|_2 \le 5\epsilon.$$

Proof.

$$\mu^{\text{new}} = (x + \widetilde{\delta}_x)(s + \widetilde{\delta}_s) = \mu + x\widetilde{\delta}_s + s\widetilde{\delta}_x + \widetilde{\delta}_x\widetilde{\delta}_s = \mu + \underbrace{\overline{x}\widetilde{\delta}_s + \overline{s}\widetilde{\delta}_x}_{\widetilde{\delta}_\mu} + \underbrace{(x-\overline{x})\widetilde{\delta}_s + (s-\overline{s})\widetilde{\delta}_x + \widetilde{\delta}_x\widetilde{\delta}_s}_{\epsilon_\mu}.$$

Taking the expectation on both sides, we have

$$\mathbb{E}[\mu^{\text{new}} - \mu - \widetilde{\delta}_\mu] = (x - \overline{x})\,\mathbb{E}[\widetilde{\delta}_s] + (s - \overline{s})\,\mathbb{E}[\widetilde{\delta}_x] + \mathbb{E}[\widetilde{\delta}_x\widetilde{\delta}_s].$$

Hence, we have that

$$\begin{aligned}
&\|\mu^{-1}\,\mathbb{E}[\mu^{\text{new}} - \mu - \widetilde{\delta}_\mu]\|_2 \\
&\le \|\mu^{-1}(x-\overline{x})s\cdot s^{-1}\,\mathbb{E}[\widetilde{\delta}_s]\|_2 + \|\mu^{-1}(s-\overline{s})x\cdot x^{-1}\,\mathbb{E}[\widetilde{\delta}_x]\|_2 + \|\mu^{-1}\,\mathbb{E}[\widetilde{\delta}_x\widetilde{\delta}_s]\|_2 \\
&\le \|\mu^{-1}(x-\overline{x})s\|_\infty\cdot\|s^{-1}\,\mathbb{E}[\widetilde{\delta}_s]\|_2 + \|\mu^{-1}(s-\overline{s})x\|_\infty\cdot\|x^{-1}\,\mathbb{E}[\widetilde{\delta}_x]\|_2 + \|\mu^{-1}\,\mathbb{E}[\widetilde{\delta}_x\widetilde{\delta}_s]\|_2 \\
&\le \epsilon_{mp}\cdot\|s^{-1}\,\mathbb{E}[\widetilde{\delta}_s]\|_2 + \epsilon_{mp}\cdot\|x^{-1}\,\mathbb{E}[\widetilde{\delta}_x]\|_2 + \|\mu^{-1}\,\mathbb{E}[\widetilde{\delta}_x\widetilde{\delta}_s]\|_2 \\
&\le 4\epsilon_{mp}\cdot\epsilon + \|\mu^{-1}\,\mathbb{E}[\widetilde{\delta}_x\widetilde{\delta}_s]\|_2, \qquad (2.15)
\end{aligned}$$

where the first step follows by triangle inequality, the second step follows by $\|ab\|_2 \le \|a\|_\infty \cdot \|b\|_2$, the third step follows by $\|\mu^{-1}(x-\overline{x})s\|_\infty \le \epsilon_{mp}$ and $\|\mu^{-1}(s-\overline{s})x\|_\infty \le \epsilon_{mp}$ (since $\overline{x} \approx_{\epsilon_{mp}} x$, $\overline{s} \approx_{\epsilon_{mp}} s$), the last step follows by $\|\,\mathbb{E}[s^{-1}\widetilde{\delta}_s]\|_2 \le 2\epsilon$ and $\|\,\mathbb{E}[x^{-1}\widetilde{\delta}_x]\|_2 \le 2\epsilon$ (Part 1 of Lemma 2.4.3).

To bound the last term, using $\mathbb{E}[\widetilde{\delta}_s] = \delta_s$ and $\mathbb{E}[\widetilde{\delta}_x] = \delta_x$, we note that

$$\mathbb{E}[\widetilde{\delta}_{x,i}\widetilde{\delta}_{s,i}] = \delta_{x,i}\delta_{s,i} + \mathbb{E}[(\widetilde{\delta}_{x,i} - \delta_{x,i})(\widetilde{\delta}_{s,i} - \delta_{s,i})].$$

Hence, we have

$$\begin{aligned}
\|\mu^{-1}\,\mathbb{E}[\widetilde{\delta}_x\widetilde{\delta}_s]\|_2 &\le \|\mu^{-1}\delta_x\delta_s\|_2 + \left(\sum_{i=1}^n\left(\mathbb{E}\left[x_i^{-1}(\widetilde{\delta}_{x,i}-\delta_{x,i})\cdot s_i^{-1}(\widetilde{\delta}_{s,i}-\delta_{s,i})\right]\right)^2\right)^{1/2} \\
&\le 4\epsilon^2 + \frac{1}{2}\left(\sum_{i=1}^n\left(\mathbb{V}[x_i^{-1}\widetilde{\delta}_{x,i}] + \mathbb{V}[s_i^{-1}\widetilde{\delta}_{s,i}]\right)^2\right)^{1/2} \\
&\le 4\epsilon^2 + \frac{1}{2}\left(\sum_{i=1}^n 2(\mathbb{V}[x_i^{-1}\widetilde{\delta}_{x,i}])^2 + 2(\mathbb{V}[s_i^{-1}\widetilde{\delta}_{s,i}])^2\right)^{1/2} \\
&\le 4\epsilon^2 + 2\sqrt{n\cdot\epsilon^4/k^2} \le 4\epsilon^2 + 2\epsilon\cdot\epsilon_{mp} \le 6\epsilon\cdot\epsilon_{mp}, \qquad (2.16)
\end{aligned}$$

where the second step follows by $\|\mu^{-1}\delta_x\delta_s\|_2 \le \|x^{-1}\delta_x\|_2\cdot\|s^{-1}\delta_s\|_2 \le 4\epsilon^2$ (Part 1 of Lemma 2.4.3) and $2ab \le a^2+b^2$, the third step follows by $(a+b)^2 \le 2a^2+2b^2$, the fourth step follows by

$\mathbb{V}[x_i^{-1}\widetilde{\delta}_{x,i}] \le 2\epsilon^2/k$ and $\mathbb{V}[s_i^{-1}\widetilde{\delta}_{s,i}] \le 2\epsilon^2/k$ (Part 2 of Lemma 2.4.3), the last step follows by $k \ge \frac{\epsilon\sqrt{n}}{\epsilon_{mp}}$.

Combining (2.15) and (2.16), we have that

$$\|\mu^{-1}(\mathbb{E}[\mu^{\text{new}} - \mu - \widetilde{\delta}_\mu])\|_2 \le 4\epsilon_{mp}\cdot\epsilon + \|\mu^{-1}\,\mathbb{E}[\widetilde{\delta}_x\widetilde{\delta}_s]\|_2 \le 10\epsilon_{mp}\cdot\epsilon.$$

where we used $\epsilon \le \epsilon_{mp}$.

From Part 1 of Lemma 2.4.3, we know that $\|\mu^{-1}\,\mathbb{E}[\widetilde{\delta}_\mu]\|_2 \le 4\epsilon$. Thus using triangle inequality, we know

$$\|\mu^{-1}(\mathbb{E}[\mu^{\text{new}} - \mu])\|_2 \le 10\epsilon_{mp}\cdot\epsilon + 4\epsilon \le 5\epsilon.$$

□

Claim 2.4.9 (Part 2 of Lemma 2.4.7)**.** $\mathbb{V}[\mu_i^{-1}\mu_i^{\text{new}}] \le 50\epsilon^2/k$ *for all* i.

Proof. Recall that

$$\mu^{\text{new}} = \mu + \widetilde{\delta}_\mu + (x-\overline{x})\widetilde{\delta}_s + (s-\overline{s})\widetilde{\delta}_x + \widetilde{\delta}_x\widetilde{\delta}_s.$$

We can upper bound the variance of $\mu_i^{-1}\mu_i^{\text{new}}$,

$$\begin{aligned}
\mathbb{V}[\mu_i^{-1}\mu_i^{\text{new}}] &\le 4\,\mathbb{V}[\mu_i^{-1}\widetilde{\delta}_{\mu,i}] + 4\,\mathbb{V}[\mu_i^{-1}(x_i-\overline{x}_i)\widetilde{\delta}_{s,i}] + 4\,\mathbb{V}[\mu_i^{-1}(s_i-\overline{s}_i)\widetilde{\delta}_{x,i}] + 4\,\mathbb{V}[\mu_i^{-1}\widetilde{\delta}_{x,i}\widetilde{\delta}_{s,i}] \\
&\le 32\frac{\epsilon^2}{k} + 4\frac{\epsilon^2}{k} + 4\frac{\epsilon^2}{k} + \mathbb{V}[\mu_i^{-1}\widetilde{\delta}_{x,i}\widetilde{\delta}_{s,i}] \\
&= 40\frac{\epsilon^2}{k} + \mathbb{V}[x_i^{-1}\widetilde{\delta}_{x,i}\cdot s_i^{-1}\widetilde{\delta}_{s,i}] \\
&\le 40\frac{\epsilon^2}{k} + 2\,\mathbf{Sup}[(x_i^{-1}\widetilde{\delta}_{x,i})^2]\cdot\mathbb{V}[s_i^{-1}\widetilde{\delta}_{s,i}] + 2\,\mathbf{Sup}[(y_i^{-1}\widetilde{\delta}_{y,i})^2]\cdot\mathbb{V}[x_i^{-1}\widetilde{\delta}_{x,i}] \\
&\le 40\frac{\epsilon^2}{k} + 2\cdot(\frac{0.02}{\log n})^2\cdot\frac{\epsilon^2}{k} + 2\cdot(\frac{0.02}{\log n})^2\cdot\frac{\epsilon^2}{k} \le 50\frac{\epsilon^2}{k}.
\end{aligned}$$

where the second step follows by $\mathbb{V}[\mu_i^{-1}\widetilde{\delta}_{\mu,i}] \le 8\epsilon^2/k$ (Part 2 of Lemma 2.4.3),

$$\mathbb{V}[\mu_i^{-1}(x_i - \overline{x}_i)\widetilde{\delta}_{s,i}] = \mathbb{V}[x_i^{-1}(x_i - \overline{x}_i)s_i^{-1}\widetilde{\delta}_{s,i}] \le 2\epsilon_{mp}^2\,\mathbb{V}[s_i^{-1}\widetilde{\delta}_{s,i}] \le \epsilon^2/k.$$

and a similar inequality $\mathbb{V}[\mu_i^{-1}(s_i - \overline{s}_i)\widetilde{\delta}_{x,i}] \le \epsilon^2/k$, the third step follows by $\mu = xs$, the fourth step follows by $\mathbb{V}[xy] \le 2\,\mathbf{Sup}[x^2]\,\mathbb{V}[y] + 2\,\mathbf{Sup}[y^2]\,\mathbb{V}[x]$ (Lemma 2.6.1) with **Sup** denoting the deterministic maximum of the random variable, the fifth step follows by $\mathbb{V}[s_i^{-1}\widetilde{\delta}_{s,i}] \le 2\epsilon^2/k$ and $\mathbb{V}[x_i^{-1}\widetilde{\delta}_{x,i}] \le 2\epsilon^2/k$ (Part 2 of Lemma 2.4.3). □

Claim 2.4.10 (Part 3 of Lemma 2.4.7)**.** $\|\mu^{-1}(\mu^{\text{new}} - \mu)\|_\infty \le \frac{0.021}{\log n}$.

Proof. We again note that

$$\mu^{\text{new}} = \mu + \widetilde{\delta}_\mu + (x - \overline{x})\widetilde{\delta}_s + (s - \overline{s})\widetilde{\delta}_x + \widetilde{\delta}_x\widetilde{\delta}_s.$$

Hence, we have

$$\begin{aligned}
&|\mu_i^{-1}(\mu_i^{\text{new}} - \mu_i - \widetilde{\delta}_{\mu,i})| \\
&\le |(x - \overline{x})_i\mu_i^{-1}\widetilde{\delta}_{s,i}| + |(s - \overline{s})_i\mu_i^{-1}\widetilde{\delta}_{x,i}| + |\mu_i^{-1}\widetilde{\delta}_{x,i}\widetilde{\delta}_{s,i}| \\
&= |(x - \overline{x})_i x_i^{-1}| \cdot |s_i^{-1}\widetilde{\delta}_{s,i}| + |(s - \overline{s})_i s_i^{-1}| \cdot |x_i^{-1}\widetilde{\delta}_{x,i}| + |x_i^{-1}\widetilde{\delta}_{x,i}| \cdot |s_i^{-1}\widetilde{\delta}_{s,i}| \\
&\le \epsilon_{mp}|s_i^{-1}\widetilde{\delta}_{s,i}| + \epsilon_{mp}|x_i^{-1}\widetilde{\delta}_{x,i}| + |s_i^{-1}\widetilde{\delta}_{s,i}||x_i^{-1}\widetilde{\delta}_{x,i}| \\
&\le \epsilon_{mp} \cdot \frac{0.2}{\log n} + \epsilon_{mp} \cdot \frac{0.02}{\log n} + (\frac{0.02}{\log n})^2 \\
&\le \frac{1}{1000 \log n},
\end{aligned}$$

where the first step follows by triangle inequality, the second step follows by $\mu_i = x_i s_i$, the third step follows by $x \approx_{\epsilon_{mp}} \overline{x}$ and $s \approx_{\epsilon_{mp}} \overline{s}$, the fifth step follows by $|s_i^{-1}\widetilde{\delta}_{s,i}| \le \frac{0.02}{\log n}$ and $|x_i^{-1}\widetilde{\delta}_{x,i}| \le \frac{0.02}{\log n}$ (Part 3 of Lemma 2.4.3).

Since we know that $|\mu_i^{-1}\widetilde{\delta}_{\mu,i}| \leq \frac{0.02}{\log n}$ (Part 3 of Lemma 2.4.3), we have

$$|\mu_i^{-1}(\mu_i^{\text{new}} - \mu_i)| \leq \frac{1}{1000 \log n} + \frac{0.02}{\log n} \leq \frac{0.021}{\log n}.$$

□

2.4.3 Stochastic central path

Now, we are ready to prove $x_i s_i \approx_{0.1} t$ during the whole algorithm. As explained in the proof outline (see Section 2.4.1), we will prove this bound by analyzing the potential $\Phi_\lambda(\mu/t - 1)$ where $\Phi_\lambda(r) = \sum_{i=1}^n \cosh(\lambda r_i)$.

First, we give some basic properties of Φ_λ.

Lemma 2.4.11 (Basic properties of potential function)**.** *Let $\Phi_\lambda(r) = \sum_{i=1}^n \cosh(\lambda r_i)$ for some $\lambda > 0$. For any vector $r \in \mathbb{R}^n$,*

1. For any vector $\|v\|_\infty \leq 1/\lambda$, we have that

$$\Phi_\lambda(r+v) \leq \Phi_\lambda(r) + \langle \nabla \Phi_\lambda(r), v \rangle + 2\|v\|^2_{\nabla^2 \Phi_\lambda(r)}.$$

2. $\|\nabla \Phi_\lambda(r)\|_2 \geq \frac{\lambda}{\sqrt{n}}(\Phi_\lambda(r) - n)$.

3. $\left(\sum_{i=1}^n \lambda^2 \cosh^2(\lambda r_i)\right)^{1/2} \leq \lambda\sqrt{n} + \|\nabla \Phi_\lambda(r)\|_2$.

Proof. For each $i \in [n]$, we use r_i to denote the i-th coordinate of vector r.

Proof of Part 1. We have that

$$\cosh(\lambda(r_i + v_i)) = \cosh(\lambda r_i) + \lambda \sinh(\lambda r_i) v_i + \frac{\lambda^2}{2} \cosh(\zeta_i) v_i^2,$$

where ζ_i is between λr_i and $\lambda(r_i + v_i)$. By definition of cosh and the assumption that $\|v\|_\infty \leq \frac{1}{2\lambda}$, we have that

$$\cosh(\zeta_i) = \frac{1}{2}\exp(\zeta_i) + \frac{1}{2}\exp(-\zeta_i) \leq \exp(1) \cdot \frac{1}{2}(\exp(\lambda r_i) + \exp(-\lambda r_i)) \leq 3\cosh(\lambda r_i).$$

Hence, we have

$$\cosh(\lambda(r_i + v_i)) \leq \cosh(\lambda r_i) + \lambda \sinh(\lambda r_i) v_i + 2\lambda^2 \cosh(\lambda r_i) v_i^2.$$

Summing over all the coordinates gives

$$\begin{aligned}
&\sum_{i=1}^{n} \cosh(\lambda(r_i + v_i)) \leq \sum_{i=1}^{n} \left[\cosh(\lambda r_i) + 2\lambda \sinh(\lambda r_i) v_i + \lambda^2 \cosh(\lambda r_i) v_i^2\right] \\
\implies\ &\Phi_\lambda(r + v) \leq \Phi_\lambda(r) + \langle \nabla \Phi_\lambda(r), v \rangle + 2\|v\|^2_{\nabla^2 \Phi_\lambda(r)}.
\end{aligned}$$

Proof of Part 2. Since $\Phi_\lambda(r) = \sum_{i=1}^{n} \cosh(\lambda r_i)$, then

$$\nabla \Phi_\lambda(r) = \begin{bmatrix} \lambda \sinh(\lambda r_1) & \lambda \sinh(\lambda r_2) & \cdots & \lambda \sinh(\lambda r_n) \end{bmatrix}^\top.$$

Thus, we can lower bound $\|\nabla \Phi_\lambda(r)\|_2$ in the following way,

$$\begin{aligned}
\|\nabla \Phi_\lambda(r)\|_2 &= \left(\sum_{i=1}^{n} \lambda^2 \sinh^2(\lambda r_i)\right)^{1/2} \\
&= \left(\sum_{i=1}^{n} \lambda^2 (\cosh^2(\lambda r_i) - 1)\right)^{1/2} && \text{by } \cosh^2(y) - \sinh^2(y) = 1, \forall y \\
&\geq \frac{\lambda}{\sqrt{n}} \sum_{i=1}^{n} \sqrt{\cosh^2(\lambda r_i) - 1} && \text{by } \|\cdot\|_2 \geq \frac{1}{\sqrt{n}} \|\cdot\|_1 \\
&\geq \frac{\lambda}{\sqrt{n}} \sum_{i=1}^{n} (\cosh(\lambda r_i) - 1) && \text{by } \cosh(\lambda r_i) \geq 1 \\
&= \frac{\lambda}{\sqrt{n}} (\Phi_\lambda(r) - n). && \text{by def of } \Phi(r)
\end{aligned}$$

Proof of Part 3. We have

$$\begin{aligned}
\left(\sum_{i=1}^{n} \lambda^2 \cosh^2(\lambda r_i)\right)^{1/2} &= \left(\sum_{i=1}^{n} \lambda^2 + \lambda^2 \sinh^2(\lambda r_i)\right)^{1/2} \\
&\leq (n\lambda^2)^{1/2} + \left(\sum_{i=1}^{n} \lambda^2 \sinh^2(\lambda r_i)\right)^{1/2} \\
&= \lambda\sqrt{n} + \|\nabla \Phi_\lambda(r)\|_2.
\end{aligned}$$

where the first step follows from $\cosh^2(y) - \sinh^2(y) = 1, \forall y$. □

The following lemma shows that the potential Φ is decreasing in expectation when Φ is large.

Lemma 2.4.12. *Under the Assumption 2.4.1, we have*

$$\mathbb{E}\left[\Phi_\lambda\left(\frac{\mu^{\text{new}}}{t^{\text{new}}}-1\right)\right] \le \Phi_\lambda\left(\frac{\mu}{t}-1\right) - \frac{\lambda\epsilon}{15\sqrt{n}}\left(\Phi_\lambda\left(\frac{\mu}{t}-1\right)-10n\right).$$

Proof. Let $\epsilon_\mu = \mu^{\text{new}} - \mu - \widetilde{\delta}_\mu$. From the definition, we have

$$\mu^{\text{new}} - t^{\text{new}} = \mu + \widetilde{\delta}_\mu + \epsilon_\mu - t^{\text{new}},$$

which implies

$$\begin{aligned}
\frac{\mu^{\text{new}}}{t^{\text{new}}} - 1 &= \frac{\mu}{t^{\text{new}}} + \frac{1}{t^{\text{new}}}(\widetilde{\delta}_\mu + \epsilon_\mu) - 1 \\
&= \frac{\mu}{t}\frac{t}{t^{\text{new}}} + \frac{1}{t^{\text{new}}}(\widetilde{\delta}_\mu + \epsilon_\mu) - 1 \\
&= \frac{\mu}{t} + \frac{\mu}{t}(\frac{t}{t^{\text{new}}} - 1) + \frac{1}{t^{\text{new}}}(\widetilde{\delta}_\mu + \epsilon_\mu) - 1 \\
&= \frac{\mu}{t} - 1 + \underbrace{\frac{\mu}{t}(\frac{t}{t^{\text{new}}} - 1) + \frac{1}{t^{\text{new}}}(\widetilde{\delta}_\mu + \epsilon_\mu)}_{v}. \qquad (2.17)
\end{aligned}$$

To apply Lemma 2.4.11 with $r = \mu/t - 1$ and $r + v = \mu^{\text{new}}/t^{\text{new}} - 1$, we first compute the expectation of v

$$\begin{aligned}
\mathbb{E}[v] &= \frac{\mu}{t}(\frac{t}{t^{\text{new}}} - 1) + \frac{1}{t^{\text{new}}}(\mathbb{E}[\widetilde{\delta}_\mu] + \mathbb{E}[\epsilon_\mu]) \\
&= \frac{\mu}{t}(\frac{t}{t^{\text{new}}} - 1) + \frac{1}{t^{\text{new}}}(\delta_\mu + \mathbb{E}[\epsilon_\mu]) \\
&= \frac{\mu}{t}(\frac{t}{t^{\text{new}}} - 1) + \frac{1}{t^{\text{new}}}\left(\left((\frac{t^{\text{new}}}{t} - 1)\mu - \frac{\epsilon}{2}t^{\text{new}}\frac{\nabla\Phi_\lambda(\mu/t-1)}{\|\nabla\Phi_\lambda(\mu/t-1)\|_2}\right) + \mathbb{E}[\epsilon_\mu]\right) \\
&= -\frac{\epsilon}{2}\frac{\nabla\Phi_\lambda(\mu/t-1)}{\|\nabla\Phi_\lambda(\mu/t-1)\|_2} + \frac{1}{t^{\text{new}}}\mathbb{E}[\epsilon_\mu], \qquad (2.18)
\end{aligned}$$

where the third step follows by definition of δ_μ.

Next, we bound the $\|v\|_\infty$ as follows

$$\begin{aligned}\|v\|_\infty &\le \left\|\frac{\mu}{t}(\frac{t}{t^{\text{new}}}-1)\right\|_\infty + \left\|\frac{1}{t^{\text{new}}}(\widetilde{\delta}_\mu+\epsilon_\mu)\right\|_\infty \le \frac{\epsilon}{\sqrt{n}} + \frac{\|\mu^{-1}(\mu^{\text{new}}-\mu)\|_\infty}{0.9} \\ &\le \frac{\epsilon}{\sqrt{n}} + \frac{0.021}{0.9\log n} \le \frac{1}{\lambda}.\end{aligned}$$

where we used Part 3 of Lemma 2.4.7 and $\epsilon \le \frac{1}{400\log n}$.

Since $\|v\|_\infty \le \frac{1}{\lambda}$, we can apply Part 1 of Lemma 2.4.11 and get

$$\begin{aligned}&\mathbb{E}[\Phi_\lambda(\mu/t+v-1)] \\ &\le \Phi_\lambda(\mu/t-1) + \langle \nabla\Phi_\lambda(\mu/t-1), \mathbb{E}[v]\rangle + 2\,\mathbb{E}[\|v\|^2_{\nabla^2\Phi_\lambda(\mu/t+v-1)}] \\ &= \Phi_\lambda(\mu/t-1) - \frac{\epsilon}{2}\|\nabla\Phi_\lambda(\mu/t-1)\|_2 + \frac{t}{t^{\text{new}}}\langle \nabla\Phi_\lambda(\mu/t-1), \mathbb{E}[t^{-1}\epsilon_\mu]\rangle + 2\,\mathbb{E}[\|v\|^2_{\nabla^2\Phi_\lambda(\mu/t-1)}] \\ &\le \Phi_\lambda(\mu/t-1) - \frac{\epsilon}{2}\|\nabla\Phi_\lambda(\mu/t-1)\|_2 + \frac{t}{t^{\text{new}}}\|\nabla\Phi_\lambda(\mu/t-1)\|_2 \cdot \|\,\mathbb{E}[t^{-1}\epsilon_\mu]\|_2 + 2\,\mathbb{E}[\|[v]\|^2_{\nabla^2\Phi_\lambda(\mu/t-1)}] \\ &\le \Phi_\lambda(\mu/t-1) - \frac{\epsilon}{2}\|\nabla\Phi_\lambda(\mu/t-1)\|_2 + 10\epsilon_{mp}\cdot\epsilon\|\nabla\Phi_\lambda(\mu/t-1)\|_2 + 2\,\mathbb{E}[\|v\|^2_{\nabla^2\Phi_\lambda(\mu/t-1)}],\end{aligned}$$

where the second step follows by substituting $\mathbb{E}[v]$ by (2.18), the third step follows by $\langle a,b\rangle \le \|a\|_2\cdot\|b\|_2$, the fourth step follows by $\|\,\mathbb{E}[t^{-1}\epsilon_\mu]\|_2 \le 10\epsilon_{mp}\cdot\epsilon$ (from Part 1 of Lemma 2.4.7 and $\mu \approx_{0.1} t$).

We still need to bound $\mathbb{E}[\|v\|^2_{\nabla^2\Phi_\lambda(\mu/t-1)}]$. Before bounding it, we first bound $\mathbb{E}[v_i^2]$,

$$\begin{aligned}\mathbb{E}[v_i^2] &\le 2\,\mathbb{E}\left[\left(\frac{\mu_i}{t}(\frac{t}{t^{\text{new}}}-1)\right)^2\right] + 2\,\mathbb{E}\left[\left(\frac{1}{t^{\text{new}}}(\widetilde{\delta}_{\mu,i}+\widehat{\delta}_{\mu,i})\right)^2\right] \\ &\le \epsilon^2/n + 2.5\,\mathbb{E}\left[((\mu_i^{\text{new}}-\mu_i)/\mu_i)^2\right] \\ &= \epsilon^2/n + 2.5\,\mathbb{V}[(\mu_i^{\text{new}}-\mu_i)/\mu_i] + 2.5(\mathbb{E}[(\mu_i^{\text{new}}-\mu_i)/\mu_i])^2 \\ &\le \epsilon^2/n + 125\epsilon^2/k + 2.5(\mathbb{E}[(\mu_i^{\text{new}}-\mu_i)/\mu_i])^2 \\ &\le 126\epsilon^2/k + 3(\mathbb{E}[(\mu_i^{\text{new}}-\mu_i)/\mu_i])^2, \qquad (2.19)\end{aligned}$$

where the first step follows by definition of v (see (2.17)), the second step follows by $\mu \approx_{0.1} t$ and $(t/t^{\text{new}} - 1)^2 \leq \epsilon^2/(4n)$, the third step follows by $\mathbb{E}[x^2] = \mathbb{V}[x] + (\mathbb{E}[x])^2$, the fourth step follows by Part 2 of Lemma 2.4.7, and the last step follows by $n \geq k$.

Now, we are ready to bound $\mathbb{E}[\|v\|^2_{\nabla^2\Phi_\lambda(\mu/t-1)}]$

$$
\begin{aligned}
&\mathbb{E}[\|v\|^2_{\nabla^2\Phi_\lambda(\mu/t-1)}] \\
&= \lambda^2 \sum_{i=1}^n \mathbb{E}[\Phi_\lambda(\mu/t-1)_i v_i^2] \\
&\leq \lambda^2 \sum_{i=1}^n \Phi_\lambda(\mu/t-1)_i \cdot (126\epsilon^2/k + 3(\mathbb{E}[(\mu_i^{\text{new}} - \mu_i)/\mu_i])^2) \\
&= 126\frac{\lambda^2\epsilon^2}{k}\Phi_\lambda(\mu/t-1) + 3\lambda^2 \sum_{i=1}^n \Phi_\lambda(\mu/t-1)_i \cdot (\mathbb{E}[(\mu_i^{\text{new}} - \mu_i)/\mu_i])^2 \\
&\leq 126\frac{\lambda^2\epsilon^2}{k}\Phi_\lambda(\mu/t-1) + 3\lambda \left(\sum_{i=1}^n \lambda^2 \Phi_\lambda(\mu/t-1)_i^2\right)^{1/2} \cdot \|\mathbb{E}[\mu^{-1}(\mu^{\text{new}} - \mu)]\|_4^2 \\
&\leq 126\frac{\lambda^2\epsilon^2}{k}\Phi_\lambda(\mu/t-1) + 3\lambda \left(\lambda\sqrt{n} + \|\nabla\Phi_\lambda(\mu/t-1)\|_2\right) \cdot (5\epsilon)^2,
\end{aligned}
$$

where the first step follows by defining $\Phi_\lambda(x)_i = \cosh(\lambda x_i)$, the second step follows from (2.19), the fourth step follows from Cauchy-Schwarz inequality, the fifth step follows from Part 3 of Lemma 2.4.11 and the fact that $\|\mathbb{E}[\mu^{-1}(\mu^{\text{new}} - \mu)]\|_4^2 \leq \|\mathbb{E}[\mu^{-1}(\mu^{\text{new}} - \mu)]\|_2^2 \leq (5\epsilon)^2$ (Lemma 2.4.7).

Then,

$$\begin{aligned}
&\mathbb{E}[\Phi_\lambda(\mu/t + v - 1)] \\
&\leq \Phi_\lambda(\mu/t - 1) - (\frac{\epsilon}{2} - 10\epsilon_{mp} \cdot \epsilon)\|\nabla\Phi_\lambda(\mu/t - 1)\|_2 + 252\frac{\lambda^2\epsilon^2}{k}\Phi_\lambda(\mu/t - 1) \\
&\quad + 150\lambda^2\epsilon^2\sqrt{n} + 150\lambda\epsilon^2\|\Phi_\lambda(\mu/t - 1)\|_2 \\
&\leq \Phi_\lambda(\mu/t - 1) - \frac{\epsilon}{3}\|\nabla\Phi_\lambda(\mu/t - 1)\|_2 + 252\frac{\lambda^2\epsilon^2}{k}\Phi_\lambda(\mu/t - 1) + 150\lambda^2\epsilon^2\sqrt{n} \\
&\leq \Phi_\lambda(\mu/t - 1) - \frac{\lambda\epsilon}{3\sqrt{n}}(\Phi_\lambda(\mu/t - 1) - n) + 252\frac{\lambda^2\epsilon^2}{k}\Phi_\lambda(\mu/t - 1) + 150\lambda^2\epsilon^2\sqrt{n} \\
&\leq \Phi_\lambda(\mu/t - 1) - \frac{\lambda\epsilon}{3\sqrt{n}}(\Phi_\lambda(\mu/t - 1)/5 - 2n),
\end{aligned}$$

where the second step follows from $1000\lambda\epsilon \leq 1$ and $1000\epsilon_{mp} \leq 1$, the third step follows from Part 2 of Lemma 2.4.11, and the last step follows from $1000\lambda\epsilon_{mp} \leq \log n$ and $k \geq \frac{\sqrt{n}\epsilon\log n}{\epsilon_{mp}}$. □

As a corollary, we have the following:

Lemma 2.4.13. *During the* Main *algorithm, Assumption 2.4.1 is always satisfied. Furthermore, the* ClassicalStep *happens with probability* $O(\frac{1}{n^2})$ *each step.*

Proof. The second and the fourth assumptions simply follow from the choice of ϵ_{mp} and k.

Let $\Phi^{(k)}$ be the potential at the k-th iteration of the Main. The ClassicalStep ensures that $\Phi^{(k)} \leq n^3$ at the end of each iteration. By the definition of Φ and the choice of λ in Main, we have that

$$\left\|\frac{xs}{t} - 1\right\|_\infty \leq \frac{\ln(2n^3)}{\lambda} \leq 0.1.$$

This proves the first assumption $xs \approx_{0.1} t$ with $t > 0$.

For the third assumption, we note that

$$\begin{aligned}\|\delta_\mu\|_2 &= \left\| \left(\frac{t^{\text{new}}}{t} - 1 \right) xs - \frac{\epsilon}{2} \cdot t^{\text{new}} \cdot \frac{\nabla \Phi_\lambda(\mu/t - 1)}{\|\nabla \Phi_\lambda(\mu/t - 1)\|_2} \right\|_2 \\ &\leq \left| \frac{t^{\text{new}}}{t} - 1 \right| \|xs\|_2 + \frac{\epsilon}{2} t^{\text{new}} \\ &\leq \frac{\epsilon}{3\sqrt{n}} \cdot 1.1\sqrt{n}t + 1.01 \cdot \frac{\epsilon}{2} t \leq \epsilon t,\end{aligned}$$

where we used $xs \approx_{0.1} t$ and the formula of t^{new}. Hence, we proved all assumptions in Assumption 2.4.1.

Now, we bound the probability that ClassicalStep happens. In the beginning of the Main, Lemma 3.8.2 is used to modify the linear program with parameter $\min(\frac{\delta}{2}, \frac{1}{\lambda})$. Hence, the initial point x and s satisfies $xs \approx_{1/\lambda} 1$. Therefore, we have $\Phi^{(0)} \leq 10n$. Lemma 2.4.12 shows $\mathbb{E}[\Phi^{(k+1)}] \leq (1 - \frac{\lambda\epsilon}{15\sqrt{n}}) \mathbb{E}[\Phi^{(k)}] + \frac{\lambda\epsilon}{15\sqrt{n}} 10n$. By induction, we have that $\mathbb{E}[\Phi^{(k)}] \leq 10n$ for all k. Since the potential is positive, Markov inequality shows that for any k, $\Phi^{(k)} \geq n^3$ with probability at most $O(\frac{1}{n^2})$. □

2.4.4 Analysis of cost per iteration

To apply the data structure for projection maintenance (Theorem 2.5.1), we need to first prove the input vector w does not change too much for each step.

Lemma 2.4.14. *Let $x^{\text{new}} = x + \widetilde{\delta}_x$ and $s^{\text{new}} = s + \widetilde{\delta}_s$. Let $w = \frac{x}{s}$ and $w^{\text{new}} = \frac{x^{\text{new}}}{s^{\text{new}}}$. Then we have*

$$\sum_{i=1}^n \left(\frac{\mathbb{E}[w_i^{\text{new}}] - w_i}{w_i} \right)^2 \leq 64\epsilon^2, \sum_{i=1}^n \left(\mathbb{E}\left[\left(\frac{w_i^{\text{new}} - w_i}{w_i} \right)^2 \right] \right)^2 \leq 1000\epsilon^2, \left| \frac{w_i^{\text{new}} - w_i}{w_i} \right| \leq 0.1.$$

Proof. From the definition, we know that

$$\frac{w_i^{\text{new}}}{w_i} = \frac{1}{s_i^{-1} x_i} \frac{x_i + \widetilde{\delta}_{x,i}}{s_i + \widetilde{\delta}_{s,i}} = \frac{1 + x_i^{-1}\widetilde{\delta}_{x,i}}{1 + s_i^{-1}\widetilde{\delta}_{s,i}}.$$

Part 1. For each $i \in [n]$, we have

$$\begin{aligned}
\frac{\mathbb{E}[w_i^{\text{new}}]}{w_i} - 1 = & \ \mathbb{E}\left[\frac{1 + x_i^{-1}\widetilde{\delta}_{x,i}}{1 + s_i^{-1}\widetilde{\delta}_{s,i}} \right] - 1 \\
= & \ \mathbb{E}\left[\frac{x_i^{-1}\widetilde{\delta}_{x,i} - s_i^{-1}\widetilde{\delta}_{s,i}}{1 + s_i^{-1}\widetilde{\delta}_{s,i}} \right] \\
\leq & \ 2|\,\mathbb{E}[x_i^{-1}\widetilde{\delta}_{x,i} - s_i^{-1}\widetilde{\delta}_{s,i}]| \qquad \text{by } |s_i^{-1}\widetilde{\delta}_{s,i}| \leq 0.2, \quad \text{part 3 of Lemma 2.4.3} \\
\leq & \ 2|\,\mathbb{E}[x_i^{-1}\widetilde{\delta}_{x,i}]| + 2|\,\mathbb{E}[s_i^{-1}\widetilde{\delta}_{s,i}]|. \qquad \text{by triangle inequality}
\end{aligned}$$

Thus, summing over all the coordinates gives

$$\sum_{i=1}^n \left(\frac{\mathbb{E}[w_i^{\text{new}}] - w_i}{w_i} \right)^2 \leq \sum_{i=1}^n 8(\mathbb{E}[x_i^{-1}\widetilde{\delta}_{x,i}])^2 + 8(\mathbb{E}[s_i^{-1}\widetilde{\delta}_{s,i}])^2 \leq 64\epsilon^2.$$

where the first step follows by triangle inequality, the last step follows by $\|\,\mathbb{E}[s^{-1}\widetilde{\delta}_s]\|_2^2, \|\,\mathbb{E}[x^{-1}\widetilde{\delta}_x]\|_2^2 \leq 4\epsilon^2$ (Part 1 of Lemma 2.4.3).

Part 2. For each $i \in [n]$, we have

$$\begin{aligned}
\mathbb{E}\left[\left(\frac{w_i^{\text{new}}}{w_i} - 1\right)^2\right] &= \mathbb{E}\left[\left(\frac{x_i^{-1}\widetilde{\delta}_{x,i} - s_i^{-1}\widetilde{\delta}_{s,i}}{1 + s_i^{-1}\widetilde{\delta}_{s,i}}\right)^2\right] \\
&\le 2\,\mathbb{E}[(x_i^{-1}\widetilde{\delta}_{x,i} - s_i^{-1}\widetilde{\delta}_{s,i})^2] \\
&\le 2\,\mathbb{E}[2(x_i^{-1}\widetilde{\delta}_{x,i})^2 + 2(s_i^{-1}\widetilde{\delta}_{s,i})^2] \\
&= 4\,\mathbb{E}[(x_i^{-1}\widetilde{\delta}_{x,i})^2] + 4\,\mathbb{E}[(s_i^{-1}\widetilde{\delta}_{s,i})^2] \\
&= 4\,\mathbb{V}[x_i^{-1}\widetilde{\delta}_{x,i}] + 4(\mathbb{E}[x_i^{-1}\widetilde{\delta}_{x,i}])^2 + 4\,\mathbb{V}[s_i^{-1}\widetilde{\delta}_{s,i}] + 4(\mathbb{E}[s_i^{-1}\widetilde{\delta}_{s,i}])^2 \\
&\le 16\epsilon^2/k + 4(\mathbb{E}[x_i^{-1}\widetilde{\delta}_{x,i}])^2 + 4(\mathbb{E}[s_i^{-1}\widetilde{\delta}_{s,i}])^2,
\end{aligned}$$

where the last step follows by $\mathbb{V}[x_i^{-1}\widetilde{\delta}_{x,i}], \mathbb{V}[s_i^{-1}\widetilde{\delta}_{s,i}] \le 2\epsilon^2/k$ (Part 2 of Lemma 2.4.3).

Thus summing over all the coordinates

$$\begin{aligned}
\sum_{i=1}^{n}\left(\mathbb{E}\left[\left(\frac{w_i^{\text{new}}}{w_i} - 1\right)^2\right]\right)^2 &\le \frac{512n\epsilon^4}{k^2} + 64\sum_{i=1}^{n}\left((\mathbb{E}[x_i^{-1}\widetilde{\delta}_{x,i}])^4 + (\mathbb{E}[s_i^{-1}\widetilde{\delta}_{s,i}])^4\right) \\
&\le \frac{512n\epsilon^4}{k^2} + 2048\epsilon^4 \\
&\le 1000\epsilon^2,
\end{aligned}$$

where the last step follows by $\|\,\mathbb{E}[s^{-1}\widetilde{\delta}_s]\|_2^2, \|\,\mathbb{E}[x^{-1}\widetilde{\delta}_x]\|_2^2 \le 4\epsilon^2$ and $k \ge \sqrt{n}\epsilon$.

Part 3. For each $i \in [n]$

$$\left|\frac{w_i^{\text{new}}}{w_i} - 1\right| = \left|\frac{1 + x_i^{-1}\widetilde{\delta}_{x,i}}{1 + s_i^{-1}\widetilde{\delta}_{s,i}} - 1\right| \le \left|\frac{1 + 0.02}{1 - 0.02} - 1\right| \le 0.1.$$

where the second step follows by $|x_i^{-1}\widetilde{\delta}_{x,i}| \le 0.02$ and $|s_i^{-1}\widetilde{\delta}_{s,i}| \le 0.02$ (Part 3 of Lemma 2.4.3).

□

Now, we analyze the cost per iteration in procedure Main. This is a direct application of our projection maintenance result.

Lemma 2.4.15. *For $\epsilon \geq \frac{1}{\sqrt{n}}$, each iteration of* Main *(Algorithm 3.6) takes*

$$n^{1+a+o(1)} + \epsilon \cdot (n^{\omega-1/2+o(1)} + n^{2-a/2+o(1)})$$

expected time per iteration in amortized where $0 \leq a \leq \alpha$ controls the batch size in the data structure and α is the dual exponent of matrix multiplication.

Proof. Lemma 2.4.13 shows that ClassicalStep happens with only $O(1/n^2)$ probability each step. Since the cost of each step only takes $\widetilde{O}(n^{2.5})$, the expected cost is only $\widetilde{O}(n^{0.5})$.

Lemma 2.4.14 shows that the conditions in Theorem 2.5.1 holds with the parameter $C_1 = O(\epsilon), C_2 = O(\epsilon), \epsilon_{mp} = \Theta(1)$.

In the procedure StochasticStep, Theorem 2.5.1 shows that the amortized time per iteration is mainly dominated by two steps:

1. mp.Update(w): $O(\epsilon \cdot (n^{\omega-1/2+o(1)} + n^{2-a/2+o(1)}))$.
2. mp.Query($\frac{1}{\sqrt{XS}}\widetilde{\delta}_\mu$): $O(n \cdot \|\widetilde{\delta}_\mu\|_0 + n^{1+a+o(1)})$.

Combining both running time and using $\mathbb{E}[\|\widetilde{\delta}_\mu\|_0] = O(1+k) = O(\epsilon\sqrt{n}\log^2 n)$ (according to the probability of success in Claim 2.4.6 and matching Assumption 2.4.1), we have the result.

□

2.4.5 Main result

Proof of Theorem 2.2.1. In the beginning of the MAIN algorithm, Lemma 3.8.2 is called to modify the linear program. Then, we run the stochastic central path method on this modified linear program.

When the algorithm stops, we obtain a vector x and s such that $xs \approx_{0.1} t$ with $t \leq \frac{\delta^2}{2n}$. Hence, the duality gap is bounded by $\sum_i x_i s_i \leq \delta^2$. Lemma 3.8.2 shows how to obtain an approximate solution of the original linear program with the guarantee needed using the x and s we just found.

Since t is decreased by $1 - \frac{\epsilon}{3\sqrt{n}}$ factor each iteration, it takes $O(\frac{\sqrt{n}}{\epsilon} \cdot \log(\frac{n}{\delta}))$ iterations in total. In Lemma 2.4.15, we proved that each iteration takes

$$n^{1+a+o(1)} + \epsilon \cdot (n^{\omega-1/2+o(1)} + n^{2-a/2+o(1)}).$$

and hence the total runtime is

$$O(n^{2.5-a/2+o(1)} + n^{\omega+o(1)} + \frac{n^{1.5+a+o(1)}}{\epsilon}) \cdot \log(\frac{n}{\delta}).$$

Since $\epsilon = \Theta(\frac{1}{\log n})$, the total runtime is

$$O(n^{2.5-a/2+o(1)} + n^{\omega+o(1)} + n^{1.5+a+o(1)}) \cdot \log(\frac{n}{\delta}).$$

Finally, we note that the optimal choice of a is $\min(\frac{2}{3}, \alpha)$, which gives the promised runtime.

□

Using the same proof, but different choice of the parameters, we can analyze the ultra short step stochastic central path method, where each step involves sampling only polylogarithmic coordinates. As we mentioned before, the runtime is still around n^ω.

Corollary 2.4.16. *Under the same assumption as Theorem 2.2.1, if we choose* $\epsilon = \Theta(1/\sqrt{n})$ *and* $a = \min(\frac{1}{3}, \alpha)$*, the expected time of* Main *(Algorithm 3.6) is*

$$\left(n^{\omega+o(1)} + n^{2.5-\alpha/2+o(1)} + n^{2+1/3+o(1)}\right) \cdot \log(\frac{n}{\delta}).$$

2.5 Projection Maintenance

The goal of this section is to prove the following theorem:

Theorem 2.5.1 (Projection maintenance)**.** *Given a full rank matrix $A \in \mathbb{R}^{d\times n}$ with $n \geq d$ and a tolerance parameter $0 < \epsilon_{mp} < 1/4$. Given any positive number a such that $a \leq \alpha$ where α is the dual exponent of matrix multiplication. There is a deterministic data structure (Algorithm 2.3, 2.4) that approximately maintains the projection matrices*

$$\sqrt{W}A^\top (AWA^\top)^{-1}A\sqrt{W}$$

for positive diagonal matrices W through the following two operations:

1. UPDATE(w)*: Output a vector $\widetilde{v}$ such that for all i,*

$$(1-\epsilon_{mp})\widetilde{v_i} \leq w_i \leq (1+\epsilon_{mp})\widetilde{v_i}.$$

2. QUERY(h)*: Output $\sqrt{\widetilde{V}}A^\top (A\widetilde{V}A^\top)^{-1}A\sqrt{\widetilde{V}}h$ for the $\widetilde{v}$ outputted by the last call to* UPDATE.

The data structure takes $n^2 d^{\omega-2}$ time to initialize and each call of QUERY(h) *takes time*

$$n \cdot \|h\|_0 + n^{1+a+o(1)}.$$

Furthermore, if the initial vector $w^{(0)}$ and the (random) update sequence $w^{(1)}, \cdots, w^{(T)} \in \mathbb{R}^n$ satisfies

$$\sum_{i=1}^n \left(\frac{\mathbb{E}[w_i^{(k+1)}] - w_i^{(k)}}{w_i^{(k)}}\right)^2 \leq C_1^2, \sum_{i=1}^n \left(\mathbb{E}\left[\left(\frac{w_i^{(k+1)} - w_i^{(k)}}{w_i^{(k)}}\right)^2\right]\right)^2 \leq C_2^2, \left|\frac{w_i^{(k+1)} - w_i^{(k)}}{w_i^{(k)}}\right| \leq \frac{1}{4}.$$

  return $\widetilde{v}$
end procedure
end datastructure

2.5.1 Proof outline

For intuition, we consider the case $C_1 = \Theta(1)$, $C_2 = \Theta(1)$, and $\epsilon_{mp} = \Theta(1)$ in this explanation. The correctness of the data structure directly follows from Woodbury matrix identity. The amortized time analysis is based on a potential function that measures the

distance of the approximate vector v and the target vector w. We will show that

- The cost to update the projection M is proportional to the decrease of the potential.
- Each call to query increase the potential by a fixed amount.

Combining both together gives the amortized runtime bound of our data structure.

Now, we explain the definition of the potential. Consider the k-th round of the algorithm. For all $i \in [n]$, we define $x_i^{(k)} = \frac{w_i^{(k)}}{v_i^{(k)}} - 1$. Note that $|x_i^{(k)}|$ measures the relative distance between $w_i^{(k)}$ and $v_i^{(k)}$. Our algorithm fixes the indices with largest error $x_i^{(k)}$. To capture the fact that updating in a larger batch is more efficient, we define the potential as a weighted combination of the error where we put more weight to higher $x_i^{(k)}$. Formally, we sort the coordinates of $x^{(k)}$ such that $|x_i^{(k)}| \geq |x_{i+1}^{(k)}|$ and define the potential by

$$\Psi_k = \sum_{i=1}^{n} g_i \cdot \psi(x_i^{(k)}).$$

where g_i are positive decreasing numbers to be chosen and ψ is a symmetric ($\psi(x) = \psi(-x)$) positive function that increases on both sides. For intuition, one can think $\psi(x)$ behaves roughly like $|x|$.

Each iteration we update the projection matrix such that the error of $|x_1|, \cdots, |x_r|$ drops from roughly ϵ_{mp} to 0. This decreases the potential of $\psi(x_i^{(k)})$ by $\Omega(\epsilon_{mp})$ from $i = 1, \cdots, r$. Therefore, the whole potential decreases by $\Omega(\epsilon_{mp} \sum_{i=1}^{r} g_i)$. To make the term $\sum_{i=1}^{r} g_i$ proportional to the time to update a rank r part of the projection matrix, we set

$$g_i = \begin{cases} n^{-a}, & \text{if } i < n^a; \\ i^{\frac{\omega-2}{1-a}-1} n^{-\frac{a(\omega-2)}{1-a}}, & \text{otherwise.} \end{cases} \tag{2.20}$$

where ω is the exponent of matrix multiplication and a is any positive number less than or equals to the dual exponent of matrix multiplication. Lemma 2.6.3 shows that g is indeed non-increasing and Lemma 2.5.3 shows that the update time of data-structure is indeed $O(rg_r n^{2+o(1)}) = O(\sum_{i=1}^{r} g_i n^{2+o(1)})$ for any $r \geq n^a$.

Each call to UPDATE, the expectation of the error vector $x^{(k)}$ moves roughly in an unit ℓ_2 ball. Therefore, the changes of the potential is roughly upper bounded $(\sum_{i=1}^{n} g_i^2)^{1/2} \approx n^{\omega-5/2}$. Since it takes us $n^{2+o(1)}$ time to decrease the potential by roughly 1 in the update step, the total time is roughly $n^{\omega-1/2}$.

For the case of stochastic central path, we note that the variance of the vector x is quite small. By choosing a smooth potential function ψ (see (2.21)), we can essentially give the same result as if there is no variance.

2.5.2 Proof of Theorem 2.5.1

Now, we give the proof of Theorem 2.5.1. We will defer some simple calculations into later sections.

Proof of Theorem 2.5.1.

Proof of Correctness. The definition of $\widetilde{v}$ in Line 20 ensures that $(1-\epsilon_{mp})\widetilde{v}_i \leq w_i \leq (1+\epsilon_{mp})\widetilde{v}_i$.

Using the Matrix Woodbury formula, one can verify that the update rule in Line 17 correctly maintains $M = A^\top (AVA^\top)^{-1}A$. See the deviation of the formula in Lemma 2.5.2. By the same reasoning, the Line 19 outputs the vector $\sqrt{\widetilde{V}}A^\top(A\widetilde{V}A^\top)^{-1}A\sqrt{\widetilde{V}}h$. This completes the proof of correctness.

Definition of x and y. Consider the k-th round of the algorithm. For all $i \in [n]$, we define $x_i^{(k)}$, $x_i^{(k+1)}$ and $y_i^{(k)}$ as follows:

$$x_i^{(k)} = \frac{w_i^{(k)}}{v_i^{(k)}} - 1, y_i^{(k)} = \frac{w_i^{(k+1)}}{v_i^{(k)}} - 1, x_i^{(k+1)} = \frac{w_i^{(k+1)}}{v_i^{(k+1)}} - 1.$$

Note that the difference between $x_i^{(k)}$ and $y_i^{(k)}$ is that w is changing. The difference between $y_i^{(k)}$ and $x_i^{(k+1)}$ is that v is changing. For simplicity, we define $\beta_i = (\mathbb{E}[w_i^{(k+1)}] - w_i^{(k)})/w_i^{(k)}$, then one of assumption becomes $\sum_{i=1}^n \beta_i^2 \leq C_1^2$.

Assume sorting. Assume the coordinates of vector $x^{(k)} \in \mathbb{R}^n$ are sorted such that $|x_i^{(k)}| \geq |x_{i+1}^{(k)}|$. Let τ and π are permutations such that $|x_{\tau(i)}^{(k+1)}| \geq |x_{\tau(i+1)}^{(k+1)}|$ and $|y_{\pi(i)}^{(k)}| \geq |y_{\pi(i+1)}^{(k)}|$.

Definition of Potential function. Let g be defined in (2.20). Let $\psi : \mathbb{R} \to \mathbb{R}$ be defined by

$$\psi(x) = \begin{cases} \frac{|x|^2}{2\epsilon_{mp}}, & |x| \in [0, \epsilon_{mp}] \\ \epsilon_{mp} - \frac{(2\epsilon_{mp} - |x|)^2}{2\epsilon_{mp}}, & |x| \in (\epsilon_{mp}, 2\epsilon_{mp}] \\ \epsilon_{mp}. & |x| \in (2\epsilon_{mp}, +\infty) \end{cases} \tag{2.21}$$

We define the potential at the k-th round by

$$\Psi_k = \sum_{i=1}^{n} g_i \cdot \psi(x^{(k)}_{\tau_k(i)}).$$

where $\tau_k(i)$ is the permutation such that $|x^{(k)}_{\tau_k(i)}| \geq |x^{(k)}_{\tau_k(i+1)}|$.

Bounding the potential.

We can express $\Psi_{k+1} - \Psi_k$ as follows:

$$\begin{aligned} \Psi_{k+1} - \Psi_k &= \sum_{i=1}^{n} g_i \cdot \left(\psi(x^{(k+1)}_{\tau(i)}) - \psi(x^{(k)}_i) \right) \\ &= \sum_{i=1}^{n} g_i \cdot \underbrace{\left(\psi(y^{(k)}_{\pi(i)}) - \psi(x^{(k)}_i) \right)}_{w \text{ move}} - \sum_{i=1}^{n} g_i \cdot \underbrace{\left(\psi(y^{(k)}_{\pi(i)}) - \psi(x^{(k+1)}_{\tau(i)}) \right)}_{v \text{ move}}. \end{aligned} \tag{2.22}$$

Now, using Lemma 2.5.5 and 3.6.12, and the fact that $\Psi_0 = 0$ and $\Psi_T \geq 0$, with (2.22), we get

$$\begin{aligned} 0 \leq \Psi_T - \Psi_0 &= \sum_{k=0}^{T-1} (\Psi_{k+1} - \Psi_k) \\ &\leq \sum_{k=0}^{T-1} \left(O(C_1 + C_2/\epsilon_{mp}) \cdot \sqrt{\log n} \cdot (n^{-a/2} + n^{\omega - 5/2}) - \Omega(\epsilon_{mp} r_k g_{r_k} / \log n) \right) \\ &= T \cdot O(C_1 + C_2/\epsilon_{mp}) \cdot \sqrt{\log n} \cdot (n^{-a/2} + n^{\omega - 5/2}) - \sum_{k=1}^{T} \Omega(\epsilon_{mp} r_k g_{r_k} / \log n), \end{aligned}$$

where the third step follows by Lemma 2.5.5 and Lemma 3.6.12 and r_k is the number of coordinates we update during that iteration.

Therefore, we get,

$$\sum_{k=1}^{T} r_k g_{r_k} = O\left(T \cdot (C_1/\epsilon_{mp} + C_2/\epsilon_{mp}^2) \cdot \log^{3/2} n \cdot (n^{\omega-5/2} + n^{-a/2})\right).$$

Proof of running time. See the Section 2.5.3. □

2.5.3 Initialization time, update time, query time

To formalize the amortized runtime proof, we first analyze the initialization time (Lemma 2.5.2), update time (Lemma 2.5.3), and query time (Lemma 2.5.4) of our projection maintenance data-structure.

Lemma 2.5.2 (Initialization time)**.** *The initialization time of data-structure* MAINTAINPROJECTION *(Algorithm 2.3) is* $O(n^2 d^{\omega-2})$.

Proof. Given matrix $A \in \mathbb{R}^{d\times n}$ and diagonal matrix $V \in \mathbb{R}^{n\times n}$, computing $A^\top (AVA^\top)^{-1}A$ takes $O(n^2 d^{\omega-2})$. □

Lemma 2.5.3 (Update time)**.** *The update time of data-structure* MAINTAINPROJECTION *(Algorithm 2.4) is* $O(rg_r n^{2+o(1)})$ *where* r *is the number of indices we updated in* v.

Proof. Let $A_S \in \mathbb{R}^{d\times r}$ be the r columns from S of A. From k-th query to $(k+1)$-th query, we have

$$\begin{aligned}
& A^\top (AV^{(k+1)}A^\top)^{-1}A \\
= {} & A^\top (A(V^{(k)}+\Delta)A^\top)^{-1}A \\
= {} & A^\top \left((AV^{(k)}A^\top)^{-1} - (AV^{(k)}A^\top)^{-1}A_S(\Delta_{S,S}^{-1} + A_S^\top (AV^{(k)}A^\top)^{-1}A_S)^{-1}A_S^\top (AV^{(k)}A^\top)^{-1}\right) A \\
= {} & A^\top (AV^{(k)}A^\top)^{-1}A - A^\top (AV^{(k)}A^\top)^{-1}A_S(\Delta_{S,S}^{-1} + A_S^\top (AV^{(k)}A^\top)^{-1}A_S)^{-1}A_S^\top (AV^{(k)}A^\top)^{-1}A \\
= {} & M^{(k)} - M_S^{(k)}(\Delta_{S,S}^{-1} + M_{S,S}^{(k)})^{-1}(M_S^{(k)})^\top,
\end{aligned}$$

where the second step follows by Matrix Woodbury Identity and the last step follows by definition of $M^{(k)} \in \mathbb{R}^{n\times n}$.

Thus the update rule of matrix $M^{(k+1)} \in \mathbb{R}^{n \times n}$ can be written as

$$M^{(k+1)} = M^{(k)} - M_S^{(k)} (\Delta_{S,S}^{-1} + (M^{(k)})_{S,S})^{-1} (M_S^{(k)})^\top.$$

The updates in round k can be splitted into four parts:

1. Adding two $r \times r$ matrices takes $O(r^2)$ time.
2. Computing the inverse of an $r \times r$ matrix takes $O(r^{\omega+o(1)})$ time.
3. Computing the matrix multiplication of a $n \times r$ and $r \times n$ matrix takes $O(rg_r \cdot n^{2+o(1)})$ time where we used that $r \geq n^a$ (Lemma 2.2.3).
4. Adding two $n \times n$ matrices together takes $O(n^2)$ time.

Hence, the total cost is

$$O(r^2 + r^{\omega+o(1)} + rg_r \cdot n^{2+o(1)} + n^2) = O(r^2 + r^{\omega+o(1)} + rg_r \cdot n^{2+o(1)}) = O(rg_r \cdot n^{2+o(1)}).$$

where the first step follows by $rg_r \geq 1$ for all $r \geq n^a$ and the last step follows by the calculations. □

Lemma 2.5.4 (Query time)**.** *The query time of data-structure* MaintainProjection *(Algorithm 2.3) is* $O(n \cdot \|h\|_0 + n^{1+a+o(1)})$.

Proof. Let $\widetilde{\Delta}$ satisfies $\widetilde{V} = V + \widetilde{\Delta}$. Let $\widetilde{S} \subset [n]$ denote the support of $\widetilde{\Delta}$ and then $|\widetilde{S}| \leq n^a$. Let $\widetilde{r}$ denote $|\widetilde{S}|$. We abuse the notation here, $\widetilde{\Delta}$ denotes both $n \times n$ diagonal matrix and a length n vector.

Using Matrix Woodbury Identity and definition of M, a same proof as Update time (Lemma 2.5.3) shows

$$A^\top (A\widetilde{V}A^\top)^{-1}A = M + M_{\widetilde{S}} \left(\widetilde{\Delta}^{-1}_{\widetilde{S},\widetilde{S}} + M_{\widetilde{S},\widetilde{S}}\right)^{-1} M^\top_{\widetilde{S}},$$

where $\widetilde{\Delta}_{\widetilde{S}\times\widetilde{S}}$ has size $\widetilde{r}\times\widetilde{r}$, $M_{\widetilde{S},\widetilde{S}}$ has size $\widetilde{r}\times\widetilde{r}$ and $M_{\widetilde{S}}$ has size $n\times\widetilde{r}$.

To compute $\sqrt{\widetilde{V}}A^\top(A\widetilde{V}A^\top)^{-1}A\sqrt{\widetilde{V}}h$, we just need to compute

$$\sqrt{\widetilde{V}}M\sqrt{\widetilde{V}}h + \sqrt{\widetilde{V}}M_{\widetilde{S}}(\widetilde{\Delta}^{-1}_{\widetilde{S},\widetilde{S}} + M_{\widetilde{S},\widetilde{S}})^{-1}M^\top_{\widetilde{S}}\sqrt{\widetilde{V}}h.$$

Note the running time of computing the first term of the above equation only takes $O(n\cdot\|h\|_0)$ time.

Next, we analyze the cost of computing the second term of the above equation. It contains several parts:

1. Computing $\widetilde{M^\top_{\widetilde{S}}}\cdot(\sqrt{\widetilde{V}}\cdot h)\in\mathbb{R}^{\widetilde{r}}$ takes $\widetilde{r}\|h\|_0$ time.
2. Computing $(\widetilde{\Delta}^{-1}_{\widetilde{S},\widetilde{S}} + M_{\widetilde{S},\widetilde{S}})^{-1}\in\mathbb{R}^{\widetilde{r}\times\widetilde{r}}$ that is the inverse of a $\widetilde{r}\times\widetilde{r}$ matrix takes $\widetilde{r}^{\omega+o(1)}$ time.
3. Computing matrix-vector multiplication between $\widetilde{r}\times\widetilde{r}$ matrix $((\widetilde{\Delta}^{-1}_{\widetilde{S},\widetilde{S}} + M_{\widetilde{S},\widetilde{S}})^{-1})$ and $\widetilde{r}\times 1$ vector $(\widetilde{M^\top_{\widetilde{S}}}\sqrt{\widetilde{V}}h)$ takes $O(\widetilde{r}^2)$ time.
4. Computing matrix-vector multiplication between $n\times\widetilde{r}$ matrix $(M_{\widetilde{S}})$ and $\widetilde{r}\times 1$ vector $((\widetilde{\Delta}^{-1}_{\widetilde{S},\widetilde{S}} + M_{\widetilde{S},\widetilde{S}})^{-1}M^\top_{\widetilde{S}}\sqrt{\widetilde{V}}h)$ takes $O(n\widetilde{r})$ time.
5. Computing the entry-wise product of two n vectors takes $O(n)$ time

Thus, overall the running time is

$$O(\widetilde{r}\|h\|_0 + \widetilde{r}^{\omega+o(1)} + \widetilde{r}^2 + n\widetilde{r} + n) = O(\widetilde{r}^{\omega+o(1)} + n\widetilde{r}) = O(n^{a\cdot\omega+o(1)} + n^{1+a}).$$

Finally, we note that $\omega \leq 3-\alpha \leq 3-a$ (Lemma 2.6.3) and hence $a\cdot\omega \leq a(3-a) \leq 1+a$. Therefore, the runtime is $n^{1+a+o(1)}$. □

2.5.4 Bounding w move

The goal of this section is to prove Lemma 2.5.5.

Lemma 2.5.5 (w move)**.** *We have*

$$\sum_{i=1}^{n} g_i \cdot \mathbb{E}\left[\psi(y^{(k)}_{\pi(i)}) - \psi(x^{(k)}_i)\right] \leq O(C_1 + C_2/\epsilon_{mp}) \cdot \sqrt{\log n} \cdot (n^{-a/2} + n^{\omega-5/2}).$$

Proof. Observe that since the errors $|x^{(k)}_i|$ are sorted in descending order, and $\psi(x)$ is symmetric and non-decreasing function for $x \geq 0$, thus $\psi(x^{(k)}_i)$ is also in decreasing order. In addition, note that g is decreasing, we have

$$\sum_{i=1}^{n} g_i \psi(x^{(k)}_{\pi(i)}) \leq \sum_{i=1}^{n} g_i \psi(x^{(k)}_i). \tag{2.23}$$

Hence the first term in (2.22) can be upper bounded as follows:

$$\begin{aligned}
&\mathbb{E}\left[\sum_{i=1}^{n} g_i \cdot \left(\psi(y^{(k)}_{\pi(i)}) - \psi(x^{(k)}_i)\right)\right] \\
\leq\ &\mathbb{E}\left[\sum_{i=1}^{n} g_i \cdot \left(\psi(y^{(k)}_{\pi(i)}) - \psi(x^{(k)}_{\pi(i)})\right)\right] && \text{by (2.23)} \\
=\ &\sum_{i=1}^{n} g_i \cdot \mathbb{E}[\psi(y^{(k)}_{\pi(i)}) - \psi(x^{(k)}_{\pi(i)})] \\
=\ &O(C_1 + C_2/\epsilon_{mp}) \cdot \sqrt{\log n} \cdot (n^{-a/2} + n^{\omega-5/2}). && \text{by Lemma 2.5.6}
\end{aligned}$$

Thus, we complete the proof of w move Lemma. □

It remains to prove the following Lemma,

Lemma 2.5.6.

$$\sum_{i=1}^{n} g_i \cdot \mathbb{E}[\psi(y^{(k)}_{\pi(i)}) - \psi(x^{(k)}_{\pi(i)})] = O(C_1 + C_2/\epsilon_{mp}) \cdot \sqrt{\log n} \cdot (n^{-a/2} + n^{\omega - 5/2}).$$

Proof. Let I be the set of indices such that $|x_i^{(k)}| \leq 1$. We separate the term into two:

$$\sum_{i=1}^{n} g_i \cdot \mathbb{E}[\psi(y^{(k)}_{\pi(i)}) - \psi(x^{(k)}_{\pi(i)})] = \sum_{i \in I} g_{\pi^{-1}(i)} \cdot \mathbb{E}[\psi(y_i^{(k)}) - \psi(x_i^{(k)})] + \sum_{i \in I^c} g_{\pi^{-1}(i)} \cdot \mathbb{E}[\psi(y_i^{(k)}) - \psi(x_i^{(k)})].$$

Case 1: Terms from I Mean value theorem shows that

$$\begin{aligned}
\psi(y_i^{(k)}) - \psi(x_i^{(k)}) &= \psi'(x_i^{(k)})(y_i^{(k)} - x_i^{(k)}) + \frac{1}{2}\psi''(\zeta)(y_i^{(k)} - x_i^{(k)})^2 \\
&\leq \psi'(x_i^{(k)}) \frac{w_i^{(k+1)} - w_i^{(k)}}{v_i^{(k)}} + \frac{L_2}{2} \left(\frac{w_i^{(k+1)} - w_i^{(k)}}{v_i^{(k)}} \right)^2,
\end{aligned}$$

where $L_2 = \max_x \psi''(x)$. Taking conditional expectation given $w^{(k)}$ on both sides

$$\begin{aligned}
\mathbb{E}[\psi(y_i^{(k)}) - \psi(x_i^{(k)})] &\leq \psi'(x_i^{(k)}) \cdot \frac{\mathbb{E}[w_i^{(k+1)}] - w_i^{(k)}}{v_i^{(k)}} + \frac{L_2}{2} \frac{1}{(v_i^{(k)})^2} \mathbb{E}[(w_i^{(k+1)} - w_i^{(k)})^2] \\
&= \psi'(x_i^{(k)}) \cdot \frac{w_i^{(k)}}{v_i^{(k)}} \beta_i + \frac{L_2}{2} \frac{(w_i^{(k)})^2}{(v_i^{(k)})^2} \gamma_i,
\end{aligned}$$

where $\beta_i = \frac{\mathbb{E}[w_i^{(k+1)}] - w_i^{(k)}}{w_i^{(k)}}$ and $\gamma_i = \mathbb{E}\left[\left(\frac{w_i^{(k+1)} - w_i^{(k)}}{w_i^{(k)}} \right)^2 \right]$.

To bound $\sum_{i \in I} g_{\pi^{-1}(i)} \mathbb{E}[\psi(y_i^{(k)}) - \psi(x_i^{(k)})]$, we need to bound the following two terms,

$$\sum_{i \in I} g_{\pi^{-1}(i)} \psi'(x_i^{(k)}) \frac{w_i^{(k)}}{v_i^{(k)}} \beta_i, \text{ and } \sum_{i \in I} g_{\pi^{-1}(i)} \frac{L_2}{2} \frac{(w_i^{(k)})^2}{(v_i^{(k)})^2} \gamma_i. \tag{2.24}$$

For the term $\frac{w_i^{(k)}}{v_i^{(k)}}$, we note that for $i \in I$, we have $\left| \frac{w_i^{(k)}}{v_i^{(k)}} \right| \leq \left| x_i^{(k)} \right| + 1 \leq 2$. Using this,

we can bound the first term by

$$\sum_{i\in I} g_{\pi^{-1}(i)}\psi'(x_i^{(k)})\frac{w_i^{(k)}}{v_i^{(k)}}\beta_i \le \left(\sum_{i\in I}\left(g_{\pi^{-1}(i)}\psi'(x_i^{(k)})\frac{w_i^{(k)}}{v_i^{(k)}}\right)^2\sum_{i\in I}\beta_i^2\right)^{1/2}$$
$$\le O(L_1)\left(\sum_{i=1}^n g_i^2\cdot C_1^2\right)^{1/2}$$
$$= O(C_1L_1\|g\|_2). \tag{2.25}$$

where $L_1 = \max_x|\psi'(x)|$, the first step follows by Cauchy-Schwarz inequality and the second step follows by $\left|\psi'(x_i^{(k)})\cdot w_i^{(k)}/v_i^{(k)}\right| \le 2L_1$ and $\sum_{i=1}^n\beta_i^2 \le C_1^2$.

For the second term, we have

$$\sum_{i\in I} g_{\pi^{-1}(i)}\frac{L_2}{2}\frac{(w_i^{(k)})^2}{(v_i^{(k)})^2}\gamma_i \le O(L_2)\cdot\sum_{i=1}^n g_i\cdot\gamma_i = O(C_2L_2\|g\|_2). \tag{2.26}$$

Now, combining (2.25) and (2.26) and using that $L_1 = O(1)$, $L_2 = O(1/\epsilon_{mp})$ (from part 4 of Lemma 2.5.9) and $\|g\|_2 \le \sqrt{\log n}\cdot O(n^{-a/2}+n^{\omega-5/2})$ (from Lemma 2.5.7), we have that

$$\sum_{i\in I} g_{\pi^{-1}(i)}\cdot\mathbb{E}[\psi(y_i^{(k)})-\psi(x_i^{(k)})] \le O(C_1+C_2/\epsilon_{mp})\cdot\sqrt{\log n}\cdot(n^{-a/2}+n^{\omega-5/2}).$$

Case 2: Terms from I^c

For all $i\in I^c$, we have $|x_i^{(k)}|\ge 1$. Note that $\psi(x)$ is a constant for $x\ge 2\epsilon_{mp}$ and that $\epsilon_{mp}\le 1/4$. Therefore, if $|y_i^{(k)}|\ge 1/2$, we have that $\psi(y_i^{(k)})-\psi(x_i^{(k)})=0$. Hence, we only need to consider the $i\in I^c$ such that $|y_i^{(k)}|<1/2$. For these i, we have that

$$\frac{1}{2} < |y_i^{(k)}-x_i^{(k)}| = \left|\frac{w_i^{(k+1)}-w_i^{(k)}}{v_i^{(k)}}\right| = \left|\frac{w_i^{(k+1)}}{v_i^{(k)}}\right|\left|\frac{w_i^{(k+1)}-w_i^{(k)}}{w_i^{(k+1)}}\right| \le \frac{3}{2}\left|\frac{w_i^{(k+1)}-w_i^{(k)}}{w_i^{(k+1)}}\right|,$$

where we used that $\left|y_i^{(k)}\right| = \left|\frac{w_i^{(k+1)}}{v_i^{(k)}} - 1\right| \le 1/2$. Hence, we have that $\left|\frac{w_i^{(k+1)} - w_i^{(k)}}{w_i^{(k+1)}}\right| > 1/3$ and hence $\left|\frac{w_i^{(k+1)} - w_i^{(k)}}{w_i^{(k)}}\right| > 1/4$, which is impossible.

Hence, we have

$$\sum_{i \in I^c} g_{\pi^{-1}(i)} \cdot \mathbb{E}[\psi(y_i^{(k)}) - \psi(x_i^{(k)})] = 0.$$

Combining both cases, we have the result. □

Lemma 2.5.7.

$$\left(\sum_{i=1}^{n} g_i^2\right)^{1/2} \le \sqrt{\log n} \cdot O(n^{-a/2} + n^{\omega - 5/2}).$$

Proof. Since function g behaves differently when $i \le n^a$ and $i > n^a$, we split the sum into two parts.

For the first part, we have

$$\sum_{i=1}^{n^a} g_i^2 = \sum_{i=1}^{n^a} n^{-2a} = n^{-a}.$$

For the second part, we have

$$\sum_{i=n^a}^{n} g_i^2 = \sum_{i=n^a}^{n} i^{\frac{2(\omega-2)}{1-a} - 2} n^{-\frac{2a(\omega-2)}{1-a}} = \sum_{i=n^a}^{n} \frac{1}{i} \cdot i^{\frac{2(\omega-2)}{1-a} - 1} n^{-\frac{2a(\omega-2)}{1-a}}.$$

Note that

$$\max_{i \in [n^a, n]} i^{\frac{2(\omega-2)}{1-a} - 1} n^{-\frac{2a(\omega-2)}{1-a}} = \max(n^{a\frac{2(\omega-2)}{1-a} - a} n^{-\frac{2a(\omega-2)}{1-a}}, n^{\frac{2(\omega-2)}{1-a} - 1} n^{-\frac{2a(\omega-2)}{1-a}}) = \max(n^{-a}, n^{2\omega-5}).$$

Thus, the second part is

$$\sum_{i=n^a}^{n} g_i^2 = \sum_{i=n^a}^{n} \frac{1}{i} \cdot \max(n^{-a}, n^{2\omega-5}) = O(\log n) \cdot \max(n^{-a}, n^{2\omega-5}).$$

Combining the first part and the second part completes the proof. □

2.5.5 Bounding v move

Lemma 2.5.8 (v move)**.** *We have,*

$$\sum_{i=1}^{n} g_i \cdot \left(\psi(y^{(k)}_{\pi(i)}) - \psi(x^{(k+1)}_{\tau(i)})\right) \geq \Omega(\epsilon_{mp} r_k g_{r_k} / \log n).$$

Proof. We split the proof into two cases.

We first understand some simple facts which are useful in the later proof. Note that from definition of $x^{(k+1)}_i$, we know that $x^{(k+1)}$ has r_k coordinates are 0. Basically, $\|y^{(k)} - x^{(k+1)}\|_0 = r_k$. The difference between those vectors is, for the largest r_k coordinates in $y^{(k)}$, we erase them in $x^{(k+1)}$. Then for each $i \in [n - r_k]$, $x^{(k+1)}_{\tau(i)} = y^{(k)}_{\pi(i+r_k)}$. For convenience, we define $y^{(k)}_{\pi(n+i)} = 0$, $\forall i \in [r_k]$.

Case 1. We exit the while loop when $1.5 r_k \geq n$.

Let u^* denote the largest u s.t. $|y^{(k)}_{\pi(u)}| \geq \epsilon_{mp}$. If $u^* = r_k$, we have that $|y^{(k)}_{\pi(r_k)}| \geq \epsilon_{mp} \geq \epsilon_{mp}/100$. Otherwise, the condition of the loop shows that

$$|y^{(k)}_{\pi(r_k)}| \geq (1 - 1/\log n)^{\log_{1.5} r_k - \log_{1.5} u^*} |y^{(k)}_{\pi(u^*)}| \geq (1 - 1/\log n)^{\log_{1.5} n} \epsilon_{mp} \geq \epsilon_{mp}/100.$$

where we used that $n \geq 4$.

According to definition of $x^{(k+1)}_{\tau(i)}$, we have

$$\begin{aligned}\sum_{i=1}^{n} g_i(\psi(y^{(k)}_{\pi(i)}) - \psi(x^{(k+1)}_{\tau(i)})) &= \sum_{i=1}^{n} g_i(\psi(y^{(k)}_{\pi(i)}) - \psi(y^{(k)}_{\pi(i+r_k)})) \geq \sum_{i=n/3+1}^{n} g_i(\psi(y^{(k)}_{\pi(i)}) - \psi(y^{(k)}_{\pi(i+r_k)})) \\ &\geq \sum_{i=n/3+1}^{n} g_i(\psi(y^{(k)}_{\pi(i)})) \geq \sum_{i=n/3+1}^{2n/3} g_i \psi(\epsilon_{mp}/100) \geq \Omega(r_k g_{r_k} \epsilon_{mp}),\end{aligned}$$

where the first step follows from $x^{(k+1)}_{\tau(i)} = y^{(k)}_{\pi(i+r_k)}$, the second step follows from $\psi(|x|)$ is non-decreasing (part 2 of Lemma 2.5.9) and $|y^{(k)}_{\pi(i)}|$ is non-increasing, the third step follows from $1.5r_k > n$ and hence $\psi(y^{(k)}_{\pi(i+r_k)}) = 0$ for $i \geq n/3 + 1$, the fourth step follows from ψ is non-decreasing and $|y^{(k)}_{\pi(i)}| \geq |y^{(k)}_{\pi(r_k)}| \geq \epsilon_{mp}/100$ for all $i < 2n/3$, and the last step follows by g is decreasing and part 3 of Lemma 2.5.9.

Case 2. We exit the while loop when $1.5r_k < n$ and $|y^{(k)}_{\pi(1.5r_k)}| < (1 - 1/\log n)|y^{(k)}_{\pi(r_k)}|$.

By the same argument as Case 1, we have that $|y^{(k)}_{\pi(r_k)}| \geq \epsilon_{mp}/100$. Part 3 of Lemma 2.5.9 together with the fact

$$|y^{(k)}_{\pi(1.5r)}| < \min(\epsilon_{mp}, |y^{(k)}_{\pi(r)}| \cdot (1 - 1/\log n)),$$

shows that

$$\psi(|y^{(k)}_{\pi(1.5r)}|) - \psi(|y^{(k)}_{\pi(r)}|) = \Omega(\epsilon_{mp}/\log n). \tag{2.27}$$

Putting it all together, we have

$$
\begin{aligned}
&\sum_{i=1}^{n} g_i \cdot (\psi(y^{(k)}_{\pi(i)}) - \psi(x^{(k+1)}_{\tau(i)})) \\
&= \sum_{i=1}^{n} g_i \cdot (\psi(y^{(k)}_{\pi(i)}) - \psi(y^{(k)}_{\pi(i+r_k)})) && \text{by } x^{(k+1)}_{\tau(i)} = y^{(k)}_{\pi(i+r_k)} \\
&\geq \sum_{i=r_k/2}^{r_k} g_i \cdot (\psi(y^{(k)}_{\pi(i)}) - \psi(y^{(k)}_{\pi(i+r_k)})) && \text{by } \psi(y^{(k)}_{\pi(i)}) - \psi(y^{(k)}_{\pi(i+r_k)}) \geq 0 \\
&\geq \sum_{i=r_k/2}^{r_k} g_i \cdot (\psi(y^{(k)}_{\pi(r_k)}) - \psi(y^{(k)}_{\pi(1.5r_k)})) \\
&\geq \sum_{i=r_k/2}^{r_k} g_i \cdot \Omega(\frac{\epsilon_{mp}}{\log n}) && \text{by (2.27)} \\
&\geq \sum_{i=r_k/2}^{r_k} g_{r_k} \cdot \Omega(\frac{\epsilon_{mp}}{\log n}) && \text{by } g_i \text{ is decreasing} \\
&= \Omega\left(\epsilon_{mp} r_k g_{r_k} / \log n\right),
\end{aligned}
$$

where the third step follows by $|y^{(k)}_{\pi(i)}|$ is decreasing and ψ is non-decreasing (from part 2 of Lemma 2.5.9). □

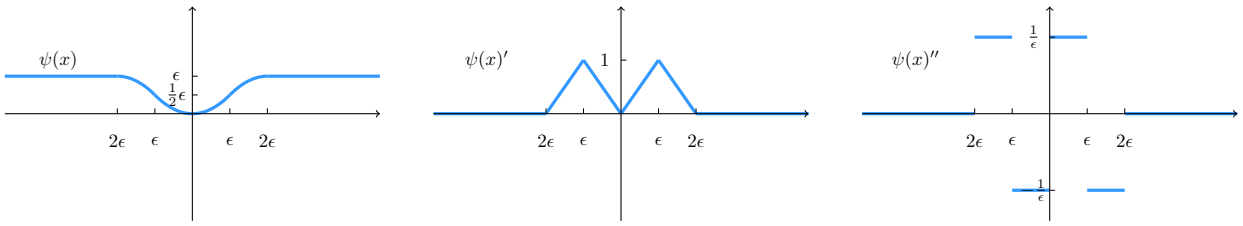

Figure 2.2: $\psi(x)$, $\psi(x)'$ and $\psi(x)''$. For $\epsilon_{mp} \in (0, 1)$.

2.5.6 Potential function ψ

Lemma 2.5.9 (Properties of function ψ)**.** *Let function ψ be defined in (2.21). Then function ψ satisfies the following properties:*

1. *Symmetric ($\psi(-x) = \psi(x)$) and $\psi(0) = 0$;*
2. *$\psi(|x|)$ is non-decreasing;*
3. *$|\psi'(x)| = \Omega(1), \forall |x| \in [0.01\epsilon_{mp}, \epsilon_{mp}]$;*
4. *$L_1 \stackrel{\text{def}}{=} \max_x \psi'(x) = 1$ and $L_2 \stackrel{\text{def}}{=} \max_x \psi''(x) = 1/\epsilon_{mp}$;*
5. *$\psi(x)$ is a constant for $|x| \geq 2\epsilon_{mp}$.*

Proof. We can see that

$$\psi(x)' = \begin{cases} \frac{|x|}{\epsilon_{mp}}, & |x| \in [0, \epsilon_{mp}] \\ \frac{2\epsilon_{mp} - |x|}{\epsilon_{mp}}, & |x| \in (\epsilon_{mp}, 2\epsilon_{mp}] \\ 0, & x \in (2\epsilon_{mp}, +\infty) \end{cases} \quad \text{and} \quad \psi(x)'' = \begin{cases} \frac{1}{\epsilon_{mp}}, & x \in [0, \epsilon_{mp}] \cup [-2\epsilon_{mp}, -\epsilon_{mp}] \\ -\frac{1}{\epsilon_{mp}}, & x \in (\epsilon_{mp}, 2\epsilon_{mp}] \cup [-\epsilon_{mp}, 0] \\ 0. & x \in (2\epsilon_{mp}, +\infty) \end{cases}$$

From the $\psi(x)'$ and $\psi(x)''$, it is not hard to see that ψ satisfies the properties needed. □

2.6 Omitted Proofs

Lemma 2.6.1. *Let x and y are (possibly dependent) random variables such that $|x| \le c_x$ and $|y| \le c_y$ almost surely. Then, we have*

$$\mathbb{V}[xy] \le 2c_x^2 \cdot \mathbb{V}[y] + 2c_y^2 \cdot \mathbb{V}[x].$$

Proof. Recall that $\mathbb{V}[xy] \le \mathbb{E}[(xy - t)^2]$ for any scalar t. Hence,

$$\begin{aligned}
\mathbb{V}[xy] &\le \mathbb{E}[(xy - \mathbb{E}[x]\,\mathbb{E}[y])^2] = \mathbb{E}[(xy - x\,\mathbb{E}[y] + x\,\mathbb{E}[y] - \mathbb{E}[x]\,\mathbb{E}[y])^2] \\
&\le 2\,\mathbb{E}[(xy - x\,\mathbb{E}[y])^2] + 2\,\mathbb{E}[(x\,\mathbb{E}[y] - \mathbb{E}[x]\,\mathbb{E}[y])^2] \\
&\le 2c_x^2 \cdot \mathbb{V}[y] + 2c_y^2 \cdot \mathbb{V}[x].
\end{aligned}$$

□

Lemma 2.6.2 ([Vai89b])**.** *Given a matrix $A \in \mathbb{R}^{d \times n}$, vectors $b \in \mathbb{R}^d, c \in \mathbb{R}^n$. Suppose $x, s, y \in \mathbb{R}^n$ satisfy that $xs \approx_{0.1} t$, $Ax = b$ and $A^\top y + s = c$ for some $t > 0$. For any $\epsilon \in (0, 1/2]$, in $\widetilde{O}(n^{2.5} \log(n/\epsilon))$ time, we can find vectors $x^{\mathrm{new}}, s^{\mathrm{new}} \in \mathbb{R}^n$ and $y^{\mathrm{new}} \in \mathbb{R}^d$ such that*

$$\begin{aligned}
\|x^{\mathrm{new}} s^{\mathrm{new}} - t\|_2 &\le \epsilon, \\
Ax^{\mathrm{new}} &= b, \\
A^\top y^{\mathrm{new}} + s &= c.
\end{aligned}$$

Remark 2.6.1. Instead of using this, one can also run our algorithm with $k = n$ for $O(\sqrt{n} \log n)$ iterations. Since $k = n$, there is no randomness involves and hence Φ will decrease deterministically to $O(n)$.

Lemma 2.6.3. $\omega \leq 3 - \alpha$.

Proof. We consider a $n \times n$ matrix A multiply another $n \times n$ B, we split A into $n^{1-\alpha}$ fat matrices where each of them has size $n^{\alpha} \times n$. Since ω is the best exponent of matrix multiplication, thus we know

$$n^{\omega+o(1)} \leq n^{1-\alpha} \cdot n^{2+o(1)},$$

which implies $\omega \leq 3 - \alpha$. □

Lemma 2.6.4 (Rectangular matrix multiplication)**.** *For any $n \geq r$, multiplying an $n \times r$ with an $r \times n$ matrix or $n \times n$ with $n \times r$ takes time*

$$n^{2+o(1)} + r^{\frac{\omega-2}{1-\alpha}} n^{2-\frac{\alpha(\omega-2)}{1-\alpha}+o(1)}.$$

Proof. The cost for multiplying a $n \times n$ and a $n \times r$ matrix is the same as multiplying a $n \times r$ and a $r \times n$ matrix. So, we focus on the later case.

For the case $r \leq n^{\alpha}$, it follows from the rectangular matrix multiplication result in [LGU18].

For the case $r \geq n^{\alpha}$, we let $k = (n/r)^{\frac{1}{1-\alpha}}$. We can view the problem as multiplying a $k \times k^{\alpha}$ and a $k^{\alpha} \times k$ block matrices and each block has size $\frac{n}{k} \times \frac{n}{k}$ size. Therefore, the total cost is

$$k^{2+o(1)} \times (\frac{n}{k})^{\omega+o(1)} = r^{\frac{\omega-2}{1-\alpha}} n^{2-\frac{\alpha(\omega-2)}{1-\alpha}+o(1)}.$$

□

For a matrix A, we define $\|A\|_1$ to be $\sum_{i,j} |A_{i,j}|$.

Lemma 2.6.5. *Consider a linear program* $\min_{Ax=b,x\geq 0} c^\top x$ *with* n *variables and* d *constraints. Assume that*

1. *Diameter of the polytope : For any* $x \geq 0$ *with* $Ax = b$*, we have that* $\|x\|_\infty \leq R$*.*
2. *Lipschitz constant of the linear program :* $\|c\|_\infty \leq L$*.*

For any $\delta \in (0, 1]$*, the modified linear program* $\min_{\overline{A}\overline{x}=\overline{b},\overline{x}\geq 0} \overline{c}^\top \overline{x}$ *with*

$$\overline{A} = \begin{bmatrix} A & 0 & \frac{1}{R}b - A1_n \\ 1_n^\top & 1 & 0 \end{bmatrix} \in \mathbb{R}^{(d+1)\times(n+2)}, \overline{b} = \begin{bmatrix} \frac{1}{R}b \\ n+1 \end{bmatrix} \in \mathbb{R}^{d+1} \text{ and, } \overline{c} = \begin{bmatrix} \frac{\delta}{L}\cdot c \\ 0 \\ 1 \end{bmatrix} \in \mathbb{R}^{n+2}$$

satisfies the following :

1. $\overline{x} = \begin{bmatrix} 1_n \\ 1 \\ 1 \end{bmatrix}, \overline{y} = \begin{bmatrix} 0_d \\ -1 \end{bmatrix}$ *and* $\overline{s} = \begin{bmatrix} 1_n + \frac{\delta}{L}\cdot c \\ 1 \\ 1 \end{bmatrix}$ *are feasible primal dual vectors.*
2. *For any feasible primal dual vectors* $(\overline{x}, \overline{y}, \overline{s})$ *with duality gap* $\leq \delta^2$*, consider the vector* $\widehat{x} = R \cdot \overline{x}_{1:n}$ *(*$\overline{x}_{1:n}$ *is the first* n *coordinates of* x*) is an approximate solution to the original linear program in the following sense*

$$\begin{aligned} c^\top \widehat{x} &\leq \min_{Ax=b,x\geq 0} c^\top x + LR\cdot\delta, \\ \|A\widehat{x} - b\|_1 &\leq 2n\delta\cdot(R\|A\|_1 + \|b\|_1), \\ \widehat{x} &\geq 0. \end{aligned}$$

Proof. For the first result, straightforward calculations show that $(\overline{x}, \overline{y}, \overline{s})$ are feasible, i.e.,

$$\overline{A}\overline{x} = \begin{bmatrix} A & 0 & \frac{1}{R}b - A1_n \\ 1_n^\top & 1 & 0 \end{bmatrix} \cdot \begin{bmatrix} 1_n \\ 1 \\ 1 \end{bmatrix} = \begin{bmatrix} \frac{1}{R}b \\ n+1 \end{bmatrix} = \overline{b}$$

and

$$\begin{aligned}
\overline{A}^\top \overline{y} + \overline{s} &= \begin{bmatrix} A^\top & 1_n \\ 0 & 1 \\ \frac{1}{R} b^\top - 1_n^\top A^\top & 0 \end{bmatrix} \cdot \begin{bmatrix} 0_d \\ -1 \end{bmatrix} + \begin{bmatrix} 1_n + \frac{\delta}{L} \cdot c \\ 1 \\ 1 \end{bmatrix} \\
&= \begin{bmatrix} -1_n \\ -1 \\ 0 \end{bmatrix} + \begin{bmatrix} 1_n + \frac{\delta}{L} \cdot c \\ 1 \\ 1 \end{bmatrix} \\
&= \begin{bmatrix} \frac{\delta}{L} \cdot c \\ 0 \\ 1 \end{bmatrix} \\
&= \overline{c}
\end{aligned}$$

For the second result, we let

$$\mathrm{OPT} = \min_{Ax=b, x \geq 0} c^\top x, \quad \text{and,} \quad \overline{\mathrm{OPT}} = \min_{\overline{A}\overline{x}=\overline{b}, \overline{x} \geq 0} \overline{c}^\top \overline{x}.$$

For any optimal x in the original LP, we consider the following $\overline{x}$

$$\overline{x} = \begin{bmatrix} \frac{1}{R} x \\ n + 1 - \frac{1}{R} \sum_i x_i \\ 0 \end{bmatrix} \tag{2.28}$$

We want to argue that $\overline{x}$ is feasible in the modified LP. It is obvious that $\overline{x} \geq 0$, it remains to show $\overline{A}\overline{x} = \overline{b}$. We have

$$\overline{A}\overline{x} = \begin{bmatrix} A & 0 & \frac{1}{R} b - A 1_n \\ 1_n^\top & 1 & 0 \end{bmatrix} \cdot \begin{bmatrix} \frac{1}{R} x \\ n + 1 - \frac{1}{R} \sum_i x_i \\ 0 \end{bmatrix} = \begin{bmatrix} \frac{1}{R} A x \\ n + 1 \end{bmatrix} = \begin{bmatrix} \frac{1}{R} b \\ n + 1 \end{bmatrix} = \overline{b},$$

where the third step follows from $Ax = b$, and the last step follows from definition of $\overline{b}$.

Therefore, using the definition of $\overline{x}$ in (2.28) we have that

$$\overline{\mathrm{OPT}} \leq \overline{c}^\top \overline{x} = \begin{bmatrix} \frac{\delta}{L} \cdot c^\top & 0 & 1 \end{bmatrix} \cdot \begin{bmatrix} \frac{1}{R} x \\ n + 1 - \frac{1}{R} \sum_i x_i \\ 0 \end{bmatrix} = \frac{\delta}{LR} \cdot c^\top x = \frac{\delta}{LR} \cdot \mathrm{OPT}\,. \tag{2.29}$$

where the first step follows from modified program is solving a minimization problem, the second step follows from definition of $\overline{c}$ and (2.28), the last step follows from x is an optimal solution in the original linear program.

Given a feasible $(\overline{x}, \overline{y}, \overline{s})$ with duality gap δ^2. Write $\overline{x} = \begin{bmatrix} \overline{x}_{1:n} \\ \tau \\ \theta \end{bmatrix}$ for some $\tau \geq 0$, $\theta \geq 0$. We can compute $\overline{c}^\top \overline{x}$ which is $\frac{\delta}{L} \cdot c^\top \overline{x}_{1:n} + \theta$. Then, we have

$$\frac{\delta}{L} \cdot c^\top \overline{x}_{1:n} + \theta \leq \overline{\mathrm{OPT}} + \delta^2 \leq \frac{\delta}{LR} \cdot \mathrm{OPT} + \delta^2, \tag{2.30}$$

where the first step follows from definition of duality gap, the last step follows from (2.29).

Hence, we can upper bound the OPT of the transformed program as follows:

$$c^\top \widehat{x} = R \cdot c^\top \overline{x}_{1:n} = \frac{RL}{\delta} \cdot \frac{\delta}{L} c^\top \overline{x}_{1:n} \leq \frac{RL}{\delta} (\frac{\delta}{LR} \cdot \mathrm{OPT} + \delta^2) = \mathrm{OPT} + LR \cdot \delta,$$

where the first step follows by $\widehat{x} = R \cdot \overline{x}_{1:n}$, the third step follows by (2.30).

We can upper bound the θ in the following sense,

$$\theta \leq \frac{\delta}{LR} \cdot \mathrm{OPT} + \delta^2 \leq n\delta + \delta^2 \leq 2n\delta$$

where the first step follows from (2.30) and $\frac{\delta}{L} c^\top \overline{x}_{1:n} \geq 0$, the second step follows by $\mathrm{OPT} = \min_{Ax=b, x \geq 0} c^\top x \leq nLR$ (because $\|c\|_\infty \leq L$ and $\|x\|_\infty \leq R$), and the last step follows from $\delta \leq 1 \leq n$.

The constraint in the new polytope shows that

$$A\overline{x}_{1:n} + (\frac{1}{R} b - A 1_n)\theta = \frac{1}{R} b.$$

Using $\widehat{x} = R x_{1:n}$, we have

$$A\frac{1}{R}\widehat{x} + (\frac{1}{R} b - A 1_n)\theta = \frac{1}{R} b.$$

Rewriting it, we have $A\widehat{x} - b = (RA1_n - b)\theta$ and hence

$$\begin{aligned}\|A\widehat{x} - b\|_1 = \|(RA1_n - b)\theta\|_1 &\leq \theta(\|RA1_n\|_1 + \|b\|_1) \leq \theta \cdot (R\|A\|_1 + \|b\|_1) \\ &\leq 2n\delta \cdot (R\|A\|_1 + \|b\|_1).\end{aligned}$$

□

Chapter 3

Empirical Risk Minimization

Many convex problems in machine learning and computer science share the same form:

$$\min_x \sum_i f_i(A_i x + b_i),$$

where f_i are convex functions on $\mathbb{R}^{n_i}$ with constant n_i, $A_i \in \mathbb{R}^{n_i \times d}$, $b_i \in \mathbb{R}^{n_i}$ and $\sum_i n_i = n$. This problem generalizes linear programming and includes many problems in empirical risk minimization.

In this chapter, we give an algorithm that runs in time

$$O^*((n^\omega + n^{2.5-\alpha/2} + n^{2+1/6}) \log(n/\delta))$$

where ω is the exponent of matrix multiplication, α is the dual exponent of matrix multiplication, and δ is the relative accuracy. Note that the runtime has only a log dependence on the condition numbers or other data dependent parameters and these are captured in δ. For the current bound $\omega \sim 2.38$ [Vassilevska Williams'12, Le Gall'14] and $\alpha \sim 0.31$ [Le Gall, Urrutia'18], our runtime $O^*(n^\omega \log(n/\delta))$ matches the current best for solving a dense least squares regression problem, a special case of the problem we consider. Very recently, [Alman'18] proved that all the current known techniques can not give a better ω below 2.168 which is larger than our $2 + 1/6$.

Our result generalizes the very recent result of solving linear programs in the current matrix multiplication time [Cohen, Lee, Song'19] to a more broad class of problems. Our algorithm proposes two concepts which are different from [Cohen, Lee, Song'19] :

• We give a robust deterministic central path method, whereas the previous one is a stochastic central path which updates weights by a random sparse vector.

• We propose an efficient data-structure to maintain the central path of interior point methods even when the weights update vector is dense.

3.1 Introduction

Empirical Risk Minimization (ERM) problem is a fundamental question in statistical machine learning. There are a huge number of papers that have considered this topic [Nes83, Vap92, PJ92, Nes04, BBM05, BB08, NJLS09, MB11, FGRW12, LRSB12, JZ13, Vap13, SSZ13, DB14, DBLJ14, FGKS15, DB16, SLC+17, ZYJ17, ZX17, ZWX+17, GSS17, MS17, NS17, AKK+17, Csi18, JLGJ18] as almost all convex optimization machine learning can be phrased in the ERM framework [SSBD14, Vap92]. While the statistical convergence properties and generalization bounds for ERM are well-understood, a general runtime bound for general ERM is not known although fast runtime bounds do exist for specific instances [AKPS19].

Examples of applications of ERM include linear regression, LASSO [Tib96], elastic net [ZH05], logistic regression [Cox58, HJLS13], support vector machines [CV95], ℓ_p regression [Cla05, DDH+09, BCLL18, AKPS19], quantile regression [Koe00, KH01, Koe05], AdaBoost [FS97], kernel regression [Nad64, Wat64], and mean-field variational inference [XJR02].

The classical Empirical Risk Minimization problem is defined as

$$\min_x \sum_{i=1}^{m} f_i(a_i^\top x + b_i)$$

where $f_i : \mathbb{R} \to \mathbb{R}$ is a convex function, $a_i \in \mathbb{R}^d$, and $b_i \in \mathbb{R}$, $\forall i \in [m]$. Note that this formulation also captures most standard forms of regularization as well.

Letting $y_i = a_i^\top x + b_i$, and $z_i = f_i(a_i^\top x + b_i)$ allows us to rewrite the original problem

in the following sense,

$$\begin{aligned} \min_{x,y,z} \quad & \sum_{i=1}^{m} z_i \\ \text{s.t.} \quad & Ax + b = y \\ & (y_i, z_i) \in K_i = \{(y_i, z_i) : f_i(y_i) \leq z_i\}, \forall i \in [m] \end{aligned} \tag{3.1}$$

We can consider a more general version where dimension of K_i can be arbitrary, e.g. n_i. Therefore, we come to study the general n-variable form

$$\min_{x \in \prod_{i=1}^{m} K_i, Ax=b} c^\top x$$

where $\sum_{i=1}^{m} n_i = n$. We state our main result for solving the general model.

Theorem 3.1.1 (Main result, informal version of Theorem 3.7.3)**.** *Given a matrix $A \in \mathbb{R}^{d \times n}$, two vectors $b \in \mathbb{R}^d$, $c \in \mathbb{R}^n$, and m compact convex sets $K_1, K_2, \cdots, K_m$. Assume that there is no redundant constraints and $n_i = O(1)$, $\forall i \in [m]$. There is an algorithm (procedure* Main *in Algorithm 3.6) that solves*

$$\min_{x \in \prod_{i=1}^{m} K_i, Ax=b} c^\top x$$

up to δ precision and runs in expected time

$$\widetilde{O}\left((n^{\omega+o(1)} + n^{2.5-\alpha/2+o(1)} + n^{2+1/6+o(1)}) \cdot \log(\frac{n}{\delta}) \right)$$

where ω is the exponent of matrix multiplication, α is the dual exponent of matrix multiplication.

For the current value of $\omega \sim 2.38$ [Wil12, LG14] and $\alpha \sim 0.31$ [LGU18], the expected time is simply $n^{\omega+o(1)}\widetilde{O}(\log(\frac{n}{\delta}))$.

Remark 3.1.1. More precisely, when n_i is super constant, our running time depends polynomially on $\max_{i \in [m]} n_i$ (but not exponential dependence).

Also note that our runtime depends on diameter, but logarithmically to the diameter. So, it can be applied to linear program by imposing an artificial bound on the solution.

3.1.1 Related Work

First-order algorithms for ERM are well-studied and a long series of accelerated stochastic gradient descent algorithms have been developed and optimized [Nes98, JZ13, XZ14, SSZ14, FGKS15, LMH15, MLF15, AY16, RHS+16, SS16, AH16, SLRB17, MS17, LMH17, LJCJ17, All17b, All17a, All18b, All18a]. However, these rates depend polynomially on the Lipschitz constant of ∇f_i and in order to achieve a $\log(1/\epsilon)$ dependence, the runtime will also have to depend on the strong convexity of the $\sum_i f_i$. In this chapter, we want to focus on algorithms that depend logarithmically on diameter/smoothness/strong convexity constants, as well as the error parameter ϵ. Note that gradient descent and a direct application of Newton's method do not belong to these class of algorithms, but for example, interior point method and ellipsoid method does.

Therefore, in order to achieve high-accuracy solutions for non-smooth and non strongly convex case, most convex optimization problems will rely on second-order methods, often under the general interior point method (IPM) or some sort of iterative refinement framework. So, we note that our algorithm is thus optimal in this general setting since second-order methods require at least n^ω runtime for general matrix inversion.

Our algorithm applies the interior point method framework to solve ERM. The most general interior point methods require $O(\sqrt{n})$-iterations of linear system solves [Nes98], requiring a naive runtime bound of $O(n^{\omega+1/2})$. Using the inverse maintenance technique [Vai89b, CLS19], one can improve the running time for LP to $O(n^\omega)$. This essentially implies that almost all convex optimization problems can be solved, up to subpolynomial factors, as fast as linear regression or matrix inversion!

The specific case of ℓ_2 regression can be solved in $O(n^\omega)$ time since the solution is explicitly given by solving a linear system. In the more general case of ℓ_p regression, [BCLL18] proposed a $\widetilde{O}_p(n^{|1/2-1/p|})$-iteration iterative solver with a naive $O(n^\omega)$ system solve at each step. Recently, [AKPS19] improved the runtime to $\widetilde{O}_p(n^{\max(\omega,7/3)})$, which is current matrix multiplication time as $\omega > 7/3$. However, both these results depend exponentially on p and fail to be impressive for large p. Otherwise, we are unaware of other ERM formulations that have have general runtime bounds for obtaining high-accuracy solutions.

Recently several works [AW18a, AW18b, Alm19] try to show the limitation of current known techniques for improving matrix multiplication time. Alman and Vassilevska Williams [AW18b] proved limitations of using the Galactic method applied to many tensors of interest (including Coppersmith-Winograd tensors [CW87]). More recently, Alman [Alm19] proved that by applying the Universal method on those tensors, we cannot hope to achieve any running time better than $n^{2.168}$ which is already above our $n^{2+1/6}$.

3.2 Overview of Techniques

In this section, we discuss the key ideas in this chapter. Generalizing the stochastic sparse update approach of [CLS19] to our setting is a natural first step to speeding up the matrix-vector multiplication that is needed in each iteration of the interior point method. In linear programs, maintaining approximate complementary slackness means that we maintain x, s to be close multiplicatively to the central path under some notion of distance. However, the generalized notion of complementary slackness requires a barrier-dependent notion of distance. Specifically, if $\phi(x)$ is a barrier function, then our distance is now defined as our function gradient being small in a norm depending on $\nabla^2\phi(x)$. One key fact of the stochastic sparse update is that the variance introduced does not perturb the approximation too much, which requires understanding the second derivative of the distance function. For our setting, this would require bounding the 4th derivative of $\phi(x)$, which may not exist for self-concordant functions. So, the stochastic approach may not work algorithmically (not just in the analysis) if $\phi(x)$ is assumed to be simply self-concordant. Even when assumptions on the 4th derivative of $\phi(x)$ are made, the analysis will become significantly more complicated due to the 4th derivative terms. To avoid these problems, the main contributions of this chapter is to 1) introduce a robust version of the central path and 2) exploit the robustness via sketching to apply the desired matrix-vector multiplication fast.

More generally, our main observation is that one can generally speed up an iterative method using sketching if the method is robust in a certain sense. To speed up interior point methods, in Section 3.4 and 3.5, we give a robust version of the interior point method; and in Section 3.6, we give a data structure to maintain the sketch; and in Section 3.7, we show how to combine them together. We provide several basic notations and definitions for

numerical linear algebra in Section 3.3. In Section 3.8, we provide some classical lemmas from the literature of interior point methods. In Section 3.9, we prove some basic properties of the sketching matrix. Now, we first begin with an overview of our robust central path and then proceed with an overview of sketching iterative methods.

3.2.1 Central Path Method

We consider the following optimization problem

$$\min_{x \in \prod_{i=1}^{m} K_i, Ax=b} c^\top x \tag{3.2}$$

where $\prod_{i=1}^{m} K_i$ is the direct product of m low-dimensional convex sets K_i. We let x_i be the i-th block of x corresponding to K_i. Interior point methods consider the path of solutions to the following optimization problem:

$$x(t) = \arg\min_{Ax=b} c^\top x + t \sum_{i=1}^{m} \phi_i(x_i) \tag{3.3}$$

where $\phi_i : K_i \to \mathbb{R}$ are self-concordant barrier functions. This parameterized path is commonly known as the *central path*. Many algorithms solve the original problem (3.2) by following the central path as the path parameter is decreased $t \to 0$. The rate at which we decrease t and subsequently the runtimes of these path-following algorithms are usually governed by the self-concordance properties of the barrier functions we use.

Definition 3.2.1. We call a function ϕ a ν self-concordant barrier for K if $\mathrm{dom}\phi = K$ and for any $x \in \mathrm{dom}\phi$ and for any $u \in \mathbb{R}^n$

$$|D^3\phi(x)[u,u,u]| \leq 2\|u\|_x^{3/2} \quad \text{and} \quad \|\nabla\phi(x)\|_x^* \leq \sqrt{\nu}$$

where $\|v\|_x := \|v\|_{\nabla^2\phi(x)}$ and $\|v\|_x^* := \|v\|_{\nabla^2\phi(x)^{-1}}$, for any vector v.

Remark 3.2.1. It is known that $\nu \geq 1$ for any self-concordant barrier function.

Nesterov and Nemirovsky showed that for any open convex set $K \subset \mathbb{R}^n$, there is a $O(n)$ self-concordant barrier function [Nes98]. In this chapter, the convex set K_i we

considered has $O(1)$ dimension. While Nesterov and Nemirovsky gave formulas for the universal barrier; in practice, most ERM problems lend themselves to explicit $O(1)$ self-concordant barriers for majority of the convex functions people use. For example, for the set $\{x : \|x\| < 1\}$, we use $-\log(1 - \|x\|^2)$; for the set $\{x : x > 0\}$, we use $-\log(x)$, and so on. That is the reason why we assume the gradient and hessian can be computed in $O(1)$ time. Therefore, in this chapter, we assume a ν_i self-concordant barrier ϕ_i is provided and that we can compute $\nabla\phi_i$ and $\nabla^2\phi_i$ in $O(1)$ time. The main result we will use about self-concordance is that the norm $\|\cdot\|_x$ is stable when we change x.

Theorem 3.2.1 (Theorem 4.1.6 in [Nes98]). *If ϕ is a self-concordant barrier and if $\|y-x\|_x < 1$, then we have :*

$$(1 - \|y - x\|_x)^2\nabla^2\phi(x) \preceq \nabla^2\phi(y) \preceq \frac{1}{(1 - \|y - x\|_x)^2}\nabla^2\phi(x).$$

In general, we can simply think of ϕ_i as a function penalizing any point $x_i \notin K_i$. It is known how to transform the original problem (3.2) by adding $O(n)$ many variables and constraints so that

- The minimizer $x(t)$ at $t = 1$ is explicitly given.
- One can obtain an approximate solution of the original problem using the minimizer at small t in linear time.

For completeness, we show how to do it in Lemma 3.8.2. Therefore, it suffices to study how we can move efficiently from $x(1)$ to $x(\epsilon)$ for some tiny ϵ where $x(t)$ is again the minimizer of the problem (3.3).

3.2.2 Robust Central Path

In the standard interior point method, we use a tight ℓ_2-bound to control how far we can deviate from $x(t)$ during the entirety of the algorithm. Specifically, if we denote $\gamma_i^t(x_i)$ as the appropriate measure of error (this will be specified later and is often called the Newton Decrement) in each block coordinate x_i at path parameter t, then as we let $t \to 0$, the old invariant that we are maintaining is,

$$\Phi_{\text{old}}^t(x) = \sum_{i=1}^{m} \gamma_i^t(x_i)^2 \leq O(1).$$

It can be shown that a Newton step in the standard direction will allow for us to maintain Φ_{old}^t to be small even as we decrease t by a multiplicative factor of $O(m^{-1/2})$ in each iteration, thereby giving a standard $O(\sqrt{m})$ iteration analysis. Therefore, the standard approach can be seen as trying to remain within a small ℓ_2 neighborhood of the central path by centering with Newton steps after making small decreases in the path parameter t. Note however that if each γ_i can be perturbed by an error that is $\Omega(m^{-1/2})$, $\Phi_{\text{old}}^t(x)$ can easily become too large for the potential argument to work.

To make our analysis more robust, we introduce a robust version that maintains the soft-max potential:

$$\Phi_{\text{new}}^t(x) = \sum_{i=1}^{m} \exp(\lambda \gamma_i^t(x_i)) \leq O(m)$$

for some $\lambda = \Theta(\log m)$. The robust central path is simply the region of all x that satisfies our potential inequality. We will specify the right constants later but we always make λ large enough to ensure that $\gamma_i \leq 1$ for all x in the robust central path. Now note that a ℓ_∞ perturbation of γ translates into a small multiplicative change in Φ^t, tolerating errors on each γ_i of up to $O(1/\text{poly}\log(n))$.

However, maintaining $\Phi^t_{\text{new}}(x) \leq O(m)$ is not obvious because the robust central path is a much wider region of x than the typical ℓ_2-neighborhood around the central path. We will show later how to modify the standard Newton direction to maintain $\Phi^t_{\text{new}}(x) \leq O(m)$ as we decrease t. Specifically, we will show that a variant of gradient descent of Φ^t_{new} in the Hessian norm suffices to provide the correct guarantees.

3.2.3 Speeding up via Sketching

To motivate our sketching algorithm, we consider an imaginary iterative method

$$z^{(k+1)} \leftarrow z^{(k)} + P \cdot F(z^{(k)})$$

where P is some dense matrix and $F(z)$ is some simple formula that can be computed efficiently in linear time. Note that the cost per iteration is dominated by multiplying P with a vector, which takes $O(n^2)$ time. To avoid the cost of multiplication, instead of storing the solution explicitly, we store it implicitly by $z^{(k)} = P \cdot u^{(k)}$. Now, the algorithm becomes

$$u^{(k+1)} \leftarrow u^{(k)} + F(P \cdot u^{(k)}).$$

This algorithm is as expensive as the previous one except that we switch the location of P. However, if we know the algorithm is robust under perturbation of the $z^{(k)}$ term in $F(z^{(k)})$, we can instead do

$$u^{(k+1)} \leftarrow u^{(k)} + F(R^\top RP \cdot u^{(k)})$$

for some random Gaussian matrix $R : \mathbb{R}^{b \times n}$. Note that the matrix RP is fixed throughout the whole algorithm and can be precomputed. Therefore, the cost of per iteration decreases from $O(n^2)$ to $O(nb)$.

For our problem, we need to make two adjustments. First, we need to sketch the change of z, that is $F(P \cdot u^{(k)})$, instead of $z^{(k)}$ directly because the change of z is smaller and this creates a smaller error. Second, we need to use a fresh random R every iteration to avoid the randomness dependence issue in the proof. For the imaginary iterative process, it

becomes

$$\overline{z}^{(k+1)} \leftarrow \overline{z}^{(k)} + R^{(k)\top} R^{(k)} P \cdot F(\overline{z}^{(k)}),$$
$$u^{(k+1)} \leftarrow u^{(k)} + F(\overline{z}^{(k)}).$$

After some iterations, $\overline{z}^{(k)}$ becomes too far from $z^{(k)}$ and hence we need to correct the error by setting $z^{(k)} = P \cdot u^{(k)}$, which zeros the error.

Note that the algorithm explicitly maintains the approximate vector $\overline{z}$ while implicitly maintaining the exact vector z by $Pu^{(k)}$. This is different from the classical way to sketch Newton method [PW16, PW17], which is to simply run $z^{(k+1)} \leftarrow z^{(k)} + R^\top RP \cdot F(z^{(k)})$ or use another way to subsample and approximate P. Such a scheme relies on the iteration method to fix the error accumulated in the sketch, while we are actively fixing the error by having both the approximate explicit vector $\overline{z}$ and the exact implicit vector z.

Without precomputation, the cost of computing $R^{(k)}P$ is in fact higher than that of $P \cdot F(z^{(k)})$. The first one involves multiplying multiple vectors with P and the second one involves multiplying 1 vector with P. However, we can precompute $[R^{(1)\top}; R^{(2)\top}; \cdots; R^{(T)\top}]^\top \cdot P$ by fast matrix multiplication. This decreases the cost of multiplying 1 vector with P to $n^{\omega-1}$ per vector. This is a huge saving from n^2. In our algorithm, we end up using only $\widetilde{O}(n)$ random vectors in total and hence the total cost is still roughly n^ω.

3.2.4 Maintaining the Sketch

The matrix P we use in interior point methods is of the form

$$P = \sqrt{W}A^\top (AWA^\top)^{-1} A\sqrt{W}$$

where W is some block diagonal matrix. [CLS19] showed one can approximately maintain the matrix P with total cost $\widetilde{O}(n^\omega)$ across all iterations of interior point method. However, the cost of applying the dense matrix P with a vector z is roughly $O(n\|z\|_0)$ which is $O(n^2)$ for dense vectors. Since interior point methods takes at least $\sqrt{n}$ iterations in general, this gives a total runtime of $O(n^{2.5})$. The key idea in [CLS19] is that one can design a stochastic interior point method such that each step only need to multiply P with a vector of density $\widetilde{O}(\sqrt{n})$. This bypasses the $n^{2.5}$ bottleneck.

In this chapter, we do not have this issue because we only need to compute RPz which is much cheaper than Pz. We summarize why it suffices to maintain RP throughout the algorithm. In general, for interior point method, the vector z is roughly an unit vector and since P is an orthogonal projection, we have $\|Pz\|_2 = O(1)$. One simple insight we have is that if we multiply a random $\sqrt{n} \times n$ matrix R with values $\pm\frac{1}{\sqrt{n}}$ by Pz, we have $\|RPz\|_\infty = \widetilde{O}(\frac{1}{\sqrt{n}})$ (Lemma 3.9.1). Since there are $\widetilde{O}(\sqrt{n})$ iterations in interior point method, the total error is roughly $\widetilde{O}(1)$ in a correctly reweighed ℓ_∞ norm. In Section 3.5, we showed that this is exactly what interior point method needs for convergence. Furthermore, we note that though each step needs to use a fresh random matrix R_l of size $\sqrt{n} \times n$, the random matrices $[R_1^\top; R_2^\top; \cdots; R_T^\top]^\top$ we need can all fit into $\widetilde{O}(n) \times n$ budget. Therefore, throughout the algorithm, we simply need to maintain the matrix $[R_1^\top; R_2^\top; \cdots; R_T^\top]^\top P$ which can be done with total cost $\widetilde{O}(n^\omega)$ across all iterations using idea similar to [CLS19].

The only reason the data structure looks complicated is that when the block matrix W changes in different location in $\sqrt{W}A^\top(AWA^\top)^{-1}A\sqrt{W}$, we need to update the matrix $[R_1; R_2; \cdots; R_T]P$ appropriately. This gives us few simple cases to handle in the algorithm and in the proof. For the intuition on how to maintain P under W change, see [CLS19, Section 2.2 and 5.1].

3.2.5 Fast rectangular matrix multiplication

Given two size $n \times n$ matrices, the time of multiplying them is $n^{2.81} < n^3$ by applying Strassen's original algorithm [Str69]. The current best running time takes n^ω time where $\omega < 2.373$ [Wil12, LG14]. One natural extension of multiplying two square matrices is multiplying two rectangular matrices. What is the running time of multiplying one $n \times n^a$ matrix with another $n^a \times n$ matrix? Let α denote the largest upper bound of a such that multiplying two rectangular matrices takes $n^{2+o(1)}$ time. The α is called the dual exponent of matrix multiplication, and the state-of-the-art result is $\alpha = 0.31$ [LGU18]. We use the similar idea as [CLS19] to delay the low-rank update when the rank is small.

3.3 Preliminaries

Given a vector $x \in \mathbb{R}^n$ and m compact convex sets $K_1 \subset \mathbb{R}^{n_1}, K_2 \subset \mathbb{R}^{n_2}, \cdots, K_m \subset \mathbb{R}^{n_m}$ with $\sum_{i=1}^m n_i = n$. We use x_i to denote the i-th block of x, then $x \in \prod_{i=1}^m K_i$ if $x_i \in K_i$, $\forall i \in [m]$.

We say a block diagonal matrix $A \in \oplus_{i=1}^m \mathbb{R}^{n_i \times n_i}$ if A can be written as

$$A = \begin{bmatrix} A_1 & & & \\ & A_2 & & \\ & & \ddots & \\ & & & A_m \end{bmatrix}$$

where $A_1 \in \mathbb{R}^{n_1 \times n_1}$, $A_2 \in \mathbb{R}^{n_2 \times n_2}$, and $A_m \in \mathbb{R}^{n_m \times n_m}$. For a matrix A, we use $\|A\|_F$ to denote its Frobenius norm and use $\|A\|$ to denote its operator norm. There are some trivial facts $\|AB\|_2 \leq \|A\|_2 \cdot \|B\|_2$ and $\|AB\|_F \leq \|A\|_F \cdot \|B\|_2$.

For notation convenience, we assume the number of variables $n \geq 10$ and there are no redundant constraints. In particular, this implies that the constraint matrix A is full rank.

For a positive integer n, let $[n]$ denote the set $\{1, 2, \cdots, n\}$.

For any function f, we define $\widetilde{O}(f)$ to be $f \cdot \log^{O(1)}(f)$. In addition to $O(\cdot)$ notation, for two functions f, g, we use the shorthand $f \lesssim g$ (resp. $\gtrsim$) to indicate that $f \leq Cg$ (resp. $\geq$) for some absolute constant C. For any function f, we use $\mathrm{dom} f$ to denote the domain of function f.

For a vector v, We denote $\|v\|$ as the standard Euclidean norm of v and for a symmetric PSD matrix A, we let $\|v\|_A = (v^\top A v)^{1/2}$. For a convex function $f(x)$ that is clear from context, we denote $\|v\|_x = \|v\|_{\nabla^2 f(x)}$ and $\|v\|_x^* = \|v\|_{\nabla^2 f(x)^{-1}}$.

3.4 Robust Central Path

In this section we show how to move move efficiently from $x(1)$ to $x(\epsilon)$ for some tiny ϵ by staying on a robust version of the central path. Because we are maintaining values that are slightly off-center, we show that our analysis still goes through despite ℓ_∞ perturbations on the order of $O(1/\text{poly}\log(n))$.

3.4.1 Newton Step

To follow the path $x(t)$, we consider the optimality condition of (3.3):

$$\begin{aligned} s/t + \nabla\phi(x) &= 0, \\ Ax &= b, \\ A^\top y + s &= c \end{aligned}$$

where $\nabla\phi(x) = (\nabla\phi_1(x_1), \nabla\phi_2(x_2), \cdots, \nabla\phi_m(x_m))$. To handle the error incurred in the progress, we consider the perturbed central path

$$\begin{aligned} s/t + \nabla\phi(x) &= \mu, \\ Ax &= b, \\ A^\top y + s &= c \end{aligned}$$

where μ represent the error between the original central path and our central path. Each iteration, we decrease t by a certain factor. It may increase the error term μ. Therefore, we need a step to decrease the norm of μ. The Newton method to move μ to $\mu + h$ is given by

$$\begin{aligned} \frac{1}{t} \cdot \delta_s^{\text{ideal}} + \nabla^2\phi(x) \cdot \delta_x^{\text{ideal}} &= h, \\ A\delta_x^{\text{ideal}} &= 0, \\ A^\top \delta_y^{\text{ideal}} + \delta_s^{\text{ideal}} &= 0 \end{aligned}$$

where $\nabla^2\phi(x)$ is a block diagonal matrix with the i-th block is given by $\nabla^2\phi_i(x_i)$. Letting $W = (\nabla^2\phi(x))^{-1}$, we can solve this:

$$\begin{aligned}
\delta_y^{\text{ideal}} &= -t \cdot \left(AWA^\top\right)^{-1} AWh, \\
\delta_s^{\text{ideal}} &= t \cdot A^\top \left(AWA^\top\right)^{-1} AWh, \\
\delta_x^{\text{ideal}} &= Wh - WA^\top \left(AWA^\top\right)^{-1} AWh.
\end{aligned}$$

We define projection matrix $P \in \mathbb{R}^{n\times n}$ as follows

$$P = W^{1/2}A^\top \left(AWA^\top\right)^{-1} AW^{1/2}$$

and then we rewrite them

$$\delta_x^{\text{ideal}} = W^{1/2}(I-P)W^{1/2}\delta_\mu, \tag{3.4}$$

$$\delta_s^{\text{ideal}} = tW^{-1/2}PW^{1/2}\delta_\mu. \tag{3.5}$$

One standard way to analyze the central path is to measure the error by $\|\mu\|_{\nabla^2\phi(x)^{-1}}$ and uses the step induced by $h = -\mu$. One can easily prove that if $\|\mu\|_{\nabla^2\phi(x)^{-1}} < \frac{1}{10}$, one step of Newton step decreases the norm by a constant factor. Therefore, one can alternatively decrease t and do a Newton step to follow the path.

3.4.2 Robust Central Path Method

In this section, we develop a central path method that is robust under certain ℓ_∞ perturbations. Due to the ℓ_∞ perturbation, we measure the error μ by a soft max instead of the ℓ_2 type potential:

Definition 3.4.1. For each $i \in [m]$, let $\mu_i^t(x,s) \in \mathbb{R}^{n_i}$ and $\gamma_i^t(x,s) \in \mathbb{R}$ be defined as follows:

$$\mu_i^t(x,s) = s_i/t + \nabla\phi_i(x_i), \tag{3.6}$$

$$\gamma_i^t(x,s) = \|\mu_i^t(x,s)\|_{\nabla^2\phi_i(x_i)^{-1}}, \tag{3.7}$$

and we define potential function Φ as follows:

$$\Phi^t(x,s) = \sum_{i=1}^{m} \exp(\lambda\gamma_i^t(x,s))$$

where $\lambda = O(\log m)$.

The *robust central path* is the region (x,s) that satisfies $\Phi^t(x,s) \leq O(m)$. To run our convergence argument, we will be setting λ appropriately so that staying on the robust central path will guarantee a ℓ_∞ bound on γ. Then, we will show how to maintain $\Phi^t(x,s)$ to be small throughout the algorithm while decreasing t, always staying on the robust central path. This is broken into a two step analysis: the progress step (decreasing t) and the centering step (moving x, s to decrease γ).

It is important to note that to follow the robust central path, we no longer pick the standard Newton direction by setting $h = -\mu$. To explain how we pick our centering step, suppose we can move $\mu \to \mu + h$ arbitrarily with the only restriction on the distance

$\|h\|_{\nabla^2\phi(x)^{-1}} = \alpha$. Then, the natural step would be

$$h = \arg \min_{\|h\|_{\nabla^2\phi(x)^{-1}}=\alpha} \langle \nabla f(\mu(x,s)), h\rangle$$

where $f(\mu) = \sum_{i=1}^m \exp(\lambda \|\mu\|_{\nabla^2\phi_i(x_i)^{-1}})$. Note that

$$\nabla f(\mu^t(x,s))_i = \lambda \exp(\lambda\gamma_i^t(x,s))/\gamma_i^t(x,s) \cdot \nabla^2\phi_i(x_i)^{-1}\mu_i^t(x,s).$$

Therefore, the solution for the minimization problem is

$$h_i^{\text{ideal}} = -\alpha \cdot c_i^t(x,s)^{\text{ideal}} \mu_i^t(x,s) \in \mathbb{R}^{n_i},$$

where $\mu_i^t(x,s) \in \mathbb{R}^{n_i}$ is defined as Eq. (3.6) and $c_i^t(x,s) \in \mathbb{R}$ is defined as

$$c_i^t(x,s)^{\text{ideal}} = \frac{\exp(\lambda\gamma_i^t(x,s))/\gamma_i^t(x,s)}{(\sum_{i=1}^m \exp(2\lambda\gamma_i^t(x,s)))^{1/2}}.$$

Eq. (3.4) and Eq. (3.5) gives the corresponding ideal step on x and s.

Now, we discuss the perturbed version of this algorithm. Instead of using the exact x and s in the formula of h, we use a $\overline{x}$ which is approximately close to x and a $\overline{s}$ which is close to s. Precisely, we have

$$h_i = -\alpha \cdot c_i^t(\overline{x},\overline{s})\mu_i^t(\overline{x},\overline{s}) \tag{3.8}$$

where

$$c_i^t(x,s) = \begin{cases} \frac{\exp(\lambda\gamma_i^t(x,s))/\gamma_i^t(x,s)}{(\sum_{i=1}^m \exp(2\lambda\gamma_i^t(x,s)))^{1/2}} & \text{if } \gamma_i^t(x,s) \geq 96\sqrt{\alpha} \\ 0 & \text{otherwise} \end{cases}. \tag{3.9}$$

Note that our definition of c_i^t ensures that $c_i^t(x,s) \leq \frac{1}{96\sqrt{\alpha}}$ regardless of the value of $\gamma_i^t(x,s)$. This makes sure we do not move too much in any coordinates and indeed when γ_i^t is small,

it is fine to set $c_i^t = 0$. Furthermore, for the formula on δ_x and δ_s, we use some matrix $\widetilde{V}$ that is close to $(\nabla^2\phi(x))^{-1}$. Precisely, we have

$$\delta_x = \widetilde{V}^{1/2}(I - \widetilde{P})\widetilde{V}^{1/2}h, \tag{3.10}$$

$$\delta_s = t \cdot \widetilde{V}^{-1/2}\widetilde{P}\ \widetilde{V}^{1/2}h. \tag{3.11}$$

where

$$\widetilde{P} = \widetilde{V}^{1/2}A^\top(A\widetilde{V}A^\top)^{-1}A\widetilde{V}^{1/2}.$$

Here we give a quick summary of our algorithm. (The more detailed of our algorithm can be found in Algorithm 3.5 and 3.6 in Section 3.7.)

- RobustIPM(A, b, c, ϕ, δ)
  - $\lambda = 2^{16}\log(m)$, $\alpha = 2^{-20}\lambda^{-2}$, $\kappa = 2^{-10}\alpha$.
  - $\delta = \min(\frac{1}{\lambda}, \delta)$.
  - $\nu = \sum_{i=1}^m \nu_i$ where ν_i are the self-concordant parameters of ϕ_i.
  - Modify the convex problem and obtain an initial x and s according to Lemma 3.8.2.
  - $t = 1$.
  - While $t > \frac{\delta^2}{4\nu}$
    - Find $\overline{x}$ and $\overline{s}$ such that $\|\overline{x}_i - x_i\|_{\overline{x}_i} < \alpha$ and $\|\overline{s}_i - s_i\|^*_{\overline{x}_i} < t\alpha$ for all i.
    - Find $\widetilde{V}_i$ such that $(1-\alpha)(\nabla^2\phi_i(\overline{x}_i))^{-1} \preceq \widetilde{V}_i \preceq (1+\alpha)(\nabla^2\phi_i(\overline{x}_i))^{-1}$ for all i.

* Compute $h = -\alpha \cdot c_i^t(\overline{x},\overline{s})\mu_i^t(\overline{x},\overline{s})$ where

$$c_i^t(\overline{x},\overline{s}) = \begin{cases} \frac{\exp(\lambda\gamma_i^t(\overline{x},\overline{s}))/\gamma_i^t(\overline{x},\overline{s})}{(\sum_{i=1}^m \exp(2\lambda\gamma_i^t(\overline{x},\overline{s})))^{1/2}} & \text{if } \gamma_i^t(\overline{x},\overline{s}) \geq 96\sqrt{\alpha} \\ 0 & \text{otherwise} \end{cases}.$$

  and $\mu_i^t(\overline{x},\overline{s}) = \overline{s}_i/t + \nabla\phi_i(\overline{x}_i)$ and $\gamma_i^t(\overline{x},\overline{s}) = \|\mu_i^t(\overline{x},\overline{s})\|_{\nabla^2\phi_i(\overline{x}_i)^{-1}}$

* Let $\widetilde{P} = \widetilde{V}^{1/2}A^\top(A\widetilde{V}A^\top)^{-1}A\widetilde{V}^{1/2}$.

* Compute $\delta_x = \widetilde{V}^{1/2}(I-\widetilde{P})\widetilde{V}^{1/2}h$ and $\delta_s = t\cdot\widetilde{V}^{-1/2}\widetilde{P}\,\widetilde{V}^{1/2}h$.

* Move $x \leftarrow x+\delta_x$, $s \leftarrow s+\delta_s$.

* $t^{\text{new}} = (1-\frac{\kappa}{\sqrt{\nu}})t$.

– Return an approximation solution of the convex problem according to Lemma 3.8.2.

Theorem 3.4.1 (Robust Interior Point Method)**.** *Consider a convex problem* $\min_{Ax=b, x\in\prod_{i=1}^m K_i} c^\top x$ *where* K_i *are compact convex sets. For each* $i\in[m]$*, we are given a* ν_i*-self concordant barrier function* ϕ_i *for* K_i*. Let* $\nu = \sum_{i=1}^m \nu_i$*. Also, we are given* $x^{(0)} = \arg\min_x \sum_{i=1}^m \phi_i(x_i)$*. Assume that*

1. *Diameter of the set: For any* $x\in\prod_{i=1}^m K_i$*, we have that* $\|x\|_2 \leq R$*.*

2. *Lipschitz constant of the program:* $\|c\|_2 \leq L$*.*

Then, the algorithm RobustIPM *finds a vector* x *such that*

$$\begin{aligned} c^\top x &\leq \min_{Ax=b, x\in\prod_{i=1}^m K_i} c^\top x + LR\cdot\delta, \\ \|Ax-b\|_1 &\leq 3\delta\cdot\left(R\sum_{i,j}|A_{i,j}| + \|b\|_1\right), \\ x &\in \prod_{i=1}^m K_i. \end{aligned}$$

in $O(\sqrt{\nu}\log^2 m \log(\frac{\nu}{\delta}))$ *iterations.*

Proof. Lemma 3.8.2 shows that the initial x and s satisfies

$$\|s + \nabla\phi(x)\|_x^* \leq \delta \leq \frac{1}{\lambda}$$

where the last inequality is due to our step $\delta \leftarrow \min(\frac{1}{\lambda}, \delta)$. This implies that $\gamma_i^1(x,s) = \|s_i + \nabla\phi_i(x_i)\|_{x_i}^* \leq \frac{1}{\lambda}$ and hence $\Phi^1(x,s) \leq e \cdot m \leq 80\frac{m}{\alpha}$ for the initial x and s. Apply Lemma 3.5.8 repetitively, we have that $\Phi^t(x,s) \leq 80\frac{m}{\alpha}$ during the whole algorithm. In particular, we have this at the end of the algorithm. This implies that

$$\|s_i + \nabla\phi_i(x_i)\|_{x_i}^* \leq \frac{\log(80\frac{m}{\alpha})}{\lambda} \leq 1$$

at the end. Therefore, we can apply Lemma 3.8.3 to show that

$$\langle c, x\rangle \leq \langle c, x^*\rangle + 4t\nu \leq \langle c, x^*\rangle + \delta^2$$

where we used the stop condition for t at the end. Note that this guarantee holds for the modified convex program. Since the error is δ^2, Lemma 3.8.2 shows how to get an approximate solution for the original convex program with error $LR \cdot \delta$.

The number of steps follows from the fact we decrease t by $1 - \frac{1}{\sqrt{\nu}\log^2 m}$ factor every iteration.

□

3.5 Robust Central Path

The goal of this section is to analyze robust central path. We provide an outline in Section 3.5.1. In Section 3.5.2, we bound the changes in μ and γ. In Section 3.5.3, we analyze the changes from (x, x, s) to $(x^{\text{new}}, x, s^{\text{new}})$. In Section 3.5.4, we analyze the changes from $(x^{\text{new}}, x, s^{\text{new}})$ to $(x^{\text{new}}, x^{\text{new}}, s^{\text{new}})$. We bound the changes in t in Section 3.5.5. Finally, we analyze entire changes of potential function in Section 3.5.6.

Statement	Section	Parameters
Lemma 3.5.2	Section 3.5.2	$\mu_i^t(x,s) \to \mu_i^t(x^{\text{new}}, s^{\text{new}})$
Lemma 3.5.4	Section 3.5.2	$\gamma_i^t(x,x,s) \to \gamma_i^t(x^{\text{new}}, x, s^{\text{new}})$
Lemma 3.5.5	Section 3.5.3	$\Phi(x,x,s) \to \Phi(x^{\text{new}}, x, s^{\text{new}})$
Lemma 3.5.6	Section 3.5.4	$\Phi(x^{\text{new}}, x, s^{\text{new}}) \to \Phi(x^{\text{new}}, x^{\text{new}}, s^{\text{new}})$
Lemma 3.5.7	Section 3.5.5	$\Phi^t \to \Phi^{t^{\text{new}}}$
Lemma 3.5.8	Section 3.5.6	$\Phi^t(x,s) \to \Phi^{t^{\text{new}}}(x^{\text{new}}, s^{\text{new}})$

Table 3.1: Bounding the changes of different variables

3.5.1 Outline of Analysis

Basically, the main proof is just a simple calculation on how $\Phi^t(x,s)$ changes during 1 iteration. It could be compared to the proof of ℓ_∞ potential reduction arguments for the convergence of long-step interior point methods, although the main difficulty arises from the perturbations from stepping using $\overline{x}, \overline{s}$ instead of x, s.

To organize the calculations, we note that the term $\gamma_i^t(x,s) = \|\mu_i^t(x,s)\|_{\nabla^2\phi_i(x_i)^{-1}}$ has two terms involving x, one in the μ term and one in the Hessian. Hence, we separate how different x affect the potential by defining

$$\gamma_i^t(x,z,s) = \|\mu_i^t(x,s)\|_{\nabla^2\phi_i(z_i)^{-1}},$$
$$\Phi^t(x,z,s) = \sum_{i=1}^m \exp(\lambda\gamma_i^t(x,z,s)).$$

One difference between our proof and standard ℓ_2 proofs of interior point is that we assume the barrier function is decomposable. We define $\alpha_i = \|\delta_{x,i}\|_{\overline{x}_i}$ is the "step" size of the coordinate i. One crucial fact we are using is that sum of squares of the step sizes is small.

Lemma 3.5.1. *Let α denote the parameter in* RobustIPM. *For all $i \in [m]$, let $\alpha_i = \|\delta_{x,i}\|_{\overline{x}_i}$.*

Then,

$$\sum_{i=1}^{m} \alpha_i^2 \leq 4\alpha^2.$$

Proof. Note that

$$\sum_{i=1}^{m} \alpha_i^2 = \|\delta_x\|_{\overline{x}}^2 = h^\top \widetilde{V}^{1/2}(I - \widetilde{P})\widetilde{V}^{1/2}\nabla^2\phi(\overline{x})\widetilde{V}^{1/2}(I - \widetilde{P})\widetilde{V}^{1/2}h.$$

Since $(1-\alpha)(\nabla^2\phi_i(\overline{x}_i))^{-1} \preceq \widetilde{V}_i \preceq (1+\alpha)(\nabla^2\phi_i(\overline{x}_i))^{-1}$, we have that

$$(1-\alpha)(\nabla^2\phi(\overline{x}))^{-1} \preceq \widetilde{V} \preceq (1+\alpha)(\nabla^2\phi(\overline{x}))^{-1}.$$

Using $\alpha \leq \frac{1}{10000}$, we have that

$$\sum_{i=1}^{m} \alpha_i^2 \leq 2h^\top \widetilde{V}^{1/2}(I - \widetilde{P})(I - \widetilde{P})\widetilde{V}^{1/2}h \leq 2h^\top \widetilde{V}h$$

where we used that $I - \widetilde{P}$ is an orthogonal projection at the end. Finally, we note that

$$\begin{aligned}
h^\top \widetilde{V}h &\leq 2\sum_{i=1}^{m} \|h_i\|_{\overline{x}_i}^{*2} \\
&= 2\alpha^2 \sum_{i=1}^{m} c_i^t(\overline{x},\overline{s})^2 \|\mu_i^t(\overline{x},\overline{s})\|_{\overline{x}_i}^{*2} \\
&\leq 2\alpha^2 \sum_{i=1}^{m} \frac{\exp(2\lambda\gamma_i^t(\overline{x},\overline{s}))/\gamma_i^t(\overline{x},\overline{s})^2}{\sum_{i=1}^m \exp(2\lambda\gamma_i^t(\overline{x},\overline{s}))^{1/2}} \|\mu_i^t(\overline{x},\overline{s})\|_{\overline{x}_i}^{*2} \\
&= 2\alpha^2 \frac{\sum_{i=1}^m \exp(2\lambda\gamma_i^t(\overline{x},\overline{s}))}{\sum_{i=1}^m \exp(2\lambda\gamma_i^t(\overline{x},\overline{s}))} \\
&= 2\alpha^2
\end{aligned}$$

where the second step follows from definition of h_i (3.8), the third step follows from definition c_i^t (3.9), the fourth step follows from definition of γ_i^t (3.7).

Therefore, putting it all together, we can show

$$\sum_{i=1}^{m} \alpha_i^2 \leq 4\alpha^2.$$

□

3.5.2 Changes in μ and γ

We provide basic lemmas that bound changes in μ, γ due to the centering steps.

Lemma 3.5.2 (Changes in μ)**.** *For all $i \in [m]$, let*

$$\mu_i^t(x^{\text{new}}, s^{\text{new}}) = \mu_i^t(x, s) + h_i + \epsilon_i^{(\mu)}.$$

Then, $\|\epsilon_i^{(\mu)}\|_{x_i}^* \leq 10\alpha \cdot \alpha_i$.

Proof. Let $x^{(u)} = ux^{\text{new}} + (1-u)x$ and $\mu_i^{\text{new}} = \mu_i^t(x^{\text{new}}, s^{\text{new}})$. The definition of μ (3.6) shows that

$$\begin{aligned}
\mu_i^{\text{new}} &= \mu_i + \frac{1}{t}\delta_{s,i} + \nabla\phi_i(x_i^{\text{new}}) - \nabla\phi_i(x_i) \\
&= \mu_i + \frac{1}{t}\delta_{s,i} + \int_0^1 \nabla^2\phi_i(x_i^{(u)})\delta_{x,i}\,\mathrm{d}u \\
&= \mu_i + \frac{1}{t}\delta_{s,i} + \nabla^2\phi_i(\overline{x}_i)\delta_{x,i} + \int_0^1 \left(\nabla^2\phi_i(x_i^{(u)}) - \nabla^2\phi_i(\overline{x}_i)\right)\delta_{x,i}\,\mathrm{d}u.
\end{aligned}$$

By the definition of δ_x and δ_s (3.10) and (3.11), we have that $\frac{1}{t}\delta_{s,i} + \widetilde{V}_i^{-1}\delta_{x,i} = h_i$. Hence, we have

$$\mu_i^{\text{new}} = \mu_i + h_i + \epsilon_i^{(\mu)}$$

where

$$\epsilon_i^{(\mu)} = \int_0^1 \left(\nabla^2\phi_i(x_i^{(u)}) - \nabla^2\phi_i(\overline{x}_i)\right)\delta_{x,i}\,\mathrm{d}u + (\nabla^2\phi_i(\overline{x}_i) - \widetilde{V}_i^{-1})\delta_{x,i}. \tag{3.12}$$

To bound $\epsilon_i^{(\mu)}$, we note that

$$\|x_i^{(t)} - \overline{x}_i\|_{\overline{x}_i} \leq \|x_i^{(t)} - x_i\|_{\overline{x}_i} + \|x_i - \overline{x}_i\|_{\overline{x}_i} \leq \|\delta_{x,i}\|_{\overline{x}_i} + \alpha = \alpha_i + \alpha \leq 3\alpha$$

where the first step follows from triangle inequality, the third step follows from definition of α_i (Lemma 3.5.1), and the last step follows from $\alpha_i \le 2\alpha$ (Lemma 3.5.1).

Using $\alpha \le \frac{1}{100}$, Theorem 3.2.1 shows that

$$-7\alpha \cdot \nabla^2\phi_i(\overline{x}_i) \preceq \nabla^2\phi_i(x_i^{(u)}) - \nabla^2\phi_i(\overline{x}_i) \preceq 7\alpha \cdot \nabla^2\phi_i(\overline{x}_i).$$

Equivalently, we have

$$(\nabla^2\phi_i(x_i^{(u)}) - \nabla^2\phi_i(\overline{x}_i)) \cdot (\nabla^2\phi_i(\overline{x}_i))^{-1} \cdot (\nabla^2\phi_i(x_i^{(u)}) - \nabla^2\phi_i(\overline{x}_i)) \preceq (7\alpha)^2 \cdot \nabla^2\phi_i(\overline{x}_i).$$

Using this, we have

$$\begin{aligned}\left\| \int_0^1 \left(\nabla^2\phi_i(x_i^{(u)}) - \nabla^2\phi_i(\overline{x}_i)\right)\delta_{x,i}\,\mathrm{d}u \right\|_{\overline{x}_i}^* &\le \int_0^1 \left\| \left(\nabla^2\phi_i(x_i^{(u)}) - \nabla^2\phi_i(\overline{x}_i)\right)\delta_{x,i} \right\|_{\overline{x}_i}^* \mathrm{d}u \\ &\le 7\alpha \|\delta_{x,i}\|_{\overline{x}_i} = 7\alpha \cdot \alpha_i, \end{aligned} \tag{3.13}$$

where the last step follows from definition of α_i (Lemma 3.5.1).

For the other term in $\epsilon_i^{(\mu)}$, we note that

$$(1-2\alpha) \cdot (\nabla^2\phi_i(\overline{x}_i)) \preceq \widetilde{V}_i^{-1} \preceq (1+2\alpha) \cdot (\nabla^2\phi_i(\overline{x}_i)).$$

Hence, we have

$$\left\| (\nabla^2\phi_i(\overline{x}_i) - \widetilde{V}_i^{-1})\delta_{x,i} \right\|_{\overline{x}_i}^* \le 2\alpha \|\delta_{x,i}\|_{\overline{x}_i} = 2\alpha \cdot \alpha_i. \tag{3.14}$$

Combining (3.12), (3.13) and (3.14), we have

$$\|\epsilon_i^{(\mu)}\|_{\overline{x}_i}^* \le 9\alpha \cdot \alpha_i.$$

Finally, we use the fact that x_i and $\overline{x}_i$ are α close and hence again by self-concordance, $\|\epsilon_i^{(\mu)}\|_{x_i}^* \le 10\alpha \cdot \alpha_i$.

□

Before bounding the change of γ, we first prove a helper lemma:

Lemma 3.5.3. *For all $i \in [m]$, we have*

$$\|\mu_i^t(x,s) - \mu_i^t(\overline{x},\overline{s})\|_{x_i}^* \le 4\alpha.$$

Proof. Note that

$$\|\mu_i^t(x,s) - \mu_i^t(\overline{x},\overline{s})\|_{\overline{x}_i}^* = \frac{1}{t}\|s_i - \overline{s}_i\|_{\overline{x}_i}^* + \|\nabla\phi_i(x_i) - \nabla\phi_i(\overline{x}_i)\|_{\overline{x}_i}^*.$$

For the first term, we have $\|s_i - \overline{s}_i\|_{\overline{x}_i}^* \le t\alpha$.

For the second term, let $x_i^{(u)} = ux_i + (1-u)\overline{x}_i$. Since x_i is close enough to $\overline{x}_i$, Theorem 3.2.1 shows that $\nabla^2\phi_i(x_i^{(u)}) \preceq 2 \cdot \nabla^2\phi_i(\overline{x}_i)$. Hence, we have

$$\|\nabla\phi_i(x_i) - \nabla\phi_i(\overline{x}_i)\|_{\overline{x}_i}^* = \left\|\int_0^1 \nabla^2\phi_i(x_i^{(u)}) \cdot (x_i - \overline{x}_i)du\right\|_{\overline{x}_i}^* \le 2\|x_i - \overline{x}_i\|_{\overline{x}_i} = 2\alpha.$$

Hence, we have $\|\mu_i^t(x,s) - \mu_i^t(\overline{x},\overline{s})\|_{\overline{x}_i}^* \le 3\alpha$ and using again x_i is close enough to $\overline{x}_i$ to get the final result.

□

Lemma 3.5.4 (Changes in γ)**.** *For all $i \in [m]$, let*

$$\gamma_i^t(x^{\text{new}}, x, s^{\text{new}}) \le (1 - \alpha \cdot c_i^t(\overline{x},\overline{s}))\gamma_i^t(x,x,s) + \epsilon_i^{(\gamma)}.$$

then $\epsilon_i^{(\gamma)} \le 10\alpha \cdot (\alpha c_i^t(\overline{x},\overline{s}) + \alpha_i)$. Furthermore, we have $|\gamma_i^t(x^{\text{new}}, x, s^{\text{new}}) - \gamma_i^t(x,x,s)| \le 3\alpha$.

Proof. For the first claim, Lemma 3.5.2, the definition of γ (3.7), h (3.8) and c (3.9) shows that

$$\begin{aligned}\gamma_i^t(x^{\text{new}}, x, s^{\text{new}}) &= \|\mu_i^t(x,s) + h_i + \epsilon_i^{(\mu)}\|_{x_i}^* \\ &= \|(1 - \alpha \cdot c_i^t(\overline{x},\overline{s}))\mu_i^t(x,s) + \epsilon_i\|_{x_i}^*\end{aligned}$$

where $\epsilon_i = \alpha \cdot c_i^t(\overline{x}, \overline{s})(\mu_i^t(x, s) - \mu_i^t(\overline{x}, \overline{s})) + \epsilon_i^{(\mu)}$.

From the definition of c_i^t, we have that $c_i^t \le \frac{1}{96\sqrt{\alpha}} \le \frac{1}{\alpha}$ and hence $0 \le 1 - \alpha \cdot c_i^t(\overline{x}, \overline{s}) \le 1$. Therefore, we have

$$\gamma_i^t(x^{\text{new}}, x, s^{\text{new}}) \le (1 - \alpha \cdot c_i^t(\overline{x}, \overline{s}))\gamma_i^t(x, x, s) + \|\epsilon_i\|_{x_i}^*. \tag{3.15}$$

Now, we bound $\|\epsilon_i\|_{x_i}^*$:

$$\begin{aligned} \|\epsilon_i\|_{x_i}^* &\le \alpha c_i^t(\overline{x}, \overline{s}) \cdot \|\mu_i^t(x, s) - \mu_i^t(\overline{x}, \overline{s})\|_{x_i}^* + \|\epsilon_i^{(\mu)}\|_{x_i}^* \\ &\le 4\alpha^2 c_i^t(\overline{x}, \overline{s}) + 10\alpha \cdot \alpha_i \end{aligned} \tag{3.16}$$

where we used Lemma 3.5.3 and Lemma 3.5.2 at the end.

For the second claim, we have

$$\left|\gamma_i^t(x^{\text{new}}, x, s^{\text{new}}) - \gamma_i^t(x, x, s)\right| \le \|h_i + \epsilon_i^{(\mu)}\|_{x_i}^* \le 2\alpha + 10\alpha \cdot \alpha_i$$

where we used (3.16) and that $\|h_i\|_{x_i}^* \le 2\|h\|_{\overline{x}}^* \le 2\alpha$. From Lemma 3.5.1 and that $\alpha \le \frac{1}{10000}$, we have $10\alpha \cdot \alpha_i \le 20\alpha^2 \le \alpha$.

□

3.5.3 Movement from (x, x, s) to $(x^{\text{new}}, x, s^{\text{new}})$

In the previous section, we see that γ_i will be expected to decrease by a factor of $\alpha \cdot c_i^t$ up to some small perturbations. We show that our potential Φ^t will therefore decrease significantly.

Lemma 3.5.5 (Movement along the first and third parameters)**.** *Assume that $\gamma_i^t(x, x, s) \leq 1$ for all i. We have*

$$\Phi^t(x^{\text{new}}, x, s^{\text{new}}) \leq \Phi^t(x, x, s) - \frac{\alpha\lambda}{5}\left(\sum_{i=1}^m \exp(2\lambda\gamma_i^t(\overline{x}, \overline{s}))\right)^{1/2} + \sqrt{m}\lambda \cdot \exp(192\lambda\sqrt{\alpha}).$$

Note that γ is a function that has three inputs. We use $\gamma(x, s)$ to denote $\gamma(x, x, s)$ for simplicity.

Proof. Let $\Phi^{\text{new}} = \Phi^t(x^{\text{new}}, x, s^{\text{new}})$, $\Phi = \Phi^t(x, x, s)$,

$$\gamma^{(u)} = u\gamma_i^t(x^{\text{new}}, x, s^{\text{new}}) + (1-u)\gamma_i^t(x, x, s).$$

Then, we have that

$$\Phi^{\text{new}} - \Phi = \sum_{i=1}^m (e^{\lambda\gamma_i^{(1)}} - e^{\lambda\gamma_i^{(0)}}) = \lambda\sum_{i=1}^m e^{\lambda\gamma_i^{(\zeta)}}(\gamma_i^{(1)} - \gamma_i^{(0)})$$

for some $0 \leq \zeta \leq 1$. Let $v_i = \gamma_i^{(1)} - \gamma_i^{(0)}$. Lemma 3.5.4 shows that

$$v_i \leq -\alpha \cdot c_i^t(\overline{x}, \overline{s}) \cdot \gamma_i^t(x, x, s) + \epsilon_i^{(\gamma)} = -\alpha \cdot c_i^t(\overline{x}, \overline{s}) \cdot \gamma_i^{(0)} + \epsilon_i^{(\gamma)}$$

and hence

$$\frac{\Phi^{\text{new}} - \Phi}{\lambda} \leq -\alpha\sum_{i=1}^m c_i^t(\overline{x}, \overline{s}) \cdot \gamma_i^{(0)} \exp(\lambda\gamma_i^{(\zeta)}) + \sum_{i=1}^m \epsilon_i^{(\gamma)} \exp(\lambda\gamma_i^{(\zeta)}). \tag{3.17}$$

To bound the first term in (3.17), we first relate $\gamma_i^{(0)}$, $\gamma_i^{(\zeta)}$ and $\gamma_i^t(\overline{x},\overline{s})$. Lemma 3.5.4 shows that

$$|\gamma_i^{(0)} - \gamma_i^{(\zeta)}| \leq |\gamma_i^{(0)} - \gamma_i^{(1)}| \leq 3\alpha. \tag{3.18}$$

Finally, we have

$$\begin{aligned}
\left|\gamma_i^t(\overline{x},\overline{s}) - \gamma_i^{(0)}\right| &= \left|\gamma_i^t(\overline{x},\overline{x},\overline{s}) - \gamma_i^t(x,x,s)\right| \\
&\leq \left|\gamma_i^t(\overline{x},\overline{x},\overline{s}) - \gamma_i^t(x,\overline{x},s)\right| + \left|\gamma_i^t(x,\overline{x},s) - \gamma_i^t(x,x,s)\right| \\
&\leq \|\mu_i^t(x,s) - \mu_i^t(\overline{x},\overline{s})\|_{\overline{x}_i}^* + \left|\|\mu_i^t(x,s)\|_{\overline{x}_i}^* - \|\mu_i^t(x,s)\|_{x_i}^*\right| \\
&\leq 2\|\mu_i^t(x,s) - \mu_i^t(\overline{x},\overline{s})\|_{x_i}^* + \left|\|\mu_i^t(x,s)\|_{\overline{x}_i}^* - \|\mu_i^t(x,s)\|_{x_i}^*\right| \\
&\leq 2\|\mu_i^t(x,s) - \mu_i^t(\overline{x},\overline{s})\|_{x_i}^* + 2\alpha\|\mu_i^t(x,s)\|_{x_i}^* \\
&\leq 8\alpha + 2\alpha = 10\alpha
\end{aligned} \tag{3.19}$$

where the first step follows from definition, the second and third step follows from triangle inequality, the fourth step follows from $\|\mu_i^t(x,s) - \mu_i^t(\overline{x},\overline{s})\|_{\overline{x}_i}^* \leq 2\|\mu_i^t(x,s) - \mu_i^t(\overline{x},\overline{s})\|_{x_i}^*$, the fifth step follows from self-concordance, the sixth step follows from Lemma 3.5.3 and that $\|\mu_i^t(x,s)\|_{x_i}^* = \gamma_i^t(x,x,s) \leq 1$ for all i

Using (3.18) and (3.19), we have

$$\begin{aligned}
&\sum_{i=1}^{m} c_i^t(\overline{x},\overline{s})\cdot\gamma_i^{(0)}\exp(\lambda\gamma_i^{(\zeta)})\\
=&\sum_{i=1}^{m} c_i^t(\overline{x},\overline{s})\cdot\gamma_i^{(0)}\exp(\lambda\gamma_i^t(\overline{x},\overline{s})-\lambda\gamma_i^t(\overline{x},\overline{s})+\lambda\gamma_i^{(0)}-\lambda\gamma_i^{(0)}+\lambda\gamma_i^{(\zeta)})\\
\geq&\sum_{i=1}^{m} c_i^t(\overline{x},\overline{s})\cdot\gamma_i^{(0)}\exp(\lambda\gamma_i^t(\overline{x},\overline{s})-13\lambda\alpha)\\
\geq&\frac{1}{2}\sum_{i=1}^{m} c_i^t(\overline{x},\overline{s})\cdot\gamma_i^{(0)}\exp(\lambda\gamma_i^t(\overline{x},\overline{s}))\\
\geq&\frac{1}{2}\sum_{i=1}^{m} c_i^t(\overline{x},\overline{s})\cdot\gamma_i^t(\overline{x},\overline{s})\exp(\lambda\gamma_i^t(\overline{x},\overline{s}))-3\alpha\sum_{i=1}^{m} c_i^t(\overline{x},\overline{s})\exp(\lambda\gamma_i^t(\overline{x},\overline{s})).
\end{aligned}\tag{3.20}$$

where the third step follows from $\exp(-13\lambda\alpha)\geq 1/2$, and the last step follows from (3.18).

For the first term in (3.20), we have

$$\begin{aligned}
&\sum_{i=1}^{m} c_i^t(\overline{x},\overline{s})\cdot\gamma_i^t(\overline{x},\overline{s})\exp(\lambda\gamma_i^t(\overline{x},\overline{s}))\\
=&\sum_{\gamma_i^t(\overline{x},\overline{s})\geq 96\sqrt{\alpha}}\frac{\exp(2\lambda\cdot\gamma_i^t(\overline{x},\overline{s}))}{(\sum_{i=1}^{m}\exp(2\lambda\gamma_i^t(\overline{x},\overline{s})))^{1/2}}\\
=&\sum_{i=1}^{m}\frac{\exp(2\lambda\cdot\gamma_i^t(\overline{x},\overline{s}))}{(\sum_{i=1}^{m}\exp(2\lambda\gamma_i^t(\overline{x},\overline{s})))^{1/2}}-\sum_{\gamma_i^t(\overline{x},\overline{s})<96\sqrt{\alpha}}\frac{\exp(2\lambda\cdot\gamma_i^t(\overline{x},\overline{s}))}{(\sum_{i=1}^{m}\exp(2\lambda\gamma_i^t(\overline{x},\overline{s})))^{1/2}}\\
\geq&\left(\sum_{i=1}^{m}\exp(2\lambda\gamma_i^t(\overline{x},\overline{s}))\right)^{1/2}-\frac{m\cdot\exp(192\lambda\cdot\sqrt{\alpha})}{(\sum_{i=1}^{m}\exp(2\lambda\gamma_i^t(\overline{x},\overline{s})))^{1/2}}.
\end{aligned}$$

So, if $\sum_{i=1}^{m}\exp(2\lambda\gamma_i^t(\overline{x},\overline{s}))\geq m\cdot\exp(192\lambda\cdot\sqrt{\alpha})$, we have

$$\sum_{i=1}^{m} c_i^t(\overline{x},\overline{s})\cdot\gamma_i^t(\overline{x},\overline{s})\exp(\lambda\gamma_i^t(\overline{x},\overline{s}))\geq\left(\sum_{i=1}^{m}\exp(2\lambda\gamma_i^t(\overline{x},\overline{s}))\right)^{1/2}-\sqrt{m}\cdot\exp(192\lambda\sqrt{\alpha}).$$

Note that if $\sum_{i=1}^{m}\exp(2\lambda\gamma_i^t(\overline{x},\overline{s}))\leq m\cdot\exp(192\lambda\cdot\sqrt{\alpha})$, this is still true because left hand

side is lower bounded by 0. For the second term in (3.20), we have

$$\begin{aligned}\sum_{i=1}^{m} c_i^t(\overline{x},\overline{s})\exp(\lambda\gamma_i^t(\overline{x},\overline{s})) &= \sum_{\gamma_i^t(\overline{x},\overline{s})\geq 96\sqrt{\alpha}} \frac{\exp(\lambda\cdot\gamma_i^t(\overline{x},\overline{s}))/\gamma_i^t(\overline{x},\overline{s})}{(\sum_{i=1}^m \exp(2\lambda\gamma_i^t(\overline{x},\overline{s})))^{1/2}}\exp(\lambda\gamma_i^t(\overline{x},\overline{s}))\\ &\leq \frac{1}{96\sqrt{\alpha}}\sum_{\gamma_i^t(\overline{x},\overline{s})\geq 96\sqrt{\alpha}} \frac{\exp(2\lambda\cdot\gamma_i^t(\overline{x},\overline{s}))}{(\sum_{i=1}^m \exp(2\lambda\gamma_i^t(\overline{x},\overline{s})))^{1/2}}\\ &\leq \frac{1}{96\sqrt{\alpha}}\sum_{i=1}^{m} \frac{\exp(2\lambda\cdot\gamma_i^t(\overline{x},\overline{s}))}{(\sum_{i=1}^m \exp(2\lambda\gamma_i^t(\overline{x},\overline{s})))^{1/2}}\\ &= \frac{1}{96\sqrt{\alpha}}\left(\sum_{i=1}^{m}\exp(2\lambda\gamma_i^t(\overline{x},\overline{s}))\right)^{1/2}.\end{aligned}$$

where the second step follows $\frac{1}{\gamma_i^t(\overline{x},\overline{s})} \leq \frac{1}{96\sqrt{\alpha}}$, and the third step follows from each term in the summation is non-negative.

Combining the bounds for both first and second term in (3.20), we have

$$\begin{aligned}\sum_{i=1}^{m} c_i^t(\overline{x},\overline{s})\cdot\gamma_i^{(0)}\exp(\lambda\gamma_i^{(\zeta)}) &\geq \frac{1}{2}\left(\left(\sum_{i=1}^{m}\exp(2\lambda\gamma_i^t(\overline{x},\overline{s}))\right)^{1/2} - \sqrt{m}\cdot\exp(192\lambda\sqrt{\alpha})\right)\\ &\quad - \frac{3\alpha}{96\sqrt{\alpha}}\left(\sum_{i=1}^{m}\exp(2\lambda\gamma_i^t(\overline{x},\overline{s}))\right)^{1/2}\\ &\geq \frac{2}{5}\left(\sum_{i=1}^{m}\exp(2\lambda\gamma_i^t(\overline{x},\overline{s}))\right)^{1/2} - \sqrt{m}\cdot\exp(192\lambda\sqrt{\alpha}). \qquad (3.21)\end{aligned}$$

where the last step follows from $\frac{1}{2} - \frac{3\alpha}{96\sqrt{\alpha}} \geq \frac{1}{2} - \frac{3}{96} = \frac{45}{96} \geq \frac{2}{5}$.

For the second term in (3.17), we note that $|\gamma_i^{(\zeta)} - \gamma_i^t(\overline{x},\overline{s})| \leq 13\alpha \leq \frac{1}{2\lambda}$ by (3.18) and (3.19). Hence,

$$\sum_{i=1}^{m}\epsilon_i^{(\gamma)}\exp(\lambda\gamma_i^{(\zeta)}) \leq 2\sum_{i=1}^{m}\epsilon_i^{(\gamma)}\exp(\lambda\gamma_i^t(\overline{x},\overline{s})).$$

Now, we use $\epsilon_i^{(\gamma)} \le 10\alpha \cdot (\alpha c_i^t(\overline{x},\overline{s}) + \alpha_i)$ (Lemma 3.5.4) to get

$$\begin{aligned}\sum_{i=1}^m \epsilon_i^{(\gamma)} \exp(\lambda\gamma_i^{(\zeta)}) &\le 20\alpha \sum_{i=1}^m (\alpha c_i^t(\overline{x},\overline{s}) + \alpha_i) \cdot \exp(\lambda\gamma_i^t(\overline{x},\overline{s})) \\ &\le 20\alpha \left(\sum_{i=1}^m (\alpha c_i^t(\overline{x},\overline{s}) + \alpha_i)^2\right)^{1/2} \left(\sum_{i=1}^m \exp(2\lambda\gamma_i^t(\overline{x},\overline{s}))\right)^{1/2}.\end{aligned}$$

where the last step follows from Cauchy-Schwarz inequality.

Note that by using Cauchy-Schwarz,

$$\begin{aligned}\left(\sum_{i=1}^m (\alpha c_i^t(\overline{x},\overline{s}) + \alpha_i)^2\right)^{1/2} &\le \alpha \left(\sum_{i=1}^m c_i^t(\overline{x},\overline{s})^2\right)^{1/2} + \left(\sum_{i=1}^m \alpha_i^2\right)^{1/2} \\ &\le \alpha \cdot \frac{1}{96\sqrt{\alpha}} + 2\alpha \le \frac{\sqrt{\alpha}}{90}.\end{aligned}$$

where we used the definition of c_i^t, Lemma 3.5.1 and $\alpha \le \frac{1}{2^{24}}$. Together, we conclude

$$\sum_{i=1}^m \epsilon_i^{(\gamma)} \exp(\lambda\gamma_i^{(\zeta)}) \le \frac{1}{5}\alpha \left(\sum_{i=1}^m \exp(2\lambda\gamma_i^t(\overline{x},\overline{s}))\right)^{1/2}. \tag{3.22}$$

Combining (3.21) and (3.22) to (3.17) gives

$$\begin{aligned}\frac{\Phi^{\text{new}} - \Phi}{\lambda} &\le -\frac{2}{5}\alpha \left(\sum_{i=1}^m \exp(2\lambda\gamma_i^t(\overline{x},\overline{s}))\right)^{1/2} + \sqrt{m} \cdot \exp(192\lambda\sqrt{\alpha}) + \frac{1}{5}\alpha \left(\sum_{i=1}^m \exp(2\lambda\gamma_i^t(\overline{x},\overline{s}))\right)^{1/2} \\ &= -\frac{1}{5}\alpha \left(\sum_{i=1}^m \exp(2\lambda\gamma_i^t(\overline{x},\overline{s}))\right)^{1/2} + \sqrt{m} \cdot \exp(192\lambda\sqrt{\alpha}).\end{aligned}$$

where the last step follows from merging the first term with the third term. □

3.5.4 Movement from $(x^{\text{new}}, x, s^{\text{new}})$ to $(x^{\text{new}}, x^{\text{new}}, s^{\text{new}})$

Next, we must analyze the potential change when we change the second term.

Lemma 3.5.6 (Movement along the second parameter)**.** *Assume that* $\|\gamma^t(x,x,s)\|_\infty \leq 1$. *Then we have*

$$\Phi^t(x^{\text{new}}, x^{\text{new}}, s^{\text{new}}) \leq \Phi^t(x^{\text{new}}, x, s^{\text{new}}) + 12\alpha(\|\gamma^t(x,x,s)\|_\infty + 3\alpha)\lambda \left(\sum_{i=1}^m \exp(2\lambda\gamma_i^t(x,x,s))\right)^{1/2}.$$

Proof. We can upper bound $\Phi^t(x^{\text{new}}, x^{\text{new}}, s^{\text{new}})$ as follows

$$\begin{aligned}\Phi^t(x^{\text{new}}, x^{\text{new}}, s^{\text{new}}) &= \sum_{i=1}^m \exp(\lambda\gamma_i^t(x^{\text{new}}, x^{\text{new}}, s^{\text{new}})) \\ &\leq \sum_{i=1}^m \exp(\lambda\gamma_i^t(x^{\text{new}}, x, s^{\text{new}})(1+2\alpha_i)).\end{aligned}$$

where the second step follows from $\gamma_i^t(x^{\text{new}}, x^{\text{new}}, s^{\text{new}}) \leq \gamma_i^t(x^{\text{new}}, x, s^{\text{new}}) \cdot (1+2\alpha_i)$ by self-concordance (Theorem 3.2.1) and $\|x_i^{\text{new}} - x_i\|_{x_i} \leq 2\|x_i^{\text{new}} - x_i\|_{\overline{x}_i} \leq 2\alpha_i$.

Now, by Lemma 3.5.4, we note that $\gamma_i^t(x^{\text{new}}, x, s^{\text{new}}) \leq \gamma_i^t(x,x,s) + 3\alpha \leq 1 + 3\alpha$ and that $\alpha \leq \frac{1}{100\lambda}$. Hence, by a simple taylor expansion, we have

$$\begin{aligned}&\Phi^t(x^{\text{new}}, x^{\text{new}}, s^{\text{new}}) \\ &\leq \sum_{i=1}^m \exp(\lambda\gamma_i^t(x^{\text{new}}, x, s^{\text{new}})) + 3\sum_{i=1}^m \alpha_i \exp(\lambda\gamma_i^t(x^{\text{new}}, x, s^{\text{new}}))\gamma_i^t(x^{\text{new}}, x, s^{\text{new}}).\end{aligned}$$

Finally, we bound the last term by

$$
\begin{aligned}
&\sum_{i=1}^{m} \exp(\lambda\gamma_i^t(x^{\text{new}}, x, s^{\text{new}}))\gamma_i^t(x^{\text{new}}, x, s^{\text{new}})\alpha_i \\
\leq &\sum_{i=1}^{m} \exp(\lambda\gamma_i^t(x, x, s) + 3\lambda\alpha)(\gamma_i^t(x, x, s) + 3\alpha)\alpha_i \\
\leq &\, 2(\|\gamma^t(x, x, s)\|_\infty + 3\alpha) \sum_{i=1}^{m} \exp(\lambda\gamma_i^t(x, x, s))\alpha_i \\
\leq &\, 2(\|\gamma^t(x, x, s)\|_\infty + 3\alpha) \left(\sum_{i=1}^{m} \exp(2\lambda\gamma_i^t(x, x, s))\right)^{1/2} \left(\sum_{i=1}^{m} \alpha_i^2\right)^{1/2} \\
\leq &\, 4\alpha(\|\gamma^t(x, x, s)\|_\infty + 3\alpha) \left(\sum_{i=1}^{m} \exp(2\lambda\gamma_i^t(x, x, s))\right)^{1/2},
\end{aligned}
$$

where the first step follows from $\lambda\gamma_i^t(x^{\text{new}}, x, s^{\text{new}}) \leq \exp(\lambda\gamma_i^t(x, x, s) + 3\lambda\alpha)$, the second step follows $\exp(3\lambda\alpha) \leq 2$, the third step follows from Cauchy-Schwarz inequality, the last step follows from $\sum_{i=1}^{m} \alpha_i^2 \leq 4\alpha^2$.

□

3.5.5 Movement of t

Lastly, we analyze the effect of setting $t \to t^{\text{new}}$.

Lemma 3.5.7 (Movement in t)**.** *For any x, s such that $\gamma_i^t(x,s) \leq 1$ for all i, let $t^{\text{new}} = \left(1 - \frac{\kappa}{\sqrt{\nu}}\right) t$ where $\nu = \sum_{i=1}^m \nu_i$, we have*

$$\Phi^{t^{\text{new}}}(x,s) \leq \Phi^t(x,s) + 10\kappa\lambda \left(\sum_{i=1}^m \exp(2\lambda \gamma_i^t(x,s)) \right)^{1/2}.$$

Proof. Note that

$$\begin{aligned}
\gamma_i^{t^{\text{new}}}(x,s) = & \left\| \frac{s}{t^{\text{new}}} + \nabla \phi_i(x_i) \right\|_{x_i}^* \\
= & \left\| \frac{s}{t(1-\kappa/\sqrt{\nu})} + \nabla \phi_i(x_i) \right\|_{x_i}^* \\
\leq & (1 + 2\kappa/\sqrt{\nu}) \gamma_i^t(x,s) + 2\|(\kappa/\sqrt{\nu}) \nabla \phi_i(x_i)\|_{x_i}^* \\
\leq & (1 + 2\kappa/\sqrt{\nu}) \gamma_i^t(x,s) + 3\kappa\sqrt{\nu_i}/\sqrt{\nu} \\
\leq & \gamma_i^t(x,s) + 5\kappa\sqrt{\nu_i}/\sqrt{\nu}
\end{aligned}$$

where the first step follows from definition, the second step follows from $t^{\text{new}} = t(1-\kappa/\sqrt{\nu})$, the second last step follows from the fact that our barriers are ν_i-self-concordant and the last step used $\gamma_i^t(x,s) \leq 1$ and $\nu_i \geq 1$. Using that $5\kappa \leq \frac{1}{10\lambda}$ and $\gamma_i^t(x,s) \leq 1$, we have by

simple taylor expansion,

$$\begin{aligned}
\Phi^{t^{\text{new}}}(x,s) &\leq \sum_{i=1}^{m} \exp(\lambda\gamma_i^t(x,s)) + 2\lambda \sum_{i=1}^{m} \exp(\lambda\gamma_i^t(x,s)) \left(5\kappa\sqrt{\nu_i/\nu}\right) \\
&= \sum_{i=1}^{m} \exp(\lambda\gamma_i^t(x,s)) + 10\kappa\lambda \sum_{i=1}^{m} \exp(\lambda\gamma_i^t(x,s)) \left(\sqrt{\nu_i/\nu}\right) \\
&\leq \sum_{i=1}^{m} \exp(\lambda\gamma_i^t(x,s)) + 10\kappa\lambda \left(\sum_{i=1}^{m} \exp(2\lambda\gamma_i^t(x,s))\right)^{1/2} \left(\sum_{i=1}^{m} \frac{\nu_i}{\nu}\right)^{1/2} \\
&= \sum_{i=1}^{m} \exp(\lambda\gamma_i^t(x,s)) + 10\kappa\lambda \left(\sum_{i=1}^{m} \exp(2\lambda\gamma_i^t(x,s))\right)^{1/2},
\end{aligned}$$

where the third step follows from Cauchy-Schwarz, and the last step follows from $\sum_{i=1}^{m} \nu_i = \nu$. □

3.5.6 Potential Maintenance

Putting it all together, we can show that our potential Φ^t can be maintained to be small throughout our algorithm.

Lemma 3.5.8 (Potential Maintenance)**.** *If* $\Phi^t(x,s) \leq 80\frac{m}{\alpha}$*, then*

$$\Phi^{t^{\text{new}}}(x^{\text{new}}, s^{\text{new}}) \leq \left(1 - \frac{\alpha\lambda}{40\sqrt{m}}\right)\Phi^t(x,s) + \sqrt{m}\lambda \cdot \exp(192\lambda\sqrt{\alpha}).$$

In particularly, we have $\Phi^{t^{\text{new}}}(x^{\text{new}}, s^{\text{new}}) \leq 80\frac{m}{\alpha}$.

Proof. Let

$$\zeta(x,s) = \left(\sum_{i=1}^{m} \exp(2\lambda\gamma_i^t(x,s))\right)^{1/2}.$$

By combining our previous lemmas,

$$\begin{aligned}
&\Phi^{t^{\text{new}}}(x^{\text{new}}, s^{\text{new}}) \\
\leq &\Phi^t(x^{\text{new}}, s^{\text{new}}) + 10\kappa\lambda \cdot \zeta(x^{\text{new}}, s^{\text{new}}) \\
\leq &\Phi^t(x^{\text{new}}, x, s^{\text{new}}) + 12\alpha\lambda(\|\gamma^t(x,s)\|_\infty + 3\alpha) \cdot \zeta(x,s) + 10\kappa\lambda \cdot \zeta(x^{\text{new}}, s^{\text{new}}) \\
\leq &\Phi^t(x,x,s) - \frac{\alpha\lambda}{5}\zeta(\overline{x}, \overline{s}) + \sqrt{m}\lambda \cdot \exp(192\lambda\sqrt{\alpha}) \\
&+ 12\alpha\lambda(\|\gamma^t(x,s)\|_\infty + 3\alpha) \cdot \zeta(x,s) + 10\kappa\lambda \cdot \zeta(x^{\text{new}}, s^{\text{new}})
\end{aligned} \tag{3.23}$$

where the first step follows from Lemma 3.5.7, the second step follows from Lemma 3.5.6, and the last step follows from Lemma 3.5.5. We note that in all lemma above, we used that fact that $\|\gamma^t\|_\infty \leq 1$ (for different combination of x, $\overline{x}$, x^{new}, s, $\overline{s}$, s^{new}) which we will show later.

We can upper bound $\gamma_i^t(x^{\text{new}}, s^{\text{new}})$ in the following sense,

$$\gamma_i^t(x^{\text{new}}, s^{\text{new}}) \leq \gamma_i^t(x^{\text{new}}, x, s^{\text{new}}) + 2\alpha \leq \gamma_i^t(x,x,s) + 5\alpha. \tag{3.24}$$

where the first step follows from self-concordance and $\gamma_i \le 1$, the second step follows from Lemma 3.5.4.

Hence, since ζ changes multiplicatively when γ changes additively, $\zeta(x^{\text{new}}, s^{\text{new}}) \le 2\zeta(x,s)$.

Lemma 3.5.3 shows that $\|\mu_i^t(x,s) - \mu_i^t(\overline{x},\overline{s})\|_{x_i}^* \le 4\alpha$ and hence

$$\begin{aligned}\zeta(\overline{x},\overline{s}) &\ge \frac{2}{3}\left(\sum_{i=1}^m \exp(2\lambda\gamma_i^t(\overline{x},x,\overline{s}))\right)^{1/2} \\ &\ge \frac{2}{3}\left(\sum_{i=1}^m \exp(2\lambda\gamma_i^t(x,x,s) - 8\alpha\lambda)\right)^{1/2} \\ &\ge \frac{1}{2}\zeta(x,s). \end{aligned} \tag{3.25}$$

Combining (3.24) and (3.25) into (3.23) gives

$$\begin{aligned}&\Phi^{t^{\text{new}}}(x^{\text{new}}, s^{\text{new}}) \\ &\ge \Phi^t(x,s) + \left(12\alpha\lambda(\|\gamma^t(x,s)\|_\infty + 3\alpha) + 20\kappa\lambda - \frac{\alpha\lambda}{10}\right)\cdot\zeta(x,s) + \sqrt{m}\lambda\cdot\exp(192\lambda\sqrt{\alpha}) \\ &\ge \Phi^t(x,s) + \left(12\alpha\lambda\|\gamma^t(x,s)\|_\infty - \frac{\alpha\lambda}{20}\right)\cdot\zeta(x,s) + \sqrt{m}\lambda\cdot\exp(192\lambda\sqrt{\alpha})\end{aligned}$$

where the last step follows from $\kappa \le \frac{\alpha}{1000}$ and $\alpha \le \frac{1}{10000}$.

Finally, we need to bound $\|\gamma^t(x,s)\|_\infty$. The bound for other $\|\gamma^t\|_\infty$, i.e. for different combination of x, $\overline{x}$, x^{new}, s, $\overline{s}$, s^{new}, are similar. We note that

$$\Phi^t(x,s) \le 80\frac{m}{\alpha}$$

implies that $\|\gamma^t(x,s)\|_\infty \le \frac{\log(80\frac{m}{\alpha})}{\lambda}$. Hence, by our choice of λ and α, we have that $\lambda \ge 480\log(80\frac{m}{\alpha})$ and hence

$$12\alpha\lambda\|\gamma^t(x,s)\|_\infty \le \frac{\alpha\lambda}{40}.$$

Finally, using $\Phi^t(x,s) \le \sqrt{m} \cdot \zeta(x,s)$, we have

$$\begin{aligned}\Phi^{t^{\text{new}}}(x^{\text{new}}, s^{\text{new}}) &\ge \Phi^t(x,s) - \frac{\alpha\lambda}{40}\zeta(x,s) + \sqrt{m}\lambda \cdot \exp(192\lambda\sqrt{\alpha}) \\ &\ge \left(1 - \frac{\alpha\lambda}{40\sqrt{m}}\right)\Phi^t(x,s) + \sqrt{m}\lambda \cdot \exp(192\lambda\sqrt{\alpha}).\end{aligned}$$

Since $\lambda \le \frac{1}{400\sqrt{\alpha}}$, we have $\Phi^t(x,s) \le 80\frac{m}{\alpha}$ implies $\Phi^{t^{\text{new}}}(x^{\text{new}}, s^{\text{new}}) \le 80\frac{m}{\alpha}$.

Table 3.2: Summary of data structure CentralPathMaintenance

3.6 Central Path Maintenance

The goal of this section is to present a data-structure to perform our centering steps in $\widetilde{O}(n^{\omega-1/2})$ amortized time and prove a theoretical guarantee of it. The original idea of inverse maintenance is from Michael B. Cohen [Lee17], then [CLS19] used it to get faster running time for solving Linear Programs. Because a simple matrix vector product would require $O(n^2)$ time, our speedup comes via a low-rank embedding that provides ℓ_∞ guarantees, which is unlike the sparse vector approach of [CLS19]. In fact, we are unsure if moving in a sparse direction h can have sufficiently controlled noise to show convergence. Here, we give a stochastic version that is faster for dense direction h.

Theorem 3.6.1 (Central path maintenance)**.** *Given a full rank matrix $A \in \mathbb{R}^{d \times n}$ with $n \geq d$, a tolerance parameter $0 < \epsilon_{mp} < 1/4$ and a block diagonal structure $n = \sum_{i=1}^{m} n_i$. Given any positive number a such $a \leq \alpha$ where α is the dual exponent of matrix multiplication. Given any linear sketch of size b, there is a randomized data structure* CentralPathMainte-

NANCE *(in Algorithm 3.1, 3.2, 3.4) that approximately maintains the projection matrices*

$$\sqrt{W}A^\top(AWA^\top)^{-1}A\sqrt{W}$$

for positive block diagonal psd matrix $W \oplus_i \mathbb{R}^{n_i \times n_i}$*; exactly implicitly maintains central path parameters* (x, s) *and approximately explicitly maintains path parameters through the following five operations:*

1. INITIALIZE$(\overline{W}^{(0)}, \cdots)$ *: Assume* $\overline{W}^{(0)} \in \otimes_i \mathbb{R}^{n_i \times n_i}$*. Initialize all the parameters in* $O(n^\omega)$ *time.*

2. UPDATE$(\overline{W})$ *: Assume* $\overline{W} \in \oplus_i \mathbb{R}^{n_i \times n_i}$*. Output a block diagonal matrix* $\widetilde{V} \oplus_i \mathbb{R}^{n_i \times n_i}$ *such that*

$$(1 - \epsilon_{mp})\widetilde{v}_i \preceq \overline{w}_i \preceq (1 + \epsilon_{mp})\widetilde{v}_i.$$

3. QUERY() *: Output* $(\overline{x}, \overline{s})$ *such that* $\|\overline{x} - x\|_{\widetilde{V}^{-1}} \leq \epsilon_{mp}$ *and* $\|\overline{s} - s\|_{\widetilde{V}} \leq t\epsilon_{mp}$ *where* t *is the last* t *used in* MULTIPLYMOVE*, where* $\epsilon_{mp} = \alpha \log^2(nT)\frac{n^{1/4}}{\sqrt{b}}$ *and the success probability is* $1 - 1/\operatorname{poly}(nT)$*. This step takes* $O(n)$ *time.*

4. MULTIPLYMOVE(h, t) *: It outputs nothing. It implicitly maintains:*

$$x = x + \widetilde{V}^{1/2}(I - \widetilde{P})\widetilde{V}^{1/2}h, s = s + t\widetilde{V}^{-1/2}\widetilde{P}\widetilde{V}^{1/2}h.$$

where $\widetilde{P} = \widetilde{V}^{1/2}A^\top(A\widetilde{V}A^\top)^{-1}A\widetilde{V}^{1/2}$*. It also explicitly maintains* $\overline{x}, \overline{s}$*. Assuming* t *is decreasing, each call takes* $O(nb + n^{a\omega+o(1)} + n^a\|h\|_0 + n^{1.5})$ *amortized time.*

Let $\overline{W}^{(0)}$ *be the initial matrix and* $\overline{W}^{(1)}, \cdots, \overline{W}^{(T)}$ *be the (random) update sequence. Under the assumption that there is a sequence of matrix* $W^{(0)}, \cdots, W^{(T)} \in \oplus_{i=1}^m \mathbb{R}^{n_i \times n_i}$ *sat-*

isfies for all k

$$\left\| w_i^{-1/2}(\overline{w}_i - w_i)w_i^{-1/2} \right\|_F \leq \epsilon_{mp},$$
$$\sum_{i=1}^{m} \left\| (w_i^{(k)})^{-1/2}(\mathbb{E}[w_i^{(k+1)}] - w_i^{(k)})(w_i^{(k)})^{-1/2} \right\|_F^2 \leq C_1^2,$$
$$\sum_{i=1}^{m} \left(\mathbb{E}\left[\left\| (w_i^{(k)})^{-1/2}(w_i^{(k+1)} - w_i^{(k)})(w_i^{(k)})^{-1/2} \right\|_F^2 \right] \right)^2 \leq C_2^2,$$
$$\left\| (w_i^{(k)})^{-1/2}(w_i^{(k+1)} - w_i^{(k)})(w_i^{(k)})^{-1/2} \right\|_F \leq \frac{1}{4}.$$

where $w_i^{(k)}$ is the i-th block of $W^{(k)}$, $\forall i \in [m]$.

Then, the amortized expected time per call of UPDATE(w) *is*

$$(C_1/\epsilon_{mp} + C_2/\epsilon_{mp}^2) \cdot (n^{\omega - 1/2 + o(1)} + n^{2 - a/2 + o(1)}).$$

Remark 3.6.1. For our algorithm, we have $C_1 = O(1/\log^2 n)$, $C_2 = O(1/\log^4 n)$ and $\epsilon_{mp} = O(1/\log^2 n)$. Note that the input of UPDATE $\overline{W}$ can move a lot. It is working as long as $\overline{W}$ is close to some W that is slowly moving. In our application, our W satisfies C_1, C_2 deterministically. We keep it for possible future applications.

Definition of matrices X and Y. Let us consider the k-th round of the algorithm. For all $i \in [m]$, matrix $\overline{y}_i^{(k)} \in \mathbb{R}^{n_i \times n_i}$ is constructed based on procedure Update (Algorithm 3.2)

:

$$\overline{y}_i^{(k)} = \frac{\overline{w}_i^{(k+1)}}{v_i^{(k)}} - I.$$

and $\overline{\pi}$ is a permutation such that $\|\overline{y}_{\overline{\pi}(i)}^{(k)}\|_F \geq \|\overline{y}_{\overline{\pi}(i+1)}^{(k)}\|_F$.

For the purpose of analysis : for all $i \in [m]$, we define $x_i^{(k)}$, $x_i^{(k)}$ and $y_i^{(k)} \in \mathbb{R}^{n_i \times n_i}$ as follows:

$$x_i^{(k)} = \frac{w_i^{(k)}}{v_i^{(k)}} - I, \quad y_i^{(k)} = \frac{w_i^{(k+1)}}{v_i^{(k)}} - I, \quad x_i^{(k+1)} = \frac{w_i^{(k+1)}}{v_i^{(k+1)}} - I,$$

where $\frac{w_i^{(k)}}{v_i^{(k)}}$ denotes $(v_i^{(k)})^{-1/2} w_i^{(k)} (v_i^{(k)})^{-1/2}$.

It is not hard to observe the difference between $x_i^{(k)}$ and $y_i^{(k)}$ is that w is changing. We call it "w move". Similarly, the difference between $y_i^{(k)}$ and $x_i^{(k+1)}$ is that v is changing. We call it "v move".

For each i, we define β_i as follows

$$\beta_i = \|(w_i^{(k)})^{-1/2} (\mathbb{E}[w_i^{(k+1)}] - w_i^{(k)}) (w_i^{(k)})^{-1/2}\|_F,$$

then one of assumption becomes

$$\sum_{i=1}^m \beta_i^2 \leq C_1^2.$$

Assume sorting for diagonal blocks. Without loss of generality, we can assume the diagonal blocks of matrix $x^{(k)} \in \oplus_{i=1}^m \mathbb{R}^{n_i \times n_i}$ are sorted such that $\|x_i^{(k)}\|_F \geq \|x_{i+1}^{(k)}\|_F$. In [CLS19], $x_i^{(k)}$ is a scalar. They sorted the sequence based on absolute value. In our situation, $x_i^{(k)}$ is a matrix. We sort the sequence based on Frobenius norm. Let τ permutation such that $\|x_{\tau(i)}^{(k+1)}\|_F \geq \|x_{\tau(i+1)}^{(k+1)}\|_F$. Let π denote the permutation such that $\|y_{\pi(i)}^{(k)}\|_F \geq \|y_{\pi(i+1)}^{(k)}\|_F$.

Definition of Potential function. We define three functions g, ψ and Φ_k here. The definition of ψ is different from [CLS19], since we need to handle matrix. The definitions of g and Φ_k are the same as [CLS19].

For the completeness, we still provide a definition of g. Let g be defined as

$$g_i = \begin{cases} n^{-a}, & \text{if } i < n^a; \\ i^{\frac{\omega-2}{1-a}} n^{-\frac{a(\omega-2)}{1-a}}, & \text{otherwise.} \end{cases}$$

In [CLS19], the input of function $\psi : \mathbb{R} \to \mathbb{R}$ has to be a number. We allow matrix here. Let ψ : square matrix $\to \mathbb{R}$ be defined by

$$\psi(x) = \begin{cases} \frac{\|x\|_F^2}{2\epsilon_{mp}}, & \|x\|_F \in [0, \epsilon_{mp}]; \\ \epsilon_{mp} - \frac{(4\epsilon_{mp}^2 - \|x\|_F^2)^2}{18\epsilon_{mp}^3}, & \|x\|_F \in (\epsilon_{mp}, 2\epsilon_{mp}]; \\ \epsilon_{mp}, & \|x\|_F \in (2\epsilon_{mp}, +\infty). \end{cases} \tag{3.26}$$

where $\|x\|_F$ denotes the Frobenius norm of square matrix x, and let $L_1 = \max_x D_x\psi[h]/\|H\|_F$, $L_2 = \max_x D_x^2\psi[h,h]/\|H\|_F^2$ where h is the vectorization of matrix H.

For the completeness, we define the potential at the k-th round by

$$\Phi_k = \sum_{i=1}^{m} g_i \cdot \psi(x_{\tau_k(i)}^{(k)})$$

where $\tau_k(i)$ is the permutation such that $\|x_{\tau_k(i)}^{(k)}\|_F \geq \|x_{\tau_k(i+1)}^{(k)}\|_F$. (Note that in [CLS19] $\|\cdot\|_F$ should be $|\cdot|$.)

Rewriting the potential, and bounding it. Following the ideas in [CLS19], we can rewrite $\Phi_{k+1} - \Phi_k$ into two terms: the first term is w move, and the second term is v move.

For the completeness, we still provide a proof.

$$\begin{aligned}\Phi_{k+1} - \Phi_k &= \sum_{i=1}^{m} g_i \cdot \left(\psi(x_{\tau(i)}^{(k+1)}) - \psi(x_i^{(k)})\right) \\ &= \sum_{i=1}^{m} g_i \cdot \underbrace{\left(\psi(y_{\pi(i)}^{(k)}) - \psi(x_i^{(k)})\right)}_{W \text{ move}} - \sum_{i=1}^{m} g_i \cdot \underbrace{\left(\psi(y_{\pi(i)}^{(k)}) - \psi(x_{\tau(i)}^{(k+1)})\right)}_{V \text{ move}}\end{aligned}$$

Using Lemma 3.6.10, we can bound the first term. Using Lemma 3.6.12, we can bound the second term.

3.6.2 Initialization time, update time, query time, move time, multiply time

Remark 3.6.2. In terms of implementing this data-structure, we only need three operations INITIALIZE, UPDATE, and QUERY. However, in order to make the proof more understoodable, we split UPDATE into many operations : FULLUPDATE, PARTIALUPDATE, MULTIPLY and MOVE. We give a list of operations in Table 3.2.

Lemma 3.6.2 (Initialization)**.** *The initialization time of data-structure* CENTRALPATHMAINTENANCE *(Algorithm 3.1) is* $O(n^{\omega+o(1)})$.

Proof. The running time is mainly dominated by two parts, the first part is computing $A^\top (AVA^\top)^{-1} A$, this takes $O(n^2 d^{\omega-2})$ time.

The second part is computing $R\sqrt{\widetilde{V}}M$. This takes $O(n^{\omega+o(1)})$ time.

□

Lemma 3.6.3 (Update time)**.** *The update time of data-structure* CENTRALPATHMAINTENANCE *(Algorithm 3.2) is* $O(rg_r n^{2+o(1)})$ *where* r *is the number of indices we updated in* V.

Proof. It is trivially follows from combining Lemma 3.6.4 and Lemma 3.6.5. □

Lemma 3.6.4 (Partial Update time)**.** *The partial update time of data-structure* CENTRALPATHMAINTENANCE *(Algorithm 3.2) is* $O(n^{1+a})$.

Proof. We first analyze the running time of F update, the update equation of F in algorithm

is

$$F^{\text{new}} \leftarrow F + ((\widetilde{V}^{\text{new}})^{1/2} - (\widetilde{V})^{1/2})M$$
$$F \leftarrow F^{\text{new}}$$

which can be implemented as

$$F \leftarrow F + ((\widetilde{V}^{\text{new}})^{1/2} - (\widetilde{V})^{1/2})M$$

where we only need to change n^a row-blocks of F. It takes $O(n^{1+a})$ time.

Similarly, for the update time of G.

Next we analyze the update time of u_1, the update equation of u_1 is

$$u_1 \leftarrow u_1 + (F - F^{\text{new}})u_2$$

Note that the difference between F and F^{new} is only n^a row-blocks, thus it takes n^{1+a} time to update.

Finally we analyze the update time of $\overline{x}$. Let $\widehat{S}$ denote the blocks where $\widetilde{V}$ and $\widetilde{V}^{\text{new}}$ are different.

$$\overline{x}_{\widehat{S}} \leftarrow (u_1)_{\widehat{S}} + (Fu_2)_{\widehat{S}}$$

This also can be done in n^{1+a} time, since $\widehat{S}$ indicates only n^a blocks.

Therefore, the overall running time is $O(n^{1+a})$.

□

Lemma 3.6.5 (Full Update time)**.** *The full update time of data-structure* CentralPathMaintenance *(Algorithm 3.3) is* $O(rg_r n^{2+o(1)})$ *where* r *is the number of indices we updated in* V*.*

Proof. The update equation we use for Q is

$$Q^{\text{new}} \leftarrow Q + R \cdot (\Gamma \cdot M^{\text{new}}) + R \cdot \sqrt{V} \cdot (M^{\text{new}} - M).$$

It can be re-written as

$$Q^{\text{new}} \leftarrow Q + R \cdot (\Gamma \cdot M^{\text{new}}) + R \cdot \sqrt{V} \cdot (-M_{*,S} \cdot (\Delta_{S,S}^{-1} + M_{S,S})^{-1} \cdot (M_{*,S})^\top)$$

The running time of computing second term is multiplying a $n \times r$ matrix with another $r \times n$ matrix. The running time of computing third term is also dominated by multiplying a $n \times r$ matrix with another $r \times n$ matrix.

Thus running time of processing Q update is the same as the processing M update.

For the running time of other parts, it is dominated by the time of updating M and Q.

Therefore, the rest of the proof is almost the same as Lemma 5.4 in [CLS19], we omitted here. □

Lemma 3.6.6 (Query time)**.** *The query time of data-structure* CentralPathMaintenance *(Algorithm 3.1) is $O(n)$ time.*

Proof. This takes only $O(n)$ time, since we stored $\overline{x}$ and $\overline{s}$. □

Lemma 3.6.7 (Move time)**.** *The move time of data-structure* CentralPathMaintenance *(Algorithm 3.4) is $O(n^{\omega+o(1)})$ time in the worst case, and is $O(n^{\omega-1/2+o(1)})$ amortized cost per iteration.*

Proof. In one case, it takes only $O(n)$ time. For the other case, the running time is dominated by INITIALIZE, which takes $n^{\omega+o(1)}$ by Lemma 3.6.5.

□

Lemma 3.6.8 (Multiply time)**.** *The multiply time of data-structure* CENTRALPATHMAINTENANCE *(Algorithm 3.4) is* $O(nb + n^{1+a+o(1)})$ *for dense vector* $\|h\|_0 = n$*, and is* $O(nb + n^{a\omega+o(1)} + n^a\|h\|_0)$ *for sparse vector* h*.*

Proof. We first analyze the running time of computing vector δ_m, the equation is

$$\delta_m \leftarrow \left(((\widetilde{\Delta}_{\widetilde{S},\widetilde{S}})^{-1} + M_{\widetilde{S},\widetilde{S}})^{-1} \cdot (M_{\widetilde{S},*})^\top \sqrt{\widetilde{V}} h\right)$$

where $\widetilde{\Delta} = \widetilde{V} - V$. Let $\widetilde{r} = \sum_{i \in \widetilde{S}} n_i = O(r)$ where r is the number of blocks are different in $\widetilde{V}$ and V.

It contains several parts:

1. Computing $\widetilde{M}_{\widetilde{S}}^\top \cdot (\sqrt{\widetilde{V}} h) \in \mathbb{R}^{\widetilde{r}}$ takes $O(\widetilde{r})\|h\|_0$.

2. Computing $(\widetilde{\Delta}^{-1}_{\widetilde{S},\widetilde{S}} + M_{\widetilde{S},\widetilde{S}})^{-1} \in \mathbb{R}^{O(\widetilde{r}) \times O(\widetilde{r})}$ that is the inverse of a $O(\widetilde{r}) \times O(\widetilde{r})$ matrix takes $O(\widetilde{r}^{\omega+o(1)})$ time.

3. Computing matrix-vector multiplication between $O(\widetilde{r}) \times O(\widetilde{r})$ matrix $((\widetilde{\Delta}_{\widetilde{S},\widetilde{S}} + M_{\widetilde{S},\widetilde{S}})^{-1})$ and $O(\widetilde{r}) \times 1$ vector $((\widetilde{M}_{\widetilde{S},*})^\top \sqrt{\widetilde{V}} h)$ takes $O(\widetilde{r}^2)$ time.

Thus, the running time of computing δ_m is

$$O(\widetilde{r}\|h\|_0 + \widetilde{r}^{\omega+o(1)} + \widetilde{r}^2) = O(\widetilde{r}\|h\|_0 + \widetilde{r}^{\omega+o(1)}).$$

Next, we want to analyze the update equation of $\widetilde{\delta}_x$

$$\widetilde{\delta}_x \leftarrow \widetilde{V} h - \left((R_l^\top \cdot ((Q_l + R_l \sqrt{\widetilde{\Delta}} M) \cdot \sqrt{\widetilde{V}} \cdot h)) - (R_l^\top \cdot ((Q_{l,\widetilde{S}} + R_l \widetilde{\Gamma} M_{\widetilde{S}}) \cdot \delta_m))\right)$$

where $\widetilde{\Gamma} = \sqrt{\widetilde{V}} - \sqrt{V}$ has $O(r)$ non-zero blocks.

It is clear that the running time is dominated by the second term in the equation. We only focus on that term.

1. Computing $R_l^\top Q_l \sqrt{\widetilde{V}} h$ takes $O(bn)$ time, because $Q_l, R_l \in \mathbb{R}^{b \times n}$.

2. Computing $R_l^\top R_l \sqrt{\widetilde{\Delta}} M \sqrt{\widetilde{V}} h$ takes $O(bn + b\widetilde{r} + \widetilde{r}\|h\|_0)$ time. The reason is, computing $\sqrt{\widetilde{\Delta}} M \sqrt{\widetilde{V}} h$ takes $\widetilde{r}\|h\|_0$ time, computing $R_l \cdot (\sqrt{\widetilde{\Delta}} M \sqrt{\widetilde{V}} h)$ takes $b\widetilde{r}$, then finally computing $R_l^\top \cdot (R_l \sqrt{\widetilde{\Delta}} M \sqrt{\widetilde{V}} h)$ takes nb.

Last, the update equation of u_1, u_2, u_3, u_4 only takes the $O(n)$ time.

Finally, we note that $r \leq O(n^a)$ due to the guarantee of FullUpdate and PartialUpdate.

Thus, overall the running time of the Multiply is

$$\begin{aligned} O(\widetilde{r}\|h\|_0 + \widetilde{r}^{\omega+o(1)} + \widetilde{r}^2 + b\widetilde{r} + nb) &= O(\widetilde{r}\|h\|_0 + \widetilde{r}^{\omega+o(1)} + nb) \\ &= O(r\|h\|_0 + r^{\omega+o(1)} + nb) \\ &= O(n^a\|h\|_0 + n^{a\omega+o(1)} + nb) \end{aligned}$$

where the first step follows from $b\widetilde{r} \leq nb$ and $\widetilde{r}^2 \leq \widetilde{r}^{\omega+o(1)}$, and the second step follows from $\widetilde{r} = O(r)$, and the last step follows from $r = O(n^a)$.

If h is the dense vector, then the overall time is

$$O(nb + n^{1+a} + n^{a\omega+o(1)}).$$

Based on Lemma 5.5 in [CLS19], we know that $a\omega \leq 1 + a$. Thus, it becomes $O(nb + n^{1+a+o(1)})$ time.

If h is a sparse vector, then the overall time is

$$O(nb + n^a \|h\|_0 + n^{a\omega+o(1)}).$$

□

Lemma 3.6.9 (MultiplyMove)**.** *The running time of* MultiplyMove *(Algorithm 3.6.9) is the* Multiply *time plus* Move *time.*

3.6.3 Bounding W move

The goal of this section is to analyze the movement of W. [CLS19] provided a scalar version of W move, here we provide a matrix version.

Lemma 3.6.10 (W move, matrix version of Lemma 5.7 in [CLS19])**.**

$$\sum_{i=1}^{m} g_i \cdot \mathbb{E}\left[\psi(y_{\pi(i)}^{(k)}) - \psi(x_{\pi(i)}^{(k)})\right] = O(C_1 + C_2/\epsilon_{mp}) \cdot \sqrt{\log n} \cdot (n^{-a/2} + n^{\omega-5/2}).$$

Proof. In scalar version, [CLS19] used absolute ($|\cdot|$) to measure each $x_i^{(k)}$. In matrix version, we use Frobenius norm ($\|\|_F$) to measure each $x_i^{(k)}$. Let $I \subseteq [m]$ be the set of indices such that $\|x_i^{(k)}\|_F \leq 1$. We separate the term into two :

$$\sum_{i=1}^{m} g_i \cdot \mathbb{E}[\psi(y_{\pi(i)}^{(k)}) - \psi(x_{\pi(i)}^{(k)})] = \sum_{i \in I} g_{\pi^{-1}(i)} \cdot \mathbb{E}[\psi(y_i^{(k)}) - \psi(x_i^{(k)})] + \sum_{i \in I^c} g_{\pi^{-1}(i)} \cdot \mathbb{E}[\psi(y_i^{(k)}) - \psi(x_i^{(k)})].$$

Case 1. Let us consider the terms from I.

Let $\mathrm{vec}(y_i^{(k)})$ denote the vectorization of matrix $y_i^{(k)}$. Similarly, $\mathrm{vec}(x_i^{(k)})$ denotes the vectorization of $x_i^{(k)}$. Mean value theorem shows that

$$\begin{aligned}
\psi(y_i^{(k)}) - \psi(x_i^{(k)}) &= \langle \psi'(x_i^{(k)}), y_i^{(k)} - x_i^{(k)} \rangle + \frac{1}{2} \mathrm{vec}(y_i^{(k)} - x_i^{(k)})^\top \psi''(\zeta) \mathrm{vec}(y_i^{(k)} - x_i^{(k)}) \\
&\leq \langle \psi'(x_i^{(k)}), y_i^{(k)} - x_i^{(k)} \rangle + \frac{L_2}{2} \|y_i^{(k)} - x_i^{(k)}\|_F^2 \\
&= \langle \psi'(x_i^{(k)}), (v_i^{(k)})^{-1/2} (w_i^{(k+1)} - w_i^{(k)}) (v_i^{(k)})^{-1/2} \rangle \\
&\quad + \frac{L_2}{2} \|(v_i^{(k)})^{-1/2} (w_i^{(k+1)} - w_i^{(k)}) (v_i^{(k)})^{-1/2}\|_F^2
\end{aligned}$$

where the second step follows from definition of L_2 (see Part 4 of Lemma 3.6.14).

Taking conditional expectation given $w^{(k)}$ on both sides

$$\begin{aligned}
\mathbb{E}[\psi(y_i^{(k)}) - \psi(x_i^{(k)})] &\leq \langle \psi'(x_i^{(k)}), (v_i^{(k)})^{-1/2}(\mathbb{E}[w_i^{(k+1)}] - w_i^{(k)})(v_i^{(k)})^{-1/2}\rangle \\
&\quad + \frac{L_2}{2}\,\mathbb{E}[\|(v_i^{(k)})^{-1/2}(w_i^{(k+1)} - w_i^{(k)})(v_i^{(k)})^{-1/2}\|_F^2] \\
&\leq L_1\|(v_i^{(k)})^{-1/2}(\mathbb{E}[w_i^{(k+1)}] - w_i^{(k)})(v_i^{(k)})^{-1/2}\|_F \\
&\quad + \frac{L_2}{2}\,\mathbb{E}[\|(v_i^{(k)})^{-1/2}(w_i^{(k+1)} - w_i^{(k)})(v_i^{(k)})^{-1/2}\|_F^2] \\
&\leq L_1\|(v_i^{(k)})^{-1/2}(w_i^{(k)})^{1/2}\|^2 \cdot \|(w_i^{(k)})^{-1/2}(\mathbb{E}[w_i^{(k+1)}] - w_i^{(k)})(w_i^{(k)})^{-1/2}\|_F \\
&\quad + \frac{L_2}{2}\|(v_i^{(k)})^{-1/2}(w_i^{(k)})^{1/2}\|^4 \cdot \mathbb{E}[\|(w_i^{(k)})^{-1/2}(w_i^{(k+1)} - w_i^{(k)})(w_i^{(k)})^{-1/2}\|_F^2] \\
&= L_1\|(v_i^{(k)})^{-1/2}(w_i^{(k)})^{1/2}\|^2 \cdot \beta_i + \frac{L_2}{2}\|(v_i^{(k)})^{-1/2}(w_i^{(k)})^{1/2}\|^4 \cdot \gamma_i \qquad (3.27)
\end{aligned}$$

where the second step follows from definition of L_2 (see Part 4 of Lemma 3.6.14), the third step follows from $\|AB\|_F \leq \|A\|_F \cdot \|B\|$, and the last step follows from defining β_i and γ_i as follows:

$$\begin{aligned}
\beta_i &= \left\|(w_i^{(k)})^{-1/2}(\mathbb{E}[w_i^{(k+1)}] - w_i^{(k)})(w_i^{(k)})^{-1/2}\right\|_F \\
\gamma_i &= \mathbb{E}\left[\left\|(w_i^{(k)})^{-1/2}(w_i^{(k+1)} - w_i^{(k)})(w_i^{(k)})^{-1/2}\right\|_F^2\right].
\end{aligned}$$

To upper bound $\sum_{i\in I} g_{\pi^{-1}(i)}\,\mathbb{E}[\psi(y_i^{(k)}) - \psi(x_i^{(k)})]$, we need to bound the following two terms,

$$\sum_{i\in I} g_{\pi^{-1}(i)} L_1 \left\|(v_i^{(k)})^{-1/2}(w_i^{(k)})^{1/2}\right\|^2 \beta_i, \text{ and } \sum_{i\in I} g_{\pi^{-1}(i)} \frac{L_2}{2} \left\|(v_i^{(k)})^{-1/2}(w_i^{(k)})^{1/2}\right\|^4 \gamma_i. \qquad (3.28)$$

For the first term (which is related to β) in Eq. (3.28), we have

$$\begin{aligned}\sum_{i\in I} g_{\pi^{-1}(i)} L_1 \|(v_i^{(k)})^{-1/2}(w_i^{(k)})^{1/2}\|^2 \beta_i &\leq \left(\sum_{i\in I}\left(g_{\pi^{-1}(i)} L_1 \|(v_i^{(k)})^{-1/2}(w_i^{(k)})^{1/2}\|^2\right)^2 \sum_{i\in I}\beta_i^2\right)^{1/2} \\ &\leq O(L_1)\left(\sum_{i=1}^n g_i^2 \cdot C_1^2\right)^{1/2} \\ &= O(C_1 L_1 \|g\|_2). \end{aligned} \tag{3.29}$$

where the first step follows from Cauchy-Schwarz inequality, the second step follows from $n_i = O(1)$ and $\|(v_i^{(k)})^{-1/2}(w_i^{(k)})^{1/2}\|^2 = O(1)$.

For the second term (which is related to γ) in Eq. (3.28), we have

$$\sum_{i\in I} g_{\pi^{-1}(i)} \frac{L_2}{2} \|(v_i^{(k)})^{-1/2}(w_i^{(k)})^{1/2}\|^4 n_i \gamma_i \leq O(L_2) \cdot \sum_{i=1}^m g_i \cdot \gamma_i = O(C_2 L_2 \|g\|_2). \tag{3.30}$$

Putting Eq. (3.27), Eq. (3.29) and Eq. (3.30) together, and using several facts $L_1 = O(1)$, $L_2 = O(1/\epsilon_{mp})$ (from part 4 of Lemma 3.6.14) and $\|g\|_2 \leq \sqrt{\log n} \cdot O(n^{-a/2} + n^{\omega-5/2})$ (from Lemma 3.6.11) gives us

$$\sum_{i\in I} g_{\pi^{-1}(i)} \cdot \mathbb{E}[\psi(y_i^k) - \psi(x_i^{(k)})] \leq O(C_1 + C_2/\epsilon_{mp}) \cdot \sqrt{\log n} \cdot (n^{-a/2} + n^{\omega-5/2}).$$

(Note that, the above Equation is the same as [CLS19].)

Case 2. Let us consider the terms from I^c.

For each $i \in I^c$, we know $\|x_i^{(k)}\|_F \geq 1$. We observe that $\psi(x)$ is constant for $\|x\|_F^2 \geq (2\epsilon_{mp})^2$, where $\epsilon_{mp} \leq 1/4$. If $\|y_i^{(k)}\|_F \geq 1/2$, then $\psi(y_i^{(k)}) - \psi(x_i^{(k)}) = 0$. Therefore, we only need to focus on the $i \in I^c$ such that $\|y_i^{(k)}\|_F < 1/2$.

For each $i \in I^c$ with $\|y_i^{(k)}\|_F < 1/2$, we have

$$\begin{aligned}
\frac{1}{2} &< \|y_i^{(k)} - x_i^{(k)}\|_F \\
&= \|(v_i^{(k)})^{-1/2}(w_i^{(k+1)} - w_i^{(k)})(v_i^{(k)})^{-1/2}\|_F \\
&= \|(v_i^{(k)})^{-1/2}(w_i^{(k)})^{1/2} \cdot (w_i^{(k)})^{-1/2}(w_i^{(k+1)} - w_i^{(k)})(w_i^{(k)})^{-1/2} \cdot (w_i^{(k)})^{1/2}(v_i^{(k)})^{-1/2}\|_F \\
&\leq \|(v_i^{(k)})^{-1/2}(w_i^{(k)})^{1/2}\| \cdot \|(w_i^{(k)})^{-1/2}(w_i^{(k+1)} - w_i^{(k)})(w_i^{(k)})^{-1/2}\|_F \cdot \|(w_i^{(k)})^{1/2}(v_i^{(k)})^{-1/2}\| \\
&= \|(v_i^{(k)})^{-1/2}w_i^{(k)}(v_i^{(k)})^{-1/2}\| \cdot \|(w_i^{(k)})^{-1/2}(w_i^{(k+1)} - w_i^{(k)})(w_i^{(k)})^{-1/2}\|_F \\
&\leq \frac{3}{2}\|(w_i^{(k)})^{-1/2}(w_i^{(k+1)} - w_i^{(k)})(w_i^{(k)})^{-1/2}\|_F \qquad (3.31)
\end{aligned}$$

where the last step follows from $\|y_i^{(k)}\|_F = \|\frac{w_i^{(k+1)}}{v_i^{(k)}} - I\|_F \leq 1/2$.

It is obvious that Eq. (3.31) implies

$$\|(w_i^{(k)})^{-1/2}(w_i^{(k+1)} - w_i^{(k)})(w_i^{(k)})^{-1/2}\|_F > 1/3 > 1/4.$$

But this is impossible, since we assume it is $\leq 1/4$.

Thus, we have

$$\sum_{i \in I^c} g_{\pi^{-1}(i)} \cdot \mathbb{E}[\psi(y_i^{(k)}) - \psi(x_i^{(k)})] = 0.$$

□

We state a Lemma that was proved in previous work [CLS19].

Lemma 3.6.11 (Lemma 5.8 in [CLS19])**.**

$$\left(\sum_{i=1}^{n} g_i^2\right)^{1/2} \leq \sqrt{\log n} \cdot O(n^{-a/2} + n^{\omega - 5/2})$$

3.6.4 Bounding V move

In previous work, [CLS19] only handled the movement of V in scalar version. Here, the goal of is to understand the movement of V in matrix version. We start to give some definitions about block diagonal matrices.

Definition 3.6.1. We define block diagonal matrices $X^{(k)}$, $Y^{(k)}$, $X^{(k+1)}$ and $\overline{Y}^{(k)} \otimes_{i\in[m]} \mathbb{R}^{n_i \times n_i}$ as follows

$$x_i^{(k)} = \frac{w_i^{(k)}}{v_i^{(k)}} - I, \quad y_i^{(k)} = \frac{w_i^{(k+1)}}{v_i^{(k)}} - I, \quad x_i^{(k+1)} = \frac{w_i^{(k+1)}}{v_i^{(k+1)}} - I, \quad \overline{y}_i^{(k)} = \frac{\overline{w}_i^{(k+1)}}{v_i^{(k)}} - I.$$

Let ϵ_w denote the error between W and $\overline{W}$

$$\|W_i^{-1/2}(\overline{W}_i - W_i)W_i^{-1/2}\|_F \leq \epsilon_w.$$

Lemma 3.6.12 (V move, matrix version of Lemma 5.9 in [CLS19])**.** *We have,*

$$\sum_{i=1}^{n} g_i \cdot \left(\psi(y_{\pi(i)}^{(k)}) - \psi(x_{\tau(i)}^{(k+1)})\right) \geq \Omega(\epsilon_{mp} r_k g_{r_k} / \log n).$$

Proof. To prove the Lemma, similarly as [CLS19], we will split the proof into two cases.

Before getting into the details of each case, let us first understand several simple facts which are useful in the later proof. Note that from the definition of the algorithm, we only change the block if $\|\overline{y}_i^{(k)}\|_F$ is larger than the error between w_i and $\overline{w}_i$. Hence, all the changes only decreases the norm, namely $\psi(y_i^{(k)}) \geq \psi(x_i^{(k+1)})$ for all i. So is their sorted version $\psi(y_{\pi(i)}^{(k)}) \geq \psi(x_{\tau(i)})^{(k+1)}$ for all i.

Case 1. The procedure exits the while loop when $1.5r_k \geq n$.

Let u^* denote the largest u such that $\|\overline{y}^{(k)}_{\overline{\pi}(u)}\|_F \geq \epsilon_{mp}$.

If $u^* = r_k$, we have that

$$\|\overline{y}^{(k)}_{\overline{\pi}(r_k)}\|_F \geq \epsilon_{mp} \geq \epsilon_{mp}/100.$$

If $u^* \neq r_k$, using the condition of the loop, we have that

$$\begin{aligned}\|\overline{y}^{(k)}_{\overline{\pi}(r_k)}\|_F &\geq (1 - 1/\log n)^{\log_{1.5} r_k - \log_{1.5} u^*} \cdot \|\overline{y}^{(k)}_{\overline{\pi}(u^*)}\|_F \\ &\geq (1 - 1/\log n)^{\log_{1.5} n} \cdot \epsilon_{mp} \\ &\geq \epsilon_{mp}/100.\end{aligned}$$

where the last step follows from $n \geq 4$.

Recall the definition of $x^{(k+1)}_{\tau(i)}$. We can lower bound the LHS in the Lemma statement in the following sense,

$$\begin{aligned}\sum_{i=1}^{n} g_i \cdot \left(\psi(y^{(k)}_{\pi(i)}) - \psi(x^{(k+1)}_{\tau(i)})\right) &\geq \sum_{i=n/3+1}^{2n/3} g_i \cdot \left(\psi(y^{(k)}_{\pi(i)}) - \psi(x^{(k+1)}_{\tau(i)})\right) \\ &\geq \sum_{i=n/3+1}^{2n/3} g_i \cdot (\Omega(\epsilon_{mp}) - O(\epsilon_w)) \\ &\geq \sum_{i=n/3+1}^{2n/3} g_i \cdot \Omega(\epsilon_{mp}) \\ &= \Omega(r_k g_{r_k} \epsilon_{mp}).\end{aligned}$$

where the second step follows from $\|y^{(k)}_{\pi(i)}\|_F \geq \|y^{(k)}_{\pi(r_k)}\|_F \geq (1 - O(\epsilon_w))\|\overline{y}^{(k)}_{\overline{\pi}(r_k)}\|_F \geq \epsilon_{mp}/200$ for all $i < 2n/3$.

Case 2. The procedure exits the while loop when $1.5r_k < n$ and $\|\overline{y}^{(k)}_{\overline{\pi}(1.5r_k)}\|_F < (1 - 1/\log n)\|\overline{y}^{(k)}_{\overline{\pi}(r_k)}\|_F$.

Using the same argument as Case 1, we have

$$\|\overline{y}^{(k)}_{\overline{\pi}(r_k)}\|_F \geq \epsilon_{mp}/100.$$

Using Part 3 of Lemma 3.6.14 and the following fact

$$\|\overline{y}^{(k)}_{\overline{\pi}(1.5r)}\|_F < \min\left(\epsilon_{mp}, \|\overline{y}^{(k)}_{\overline{\pi}(r)}\|_F \cdot (1 - 1/\log n)\right),$$

we can show that

$$\psi(\overline{y}^{(k)}_{\overline{\pi}(1.5r)}) - \psi(\overline{y}^{(k)}_{\overline{\pi}(r)}) = \Omega(\epsilon_{mp}/\log n). \tag{3.32}$$

Now the question is, how to relax $\psi(\overline{y}^{(k)}_{\overline{\pi}(1.5r)})$ to $\psi(y^{(k)}_{\pi(1.5r)})$ and how to relax $\psi(\overline{y}^{(k)}_{\overline{\pi}(r)})$ to $\psi(y^{(k)}_{\pi(r)})$

Note that $\|y^{(k)}_i\|_F \geq \|x^{(k+1)}_i\|_F$ for all i. Hence, we have $\psi(y^{(k)}_{\pi(i)}) \geq \psi(x^{(k+1)}_{\tau(i)})$ for all i.

Recall the definition of y, $\overline{y}$, π and $\overline{\pi}$,

$$y^{(k)}_i = \frac{w^{(k+1)}_i}{v^{(k)}_i} - I, \quad \overline{y}^{(k)}_i = \frac{\overline{w}^{(k+1)}_i}{v^{(k)}_i} - I.$$

and π and $\overline{\pi}$ denote the permutations such that $\|y^{(k)}_{\pi(i)}\|_F \geq \|y^{(k)}_{\pi(i+1)}\|_F$ and $\|\overline{y}^{(k)}_{\overline{\pi}(i)}\|_F \geq \|\overline{y}^{(k)}_{\overline{\pi}(i+1)}\|_F$.

Using Fact 3.6.13 and $\|\cdot\|_2 = \Theta(1)\|\cdot\|_F$ when the matrix has constant dimension

$$\|y^{(k)}_{\pi(i)} - \overline{y}^{(k)}_{\overline{\pi}(i)}\|_F \leq O(\epsilon_w).$$

where ϵ_w is the error between W and $\overline{W}$.

Next, $\forall i$, we have

$$\psi(y^{(k)}_{\pi(i)}) = \psi(\overline{y}^{(k)}_{\overline{\pi}(i)}) \pm O(\epsilon_w \epsilon_{mp}) \tag{3.33}$$

Next, we note that all the blocks the algorithm updated must lies in the range $i = 1, \cdots, \frac{3r_k}{2} - 1$. After the update, the error of r_k of these block becomes so small that its rank will much higher than r_k. Hence, $r_k/2$ of the unchanged blocks in the range $i = 1, \cdots, \frac{3r_k}{2}$ will move earlier in the rank. Therefore, the $r_k/2$-th element in $x^{(k+1)}$ must be larger than the $\frac{3}{2}r_k$-th element in $y^{(k)}$. In short, we have $\psi(x^{(k+1)}_{\tau(i)}) \leq \psi(y^{(k)}_{\pi(1.5r_k)})$ for all $i \geq r_k/2$.

Putting it all together, we have

$$\begin{aligned}
&\sum_{i=1}^{n} g_i \cdot \left(\psi(y^{(k)}_{\pi(i)}) - \psi(x^{(k+1)}_{\tau(i)})\right) \\
\geq &\sum_{i=r_k/2}^{r_k} g_i \cdot \left(\psi(y^{(k)}_{\pi(i)}) - \psi(x^{(k+1)}_{\tau(i)})\right) \\
\geq &\sum_{i=r_k/2}^{r_k} g_i \cdot \left(\psi(y^{(k)}_{\pi(i)}) - \psi(y^{(k+1)}_{\pi(1.5r_k)})\right) && \text{by } \psi(x^{(k+1)}_{\tau(i)}) \leq \psi(y^{(k)}_{\pi(1.5r_k)}), \forall i \geq r_k/2 \\
\geq &\sum_{i=r_k/2}^{r_k} g_i \cdot \left(\psi(\overline{y}^{(k)}_{\overline{\pi}(i)}) - \psi(\overline{y}^{(k+1)}_{\overline{\pi}(1.5r_k)}) - O(\epsilon_w \epsilon_{mp})\right) && \text{by (3.33)} \\
\geq &\sum_{i=r_k/2}^{r_k} g_i \cdot \left(\psi(\overline{y}^{(k)}_{\overline{\pi}(r_k)}) - \psi(\overline{y}^{(k+1)}_{\overline{\pi}(1.5r_k)}) - O(\epsilon_w \epsilon_{mp})\right) && \text{by } \psi(\overline{y}^{(k)}_{\overline{\pi}(i)}) \geq \psi(\overline{y}^{(k)}_{\overline{\pi}(r_k)}), \forall i \in [r_k/2, r_k] \\
\geq &\sum_{i=r_k/2}^{r_k} g_{r_k} \cdot \left(\Omega(\frac{\epsilon_{mp}}{\log n}) - O(\epsilon_w \epsilon_{mp})\right) && \text{by (3.32)} \\
\geq &\sum_{i=r_k/2}^{r_k} g_{r_k} \cdot \Omega(\frac{\epsilon_{mp}}{\log n}) && \text{by } \epsilon_w < O(1/\log n) \\
= &\, \Omega\left(\epsilon_{mp} r_k g_{r_k} / \log n\right).
\end{aligned}$$

Therefore, we complete the proof. □

Fact 3.6.13. *Given two length n positive vectors a, b. Let a be sorted such that $a_i \geq a_{i+1}$. Let π denote the permutation such that $b_{\pi(i)} \geq b_{\pi(i+1)}$. If for all $i \in [n]$, $|a_i - b_i| \leq \epsilon a_i$. Then for all $i \in [n]$, $|a_i - b_{\pi(i)}| \leq \epsilon a_i$.*

Proof. Case 1. $\pi(i) = i$. This is trivially true.

Case 2. $\pi(i) < i$. We have

$$b_{\pi(i)} \geq b_i \geq (1 - \epsilon)a_i$$

Since $\pi(i) < i$, we know that there exists a $j > i$ such that $\pi(j) < \pi(i)$. Then we have

$$b_{\pi(i)} \leq b_{\pi(j)} \leq (1 + \epsilon)a_j \leq (1 + \epsilon)a_i$$

Combining the above two inequalities, we have $(1 - \epsilon)a_i \leq b_{\pi(i)} \leq (1 + \epsilon)a_i$.

Case 3. $\pi(i) > i$. We have

$$b_{\pi(i)} \leq b_i \leq (1 + \epsilon)a_i$$

Since $\pi > i$, we know that there exists $j < i$ such that $\pi(j) > \pi(i)$. Then we have

$$b_{\pi(i)} \geq b_{\pi(j)} \geq (1 - \epsilon)a_j \geq (1 - \epsilon)a_i.$$

Combining the above two inequalities gives us $(1 - \epsilon)a_i \leq b_{\pi(i)} \leq (1 + \epsilon)a_i$.

Therefore, putting all the three cases together completes the proof.

□

3.6.5 Potential function ψ

[CLS19] used a scalar version potential function. Here, we generalize it to the matrix version.

Lemma 3.6.14 (Matrix version of Lemma 5.10 in [CLS19])**.** *Let function* ψ : square matrix $\to \mathbb{R}$ *(defined as Eq. (3.26)) satisfies the following properties :*

1. *Symmetric* $(\psi(x) = \psi(-x))$ *and* $\psi(0) = 0$
2. *If* $\|x\|_F \geq \|y\|_F$*, then* $\psi(x) \geq \psi(y)$
3. $|f'(x)| = \Omega(1/\epsilon_{mp}), \forall x \in [(0.01\epsilon_{mp})^2, \epsilon_{mp}^2]$
4. $L_1 \stackrel{\text{def}}{=} \max_x \frac{D_x\psi[H]}{\|H\|_F} = 2$ *and* $L_2 \stackrel{\text{def}}{=} \max_x \frac{D_x^2\psi[H,H]}{\|H\|_F^2} = 10/\epsilon_{mp}$
5. $\psi(x)$ *is a constant for* $\|x\|_F \geq 2\epsilon_{mp}$

Proof. Let $f : \mathbb{R}_+ \to \mathbb{R}$ be defined as

$$f(x) = \begin{cases} \frac{x^2}{2\epsilon_{mp}^3}, & x \in [0, \epsilon_{mp}^2]; \\ \epsilon_{mp} - \frac{(4\epsilon_{mp}^2 - x)^2}{18\epsilon_{mp}^3}, & x \in (\epsilon_{mp}^2, 4\epsilon_{mp}^2]; \\ \epsilon_{mp}, & x \in (4\epsilon_{mp}^2, +\infty). \end{cases}$$

We can see that

$$f(x)' = \begin{cases} \frac{x}{\epsilon_{mp}^3}, & x \in [0, \epsilon_{mp}^2]; \\ \frac{4\epsilon_{mp}^2 - x}{9\epsilon_{mp}^3}, & x \in (\epsilon_{mp}^2, 4\epsilon_{mp}^2]; \\ 0, & x \in (4\epsilon_{mp}^2, +\infty). \end{cases} \quad \text{and} \quad f(x)'' = \begin{cases} \frac{1}{\epsilon_{mp}^3}, & x \in [0, \epsilon_{mp}^2]; \\ -\frac{1}{9\epsilon_{mp}^3}, & x \in (\epsilon_{mp}^2, 4\epsilon_{mp}^2]; \\ 0, & |x| \in (4\epsilon_{mp}^2, +\infty). \end{cases}$$

It implies that $\max_x |f(x)'| \leq \frac{1}{\epsilon_{mp}}$ and $\max_x |f(x)''| \leq \frac{1}{\epsilon_{mp}^3}$. Let $\psi(x) = f(\|X\|_F^2)$.

Proof of Part 1,2 and 5. These proofs are pretty standard from definition of ψ.

Proof of Part 3. This is trivially following from definition of scalar function f.

Proof of Part 4. By chain rule, we have

$$D_x\psi[h] = 2f'(\|X\|_F^2) \cdot \mathrm{tr}[XH]$$
$$D_x^2\psi[h,h] = 2f''(\|X\|_F^2) \cdot (\mathrm{tr}[XH])^2 + 2f'(\|x\|_F^2) \cdot \mathrm{tr}[H^2]$$

where x is the vectorization of matrix X and h is the vectorization of matrix H. We can upper bound

$$|D_x\psi[h]| \leq 2|f'(\|X\|_F^2)| \cdot |\,\mathrm{tr}[XH]| \leq 2|f'(\|X\|_F^2)| \cdot \|X\|_F \cdot \|H\|_F$$

Then, we have

$$|f'(\|X\|_F^2)| \cdot \|X\|_F = \begin{cases} \|X\|_F^3/\epsilon_{mp}^3 \leq 1, & \|X\|_F \in [0, \epsilon_{mp}] \\ (4\epsilon_{mp}^2 - \|X\|_F^2)\|X\|_F/9\epsilon_{mp} \leq 2/3, & \|X\|_F \in (\epsilon_{mp}, 2\epsilon_{mp}] \\ 0, & \|X\|_F \in (2\epsilon_{mp}, +\infty) \end{cases}$$

It implies that $|D_x\psi[h]| \leq 2\|H\|_F$, $\forall x$.

By case analysis, we have

$$|f''(\|X\|_F^2)| \cdot \|X\|_F^2 \leq \begin{cases} \frac{1}{\epsilon_{mp}^3}\|X\|_F^2 \leq 4/\epsilon_{mp}, & \|X\|_F^2 \in [0, 4\epsilon_{mp}^2] \\ 0, & \|X\|_F^2 \in (4\epsilon_{mp}, +\infty) \end{cases}$$

We can also upper bound

$$\begin{aligned} |D_x^2\psi[h,h]| &\leq 2|f''(\|X\|_F^2)| \cdot (\mathrm{tr}[XH])^2 + 2|f'(\|X\|_F^2)| \cdot \mathrm{tr}[H^2] \\ &\leq 2|f''(\|X\|_F^2)| \cdot (\|X\|_F\|H\|_F)^2 + 2|f'(\|X\|_F^2)| \cdot \|H\|_F^2 \\ &\leq 2 \cdot \frac{4}{\epsilon_{mp}}\|H\|_F^2 + 2 \cdot \frac{1}{\epsilon_{mp}}\|H\|_F^2 \\ &= \frac{10}{\epsilon_{mp}}\|H\|_F^2. \end{aligned}$$

□

3.6.6 x and $\overline{x}$ are close

Lemma 3.6.15 (x and $\overline{x}$ are close in term of $\widetilde{V}^{-1}$)**.** *With probability* $1-\delta$ *over the randomness of sketching matrix* $R \in \mathbb{R}^{b\times n}$*, we have*

$$\|\overline{x}_i - x_i\|_{\widetilde{V}_i^{-1}} \leq \epsilon_x$$

$\epsilon_x = O(\alpha \log^2(n/\delta) \cdot \frac{n^{1/4}}{\sqrt{b}})$*,* b *is the size of sketching matrix.*

Proof. Recall the definition of $\widetilde{\delta}_x$ and δ_x, we have

$$\widetilde{\delta}_{x,i} - \delta_{x,i} = \widetilde{V}_i^{1/2}(I - R^\top R\widetilde{P})\widetilde{V}^{1/2}h - \widetilde{V}_i^{1/2}(I-\widetilde{P})\widetilde{V}^{1/2}h = \widetilde{V}_i^{1/2}(\widetilde{P} - R^\top R\widetilde{P})\widetilde{V}^{1/2}h$$

For iteration t, the definition should be

$$\widetilde{\delta}_{x,i}^{(t)} - \delta_{x,i}^{(t)} = (\widetilde{V}_i^{(t)})^{1/2}(\widetilde{P}^{(t)} - (R^{(t)})^\top R^{(t)}\widetilde{P}^{(t)})(\widetilde{V}^{(t)})^{1/2}h.$$

For any i, let k be the current iteration, k_i be the last when we changed the $\widetilde{V}_i$. Then, we have that

$$x_i^{(k)} - \overline{x}_i^{(k)} = \sum_{t=k_i}^{k} \widetilde{\delta}_{x,i}^{(t)} - \delta_{x,i}^{(t)}$$

because we have $x_i^{(k_i)} = \overline{x}_i^{(k_i)}$ (guaranteed by our algorithm). Since $\widetilde{V}_i^{(t)}$ did not change during iteration k_i to k for the block i. (However, the whole other parts of matrix $\widetilde{V}$ could change). We consider

$$\begin{aligned}
(x_i^{(k)} - \overline{x}_i^{(k)})^\top \cdot (\widetilde{V}_i^{(k)})^{-1} \cdot (x_i^{(k)} - \overline{x}_i^{(k)}) = & \left(\sum_{t=k_i}^{k} \widetilde{\delta}_{x,i}^{(t)} - \delta_{x,i}^{(t)}\right)^\top \cdot (\widetilde{V}_i^{(k)})^{-1} \cdot \left(\sum_{t=k_i}^{k} \widetilde{\delta}_{x,i}^{(t)} - \delta_{x,i}^{(t)}\right) \\
= & \left\| \sum_{t=k_i}^{k} \left((I - (R^{(t)})^\top R^{(t)})\widetilde{P}^{(t)} (\widetilde{V}^{(t)})^{1/2} h^{(t)} \right)_i \right\|_2^2 .
\end{aligned}$$

We consider block i and a coordinate $j \in$ block i. We define random vector $X_t \in \mathbb{R}^{n_i}$ as follows:

$$X_t = \left((I - R^{(t)\top} R^{(t)}) \widetilde{P}^{(t)} (\widetilde{V}^{(t)})^{1/2} h^{(t)}\right)_i.$$

Let $(X_t)_j$ denote the j-th coordinate of X_t, for each $j \in [n_i]$.

By Lemma 3.9.1 in Section 3.9, we have for each t,

$$\mathbb{E}[X_t] = 0, \quad \text{and} \quad \mathbb{E}[(X_t)_j^2] = \frac{1}{b} \|(\widetilde{P}^{(t)} (\widetilde{V}^{(t)})^{1/2} h^{(t)})_i\|_2^2$$

and with probability $1 - \delta$,

$$|(X_t)_j| \leq \|(\widetilde{P}^{(t)} (\widetilde{V}^{(t)})^{1/2} h^{(t)})_i\|_2 \frac{\log(n/\delta)}{\sqrt{b}} := M.$$

Now, we apply Bernstein inequality (Lemma A.1.2),

$$\Pr\left[\sum_t (X_t)_j > \tau\right] \leq \exp\left(-\frac{\tau^2/2}{\sum_t \mathbb{E}[(X_t)_j^2] + M\tau/3}\right)$$

Choosing $\tau = 10^3 \frac{\sqrt{T}}{\sqrt{b}} \log^2(n/\delta) \cdot \|(\widetilde{P}^{(t)} (\widetilde{V}^{(t)})^{1/2} h^{(t)})_i\|_2$

$$\begin{aligned}
&\Pr\left[\sum_t (X_t)_j > 10^3 \frac{\sqrt{T}}{\sqrt{b}} \log^2(n/\delta) \cdot \|(\widetilde{P}^{(t)} (\widetilde{V}^{(t)})^{1/2} h^{(t)})_i\|_2\right] \\
\leq\ &\exp\left(-\frac{10^6 \frac{T}{b} \log^4(n/\delta) \cdot \|(\widetilde{P}^{(t)} (\widetilde{V}^{(t)})^{1/2} h^{(t)})_i\|_2^2/2}{\frac{T}{b} \|(\widetilde{P}^{(t)} (\widetilde{V}^{(t)})^{1/2} h^{(t)})_i\|_2^2 + 10^3 \frac{\sqrt{T}}{b} \log^3(n/\delta) \|(\widetilde{P}^{(t)} (\widetilde{V}^{(t)})^{1/2} h^{(t)})_i\|_2^2/3}\right) \\
\leq\ &\exp(-100 \log(n/\delta))
\end{aligned}$$

Now, taking a union, we have

$$\begin{aligned}
\left\|\sum_{t=k_i}^{k} \left((I - (R^{(t)})^\top R^{(t)}) \widetilde{P}^{(t)} (\widetilde{V}^{(t)})^{1/2} h^{(t)}\right)_i\right\|_2 &= O\left(\frac{\sqrt{T}}{\sqrt{b}} \log^2(n/\delta) \left\|(\widetilde{P}^{(t)} (\widetilde{V}^{(t)})^{1/2} h^{(t)})_i\right\|_2\right) \\
&\leq O\left(\frac{\sqrt{T}}{\sqrt{b}} \log^2(n/\delta)\alpha\right)
\end{aligned}$$

where we use that $\|(\widetilde{P}^{(t)}(\widetilde{V}^{(t)})^{1/2}h^{(t)})_i\|_2 \leq \|((\widetilde{V}^{(t)})^{1/2}h^{(t)})_i\|_2 = O(\alpha)$, $n_i = O(1)$.

Finally, we use the fact that the algorithm reset $\overline{x} = x$, $\overline{s} = s$ in less than $\sqrt{n}$ iterations.

□

3.6.7 s and $\overline{s}$ are close

Lemma 3.6.16 (s and $\overline{s}$ are close)**.** *With probability $1-\delta$ over the randomness of sketching matrix $R \in \mathbb{R}^{b\times n}$, we have*

$$t^{-1}\|\overline{s}_i - s_i\|_{\widetilde{V}_i} \leq \epsilon_s,$$

$\epsilon_s = O(\alpha \log^2(n/\delta) \cdot \frac{n^{1/4}}{\sqrt{b}}$, and b is the size of sketching matrix.

Proof. Recall the definition of $\widetilde{\delta}_s$, δ_s, we have

$$\widetilde{\delta}_{s,i} - \delta_{s,i} = t\widetilde{V}_i^{-1/2}(R^\top R - I)\widetilde{P}\widetilde{V}^{1/2}h$$

The rest of the proof is identical to Lemma 3.6.15 except we use also the fact we make $\overline{s} = s$ whenever our t changed by a constant factor. We omitted the details here. □

3.6.8 Data structure is maintaining (x, s) implicitly over all the iterations

Lemma 3.6.17. *Over all the iterations, u_1+Fu_2 is always maintaining x implicitly, u_3+Gu_4 is always maintaining s implicitly.*

Proof. We only focus on the PartialUpdate. The FullUpdate is trivial, we ignore the proof.

For x.

Note that M is not changing. Let's assume that $u_1 + Fu_2 = x$, we want to show that

$$u_1^{\text{new}} + F^{\text{new}} u_2^{\text{new}} = x^{\text{new}}.$$

which is equivalent to prove

$$u_1^{\text{new}} + F^{\text{new}} u_2^{\text{new}} - (u_1 + Fu_2) = \delta_x$$

Let $\Delta u_1 = u_1^{\text{new}} - u_1$ be the change of u_1 over iteration t, then

$$\Delta u_1 = \widetilde{V}^{\text{new}} h + (F - F^{\text{new}}) u_2$$

Let $\Delta u_2 = u_2^{\text{new}} - u_2$ be the change of u_2 over iteration t, then

$$\Delta u_2 = -(\widetilde{V}^{\text{new}})^{1/2} h + \mathbf{1}_{\widetilde{S}} (\widetilde{\Delta}_{\widetilde{S},\widetilde{S}}^{-1} + M_{\widetilde{S},\widetilde{S}})^{-1} M_{\widetilde{S}}^\top (\widetilde{V}^{\text{new}})^{1/2} h.$$

By definition of δ_x at iteration t, we have

$$\delta_x = \widetilde{V}^{\text{new}} h - \left(\sqrt{\widetilde{V}^{\text{new}}} M \sqrt{\widetilde{V}^{\text{new}}} h - \sqrt{\widetilde{V}^{\text{new}}} M_{\widetilde{S}} (\widetilde{\Delta}_{\widetilde{S},\widetilde{S}}^{-1} + M_{\widetilde{S},\widetilde{S}})^{-1} (M_{\widetilde{S}})^\top \sqrt{\widetilde{V}^{\text{new}}} h \right).$$

We can compute

$$\begin{aligned}
&u_1^{\text{new}} + F^{\text{new}} u_2^{\text{new}} - (u_1 + F u_2) \\
&= \Delta u_1 + (F^{\text{new}} u_2^{\text{new}} - F u_2) \\
&= \widetilde{V}^{\text{new}} h + (F - F^{\text{new}}) u_2 + (F^{\text{new}} u_2^{\text{new}} - F u_2) \\
&= \widetilde{V}^{\text{new}} h + F^{\text{new}} (u_2^{\text{new}} - u_2) \\
&= \widetilde{V}^{\text{new}} h + F^{\text{new}} \Delta u_2 \\
&= \widetilde{V}^{\text{new}} h - F^{\text{new}} \sqrt{\widetilde{V}^{\text{new}}} h + F^{\text{new}} \mathbf{1}_{\widetilde{S}} (\widetilde{\Delta}_{\widetilde{S},\widetilde{S}}^{-1} + M_{\widetilde{S},\widetilde{S}})^{-1} (M_{\widetilde{S}})^{\top} \sqrt{\widetilde{V}^{\text{new}}} h \\
&= \delta_x
\end{aligned}$$

where we used $F^{\text{new}} = \sqrt{\widetilde{V}^{\text{new}}} M$ in the last step.

For s.

We have

$$G^{\text{new}} = \frac{1}{\sqrt{\widetilde{V}^{\text{new}}}} M, G = \frac{1}{\sqrt{\widetilde{V}}} M$$

Let $\Delta u_3 = u_3^{\text{new}} - u_3$ be the change of u_3 over iteration t, then

$$\Delta u_3 = (G - G^{\text{new}}) u_4$$

Let $\Delta u_4 = u_4^{\text{new}} - u_4$ be the change of u_4 over iteration t, then

$$\Delta u_4 = t \cdot \Delta u_2$$

By definition of δ_s in iteration t,

$$\delta_s = \left(\frac{1}{\sqrt{\widetilde{V}^{\text{new}}}} M \sqrt{\widetilde{V}^{\text{new}}}(th) - \frac{1}{\sqrt{\widetilde{V}^{\text{new}}}} M_{\widetilde{S}} (\widetilde{\Delta}^{-1}_{\widetilde{S},\widetilde{S}} + M_{\widetilde{S},\widetilde{S}})^{-1} (M_{\widetilde{S}})^\top \sqrt{\widetilde{V}^{\text{new}}}(th) \right)$$

We can compute

$$\begin{aligned}
(u_3^{\text{new}} + G^{\text{new}} u_4^{\text{new}}) - (u_3 + G u_4) &= \Delta u_3 + (G^{\text{new}} u_4^{\text{new}} - G u_4) \\
&= (G - G^{\text{new}}) u_4 + (G^{\text{new}} u_4^{\text{new}} - G u_4) \\
&= G^{\text{new}} (u_4^{\text{new}} - u_4) \\
&= G^{\text{new}} t \Delta u_2 \\
&= \delta_s
\end{aligned}$$

where the last step follows by definition of Δu_2.

□

3.7 Combining Robust Central Path with Data Structure

The goal of this section is to combine Section 3.5 and Section 3.6.

a	$\min(2/3, \alpha_m)$	α_m is the dual exponent of MM	batch size

Table 3.3: Summary of parameters. "Ntn" denotes Notation.

3.7.1 Guarantee for W matrices

Lemma 3.7.1 (Guarantee of a sequence of W)**.** *Let* $x^{\mathrm{new}} = x+\delta_x$. *Let* $W^{\mathrm{new}} = (\nabla^2\phi(x^{\mathrm{new}}))^{-1}$ *and* $W = (\nabla^2\phi(x))^{-1}$. *Then we have*

$$\sum_{i=1}^m \left\| w_i^{-1/2}(w_i^{\mathrm{new}} - w_i)w_i^{-1/2} \right\|_F^2 \leq C_1^2,$$
$$\sum_{i=1}^m \left\| w_i^{-1/2}(w_i^{\mathrm{new}} - w_i)w_i^{-1/2} \right\|_F^4 \leq C_2^2,$$
$$\left\| w_i^{-1/2}(w_i^{\mathrm{new}} - w_i)w_i^{-1/2} \right\|_F \leq \frac{1}{4}.$$

where $C_2 = \Theta(\alpha^2)$ *and* $C_1 = \Theta(\alpha)$.

Proof. For each $i \in [m]$, we have

$$\begin{aligned}
&\left\| W_i^{-1/2}(W_i^{\mathrm{new}} - W_i)W_i^{-1/2} \right\|_F^2 \\
&= n_i \left\| W_i^{-1/2}(W_i^{\mathrm{new}} - W_i)W_i^{-1/2} \right\|^2 \\
&= n_i \left\| (\nabla^2\phi(x_i))^{1/2}(\nabla^2\phi(x_i^{\mathrm{new}})^{-1} - \nabla^2\phi(x_i)^{-1})(\nabla^2\phi(x_i))^{1/2} \right\|^2 \\
&\leq \left(\frac{1}{(1 - \|x_i^{\mathrm{new}} - x_i\|_{\nabla^2\phi(x_i)})^2} - 1 \right)^2 \cdot \left\| (\nabla^2\phi(x_i))^{1/2}\nabla^2\phi(x_i)^{-1}(\nabla^2\phi(x_i))^{1/2} \right\|^2 \\
&= n_i \left(\frac{1}{(1 - \|x_i^{\mathrm{new}} - x_i\|_{\nabla^2\phi(x_i)})^2} - 1 \right)^2 \\
&\leq 100 n_i \|x_i^{\mathrm{new}} - x_i\|_{\nabla^2\phi(x_i)}^2,
\end{aligned}$$

where the second step follows by Theorem 3.2.1.

In our problem, we assume that $n_i = O(1)$. It remains to bound

$$\|x_i^{\mathrm{new}} - x_i\|_{\nabla^2\phi(x_i)}^2 = \|\delta_{x,i}\|_{\nabla^2\phi(x_i)}^2 \lesssim \|\delta_{x,i}\|_{\bar{x}_i}^2 = \alpha_i^2$$

where the last step follows from definition $\alpha_i = \|\delta_{x,i}\|_{\overline{x}_i}$.

Then, we have

$$\sum_{i=1}^{m} \|x_i^{\mathrm{new}} - x_i\|^2_{\nabla^2\phi(x_i)} \leq \sum_{i=1}^{m} O(\alpha_i^2) \leq O(\alpha^2).$$

where the last step follows by Lemma 3.5.1. □

Lemma 3.7.2 (Accuracy of $\overline{W}$)**.** *Let x and $\overline{x}$ be the vectors maintained by data-structure* StochasticProjectionMaintenance. *Let $W = (\nabla^2\phi(x))^{-1}$ and $\overline{W} = (\nabla^2\phi(\overline{x}))^{-1}$. Then we have*

$$\|w_i^{-1/2}(\overline{w}_i - w_i)w_i^{-1/2}\|_F \leq \epsilon_w,$$

where $\epsilon_w = O\Big(\alpha \log^2(nT) \cdot \frac{n^{1/4}}{\sqrt{b}}\Big)$, b is the size of sketching matrix.

Proof. By similar calculation, we have

$$\|w_i^{-1/2}(\overline{w}_i - w_i)w_i^{-1/2}\|_F = O(1) \cdot \|\overline{x}_i - x_i\|_{\nabla^2\phi(x_i)}.$$

Then, using Lemma 3.6.15 with $\delta = 1/T$

$$\|\overline{x}_i - x_i\|_{\nabla^2\phi(x_i)} \leq O\left(\alpha \log^2(nT) \cdot \frac{\sqrt{n^{1/4}}}{\sqrt{b}}\right).$$

□

3.7.2 Main result

The goal of this section is to prove our main result.

Theorem 3.7.3 (Main result, formal version of Theorem 3.1.1)**.** *Consider a convex problem*

$$\min_{Ax=b, x \in \prod_{i=1}^m K_i} c^\top x$$

where K_i are compact convex set. For each $i \in [m]$, we are given a ν_i-self concordant barrier

Algorithm 3.6 Our main algorithm (More detailed version of RobustIPM in Section 3.4)

procedure Main(A, b, c, ϕ, δ) ▷ Theorem 3.1.1, Theorem 3.7.3
  $\lambda \leftarrow 2^{16}\log(m)$, $\alpha \leftarrow 2^{-20}\lambda^{-2}$, $\kappa \leftarrow 2^{-10}\alpha$
  $\delta \leftarrow \min(\frac{1}{\lambda}, \delta)$ ▷ Choose the target accuracy
  $a \leftarrow \min(2/3, \alpha_m)$ ▷ Choose the batch size
  $b_{\text{sketch}} \leftarrow 2^{10}\sqrt{\nu}\log^6(n/\delta) \cdot \log\log(1/\delta)$ ▷ Choose the size of sketching matrix
  Modify the ERM(A, b, c, ϕ) and obtain an initial x and s
  CentralPathMaintenance mp ▷ Algorithm 3.1, Theorem 3.6.1
  mp.Initialize$(A, x, s, \alpha, a, b_{\text{sketch}})$ ▷ Algorithm 3.1, Lemma 3.6.2
  $\nu \leftarrow \sum_{i=1}^m \nu_i$ ▷ ν_i are the self-concordant parameters of ϕ_i
  $t \leftarrow 1$
  while $t > \delta^2/(4\nu)$ **do**
    $t^{\text{new}} \leftarrow (1 - \frac{\kappa}{\sqrt{\nu}})t$
    RobustCentralPath$(\text{mp}, t, \lambda, \alpha)$ ▷ Algorithm 3.5
    $t \leftarrow t^{\text{new}}$
  end while
  Return an approximate solution of the original ERM according to Section 3.8
end procedure

function ϕ_i for K_i. Also, we are given $x^{(0)} = \arg\min_x \sum_i \phi_i(x_i)$. Assume that

1. *Diameter of the set: For any $x \in \prod_{i=1}^m K_i$, we have that $\|x\|_2 \leq R$.*

2. *Lipschitz constant of the program: $\|c\|_2 \leq L$.*

Then, the algorithm Main *finds a vector x such that*

$$c^\top x \leq \min_{Ax=b, x \in \prod_{i=1}^m K_i} c^\top x + LR \cdot \delta,$$
$$\|Ax - b\|_1 \leq 3\delta \cdot \left(R \sum_{i,j} |A_{i,j}| + \|b\|_1 \right),$$
$$x \in \prod_{i=1}^m K_i.$$

in time

$$O(n^{\omega+o(1)} + n^{2.5-\alpha/2+o(1)} + n^{2+1/6+o(1)}) \cdot \widetilde{O}(\log(n/\delta)).$$

where ω is the exponent of matrix multiplication [Wil12, LG14], and α is the dual exponent of matrix multiplication [LGU18].

Proof. The number of iterations is

$$O(\sqrt{\nu}\log^2(m)\log(\nu/\delta)) = O(\sqrt{n}\log^2(n)\log(n/\delta)).$$

For each iteration, the amortized cost per iteration is

$$\begin{aligned}
&O(nb + n^{1+a} + n^{1.5}) + O(C_1/\epsilon_{mp} + C_2/\epsilon_{mp}^2) \cdot (n^{\omega-1/2+o(1)} + n^{2-a/2+o(1)}) + O(n^{\omega-1/2+o(1)}) \\
&= O(nb + n^{1+a} + n^{1.5}) + O(\alpha + \alpha^2) \cdot (n^{\omega-1/2+o(1)} + n^{2-a/2+o(1)}) + O(n^{\omega-1/2+o(1)}) \\
&= O(nb + n^{1+a} + n^{1.5}) + O(1/\log^4 n) \cdot (n^{\omega-1/2+o(1)} + n^{2-a/2+o(1)}) + O(n^{\omega-1/2+o(1)}) \\
&= O(n^{1.5+o(1)}\log^6\log(1/\delta) + n^{1+a+o(1)}) + O(n^{\omega-1/2+o(1)} + n^{2-a/2+o(1)}).
\end{aligned}$$

where the last step follows from choice of b (see Table 3.3).

Finally, we have

$$\begin{aligned}
&\text{total time} \\
&= \#\text{iterations} \cdot \text{cost per iteration} \\
&= \underbrace{O\left(\sqrt{n}\log^2 n \log(n/\delta)\right)}_{\#\text{iterations}} \cdot \underbrace{O\left(n^{1.5+o(1)}\log^6\log(1/\delta) + n^{1+a+o(1)} + n^{\omega-1/2+o(1)} + n^{2-a/2+o(1)}\right)}_{\text{cost per iteration}} \\
&= O\left(n^{1.5+a+o(1)} + n^{\omega+o(1)} + n^{2.5-a/2+o(1)}\right) \cdot \log(n/\delta) \cdot \log^6\log(1/\delta) \\
&= O\left(n^{2+1/6+o(1)} + n^{\omega+o(1)} + n^{2.5-\alpha_m/2+o(1)}\right) \cdot \log(n/\delta) \cdot \log^6\log(1/\delta)
\end{aligned}$$

where we pick $a = \min(2/3, \alpha_m)$ and α_m is the dual exponent of matrix multiplication[LGU18].

Thus, we complete the proof. □

Corollary 3.7.4 (Empirical risk minimization)**.** *Given convex function $f_i(y) : \mathbb{R} \to \mathbb{R}$. Suppose the solution $x^* \in \mathbb{R}^d$ lies in ℓ_∞-Ball$(0, R)$. Suppose f_i is L-Lipschitz in region $\{y : |y| \leq 4\sqrt{n} \cdot M \cdot R\}$. Given a matrix $A \in \mathbb{R}^{d \times n}$ with $\|A\| \leq M$ and A has no redundant constraints, and a vector $b \in \mathbb{R}^d$ with $\|b\|_2 \leq M \cdot R$. We can find $x \in \mathbb{R}^d$ s.t.*

$$\sum_{i=1}^n f_i(a_i^\top x + b_i) \leq \min_{x \in \mathbb{R}^d} \sum_{i=1}^n f_i(a_i^\top x + b_i) + \delta MR$$

in time

$$O(n^{\omega + o(1)} + n^{2.5 - \alpha/2 + o(1)} + n^{2 + 1/6 + o(1)}) \cdot \widetilde{O}(\log(n/\delta)).$$

where ω is the exponent of matrix multiplication [Wil12, LG14], and α is the dual exponent of matrix multiplication [LGU18].

Proof. It follows from applying Theorem 3.7.3 on convex program (3.1) with an extra constraint x^* lies in ℓ_∞-Ball$(0, R)$. Note that in program (3.1), $n_i = 2$. Thus $m = O(n)$. □

3.8 Initial Point and Termination Condition

We first need some result about self concordance.

Lemma 3.8.1 (Theorem 4.1.7, Lemma 4.2.4 in [Nes98]). *Let ϕ be any ν-self-concordant barrier. Then, for any $x, y \in \mathrm{dom}\phi$, we have*

$$\langle \nabla\phi(x), y - x\rangle \leq \nu,$$
$$\langle \nabla\phi(y) - \nabla\phi(x), y - x\rangle \geq \frac{\|y-x\|_x^2}{1+\|y-x\|_x}.$$

Let $x^* = \arg\min_x \phi(x)$. For any $x \in \mathbb{R}^n$ such that $\|x - x^*\|_{x^*} \leq 1$, we have that $x \in \mathrm{dom}\phi$.

$$\|x^* - y\|_{x^*} \leq \nu + 2\sqrt{\nu}.$$

Lemma 3.8.2. *Consider a convex problem $\min_{Ax=b, x\in\prod_{i=1}^m K_i} c^\top x$ where K_i are compact convex set. For each $i \in [m]$, we are given a ν_i-self concordant barrier function ϕ_i for K_i. Also, we are given $x^{(0)} = \arg\min_x \sum_i \phi_i(x_i)$. Assume that*

1. *Diameter of the set: For any $x \in \prod_{i=1}^m K_i$, we have that $\|x\|_2 \leq R$.*
2. *Lipschitz constant of the program: $\|c\|_2 \leq L$.*

For any $\delta > 0$, the modified program $\min_{\overline{A}\overline{x}=\overline{b}, \overline{x}\in\prod_{i=1}^m K_i \times \mathbb{R}_+} \overline{c}^\top \overline{x}$ with

$$\overline{A} = [A \mid b - Ax^{(0)}], \overline{b} = b, \text{ and } \overline{c} = \begin{bmatrix} \frac{\delta}{LR}\cdot c \\ 1 \end{bmatrix}$$

satisfies the following:

1. *$\overline{x} = \begin{bmatrix} x^{(0)} \\ 1 \end{bmatrix}$, $\overline{y} = 0_d$ and $\overline{s} = \begin{bmatrix} \frac{\delta}{LR}\cdot c \\ 1 \end{bmatrix}$ are feasible primal dual vectors with $\|\overline{s} + \nabla\overline{\phi}(\overline{x})\|_{\overline{x}}^* \leq \delta$ where $\overline{\phi}(\overline{x}) = \sum_{i=1}^m \phi_i(\overline{x}_i) - \log(\overline{x}_{m+1})$.*

2. *For any $\overline{x}$ such that $\overline{A}\overline{x} = \overline{b}, \overline{x} \in \prod_{i=1}^m K_i \times \mathbb{R}_+$ and $\overline{c}^\top \overline{x} \leq \min_{\overline{A}\overline{x}=\overline{b}, \overline{x} \in \prod_{i=1}^m K_i \times \mathbb{R}_+} \overline{c}^\top \overline{x} + \delta^2$, the vector $\overline{x}_{1:n}$ ($\overline{x}_{1:n}$ is the first n coordinates of $\overline{x}$) is an approximate solution to the original convex program in the following sense*

$$\begin{aligned} c^\top \overline{x}_{1:n} &\leq \min_{Ax=b, x \in \prod_{i=1}^m K_i} c^\top x + LR \cdot \delta, \\ \|A\overline{x}_{1:n} - b\|_1 &\leq 3\delta \cdot \left(R \sum_{i,j} |A_{i,j}| + \|b\|_1 \right), \\ \overline{x}_{1:n} &\in \prod_{i=1}^m K_i. \end{aligned}$$

Proof. For the first result, straightforward calculations show that $(\overline{x}, \overline{y}, \overline{s})$ are feasible.

To compute $\|\overline{s} + \nabla\overline{\phi}(\overline{x})\|^*_{\overline{x}}$, note that

$$\|\overline{s} + \nabla\overline{\phi}(\overline{x})\|^*_{\overline{x}} = \|\frac{\delta}{LR} \cdot c\|_{\nabla^2\phi(x^{(0)})^{-1}}.$$

Lemma 3.8.1 shows that $x \in \mathbb{R}^n$ such that $\|x - x^{(0)}\|_{x^{(0)}} \leq 1$, we have that $x \in \prod_{i=1}^m K_i$ because $x^{(0)} = \arg\min_x \sum_i \phi_i(x_i)$. Hence, for any v such that $v^\top \nabla^2\phi(x^{(0)})v \leq 1$, we have that $x^{(0)} \pm v \in \prod_{i=1}^m K_i$ and hence $\|x^{(0)} \pm v\|_2 \leq R$. This implies $\|v\|_2 \leq R$ for any $v^\top \nabla^2\phi(x^{(0)})v \leq 1$. Hence, $(\nabla^2\phi(x^{(0)}))^{-1} \preceq R^2 \cdot I$. Hence, we have

$$\|\overline{s} + \nabla\overline{\phi}(\overline{x})\|^*_{\overline{x}} = \|\frac{\delta}{LR} \cdot c\|_{\nabla^2\phi(x^{(0)})^{-1}} \leq \|\frac{\delta}{L} \cdot c\|_2 \leq \delta.$$

For the second result, we let

$$\mathrm{OPT} = \min_{Ax=b, x \in \prod_{i=1}^m K_i} c^\top x \quad \text{and} \quad \overline{\mathrm{OPT}} = \min_{\overline{A}\overline{x}=b, \overline{x} \in \prod_{i=1}^m K_i \times \mathbb{R}_+} \overline{c}^\top \overline{x}.$$

For any feasible x in the original problem, $\overline{x} = \begin{bmatrix} x \\ 0 \end{bmatrix}$ is a feasible in the modified problem. Therefore, we have that

$$\overline{\mathrm{OPT}} \leq \frac{\delta}{LR} \cdot c^\top x = \frac{\delta}{LR} \cdot \mathrm{OPT}.$$

Given a feasible $\overline{x}$ with additive error δ^2. Write $\overline{x} = \begin{bmatrix} \overline{x}_{1:n} \\ \tau \end{bmatrix}$ for some $\tau \geq 0$. We can compute $\bar{c}^\top \overline{x}$ which is $\frac{\delta}{LR} \cdot c^\top \overline{x}_{1:n} + \tau$. Then, we have

$$\frac{\delta}{LR} \cdot c^\top \overline{x}_{1:n} + \tau \leq \overline{\mathrm{OPT}} + \delta^2 \leq \frac{\delta}{LR} \cdot \mathrm{OPT} + \delta^2. \tag{3.34}$$

Hence, we can upper bound the OPT of the transformed program as follows:

$$c^\top \overline{x}_{1:n} = \frac{LR}{\delta} \cdot \frac{\delta}{LR} c^\top \overline{x}_{1:n} \leq \frac{LR}{\delta} \left(\frac{\delta}{LR} \cdot \mathrm{OPT} + \delta^2 \right) = \mathrm{OPT} + LR \cdot \delta,$$

where the second step follows by (3.34).

For the feasibility, we have that $\tau \leq -\frac{\delta}{LR} \cdot c^\top \overline{x}_{1:n} + \frac{\delta}{LR} \cdot \mathrm{OPT} + \delta^2 \leq \delta + \delta + \delta$ because $\mathrm{OPT} = \min_{Ax=b, x \geq 0} c^\top x \leq LR$ and that $c^\top \overline{x}_{1:n} \leq LR$. The constraint in the new polytope shows that

$$A\overline{x}_{1:n} + (b - Ax^{(0)})\tau = b.$$

Rewriting it, we have $A\overline{x}_{1:n} - b = (Ax^{(0)} - b)\tau$ and hence

$$\|A\overline{x}_{1:n} - b\|_1 \leq \|Ax^{(0)} - b\|_1 \cdot \tau.$$

□

Lemma 3.8.3. *Let $\phi_i(x_i)$ be a ν_i-self-concordant barrier. Suppose we have $\frac{s_i}{t} + \nabla \phi_i(x_i) = \mu_i$ for all $i \in [m]$, $A^\top y + s = c$ and $Ax = b$. Suppose that $\|\mu_i\|^*_{x,i} \leq 1$ for all i, we have that*

$$\langle c, x \rangle \leq \langle c, x^* \rangle + 4t\nu$$

where $x^* = \arg\min_{Ax=b, x \in \prod_{i=1}^m K_i} c^\top x$ and $\nu = \sum_{i=1}^m \nu_i$.

Proof. Let $x_\alpha = (1-\alpha)x + \alpha x^*$ for some α to be chosen. By Lemma 3.8.1, we have that $\langle \nabla\phi(x_\alpha), x^* - x_\alpha\rangle \le \nu$. Hence, we have $\frac{\nu}{1-\alpha} \ge \langle \nabla\phi(x_\alpha), x^* - x\rangle$. Hence, we have

$$\begin{aligned}
\frac{\nu\alpha}{1-\alpha} &\ge \langle \nabla\phi(x_\alpha), x_\alpha - x\rangle \\
&= \langle \nabla\phi(x_\alpha) - \nabla\phi(x), x_\alpha - x\rangle + \left\langle \mu - \frac{s}{t}, x_\alpha - x\right\rangle \\
&\ge \sum_{i=1}^m \frac{\|x_{\alpha,i} - x_i\|_{x_i}^2}{1 + \|x_{\alpha,i} - x_i\|_{x_i}} + \langle \mu, x_\alpha - x\rangle - \frac{1}{t}\left\langle c - A^\top y, x_\alpha - x\right\rangle \\
&\ge \sum_{i=1}^m \frac{\alpha^2\|x_i^* - x_i\|_{x_i}^2}{1 + \alpha\|x_i^* - x_i\|_{x_i}} - \alpha\sum_{i=1}^m \|\mu_i\|_{x_i}^*\|x_i^* - x_i\|_{x_i} - \frac{\alpha}{t}\left\langle c, x^* - x\right\rangle.
\end{aligned}$$

where we used Lemma 3.8.1 on the second first, $Ax_\alpha = Ax$ on the second inequality. Hence, we have

$$\frac{\langle c, x\rangle}{t} \le \frac{\langle c, x^*\rangle}{t} + \frac{\nu}{1-\alpha} + \sum_{i=1}^m \|\mu_i\|_{x_i}^*\|x_i^* - x_i\|_{x_i} - \sum_{i=1}^m \frac{\alpha\|x_i^* - x_i\|_{x_i}^2}{1 + \alpha\|x_i^* - x_i\|_{x_i}}.$$

Using $\|\mu_i\|_{x_i}^* \le 1$ for all i, we have

$$\frac{\langle c, x\rangle}{t} \le \frac{\langle c, x^*\rangle}{t} + \frac{\nu}{1-\alpha} + \sum_{i=1}^m \frac{\|x_i^* - x_i\|_{x_i}}{1 + \alpha\|x_i^* - x_i\|_{x_i}} \le \frac{\langle c, x^*\rangle}{t} + \frac{\nu}{1-\alpha} + \frac{m}{\alpha}.$$

Setting $\alpha = \frac{1}{2}$, we have $\langle c, x\rangle \le \langle c, x^*\rangle + 2t(\nu + m) \le \langle c, x^*\rangle + 4t\nu$ because the self-concordance ν_i is always larger than 1.

□

3.9 Basic Properties of Subsampled Hadamard Transform Matrix

This section provides some standard calculations about sketching matrices, it can be found in previous literatures [PSW17]. Usually, the reason for using subsampled randomized Hadamard/Fourier transform [LDFU13] is multiplying the matrix with k vectors only takes $kn \log n$ time. Unfortunately, in our application, the best way to optimize the running is using matrix multiplication directly (without doing any fast Fourier transform [CT65], or more fancy sparse Fourier transform [HIKP12b, HIKP12a, Pri13, IKP14, IK14, PS15, CKPS16, Kap16, Kap17, NSW19a]). In order to have an easy analysis, we still use subsampled randomized Hadamard/Fourier matrix.

3.9.1 Properties obtained by random projection

Remark 3.9.1. The Subsampled Randomized Hadamard Transform [LDFU13] can be defined as $R = SH_n\Sigma \in \mathbb{R}^{b\times}$, where Σ is an $n \times n$ diagonal matrix with i.i.d. diagonal entries $\Sigma_{i,i}$ in which $\Sigma_{i,i} = 1$ with probability $1/2$, and $\Sigma_{i,i} = -1$ with probability $1/2$. H_n refers to the Hadamard matrix of size n, which we assume is a power of 2. The $b \times n$ matrix S samples b coordinates of n dimensional vector uniformly at random. If we replace the definition of sketching matrix in Lemma 3.9.1 by Subsampled Randomized Hadamard Transform and let $\overline{R} = SH_n$, then the same proof will go through.

Lemma 3.9.1 (Expectation, variance, absolute guarantees for sketching a fixed vector)**.** *Let $h \in \mathbb{R}^n$ be a fixed vector. Let $\overline{R} \in \mathbb{R}^{b\times n}$ denote a random matrix where each entry is i.i.d. sampled from $+1/\sqrt{b}$ with probability $1/2$ and $-1/\sqrt{b}$ with probability $1/2$. Let $\Sigma \in \mathbb{R}^{n\times n}$ denote a diagonal matrix where each entry is 1 with probability $1/2$ and -1 with probability $1/2$. Let $R = \overline{R}\Sigma$, then we have*

$$\mathbb{E}[R^\top Rh] = h, \quad \mathbb{E}[(R^\top Rh)_i^2] \leq h_i^2 + \frac{1}{b}\|h\|_2^2, \quad \Pr\left[|(R^\top Rh)_i - h_i| > \|h\|_2 \frac{\log(n/\delta)}{\sqrt{b}}\right] \leq \delta.$$

Proof. Let $R_{i,j}$ denote the entry at i-th row and j-th column in matrix $R \in \mathbb{R}^{b\times n}$. Let $R_{*,i} \in \mathbb{R}^b$ denote the vector in i-th column of R.

We first show expectation,

$$\begin{aligned}
\mathbb{E}[(R^\top Rh)_i] &= \mathbb{E}[\langle R, R_{*,i}h^\top\rangle] \\
&= \mathbb{E}\left[\sum_{j=1}^{b}\sum_{l=1}^{n} R_{j,l}R_{j,i}h_l\right] \\
&= \mathbb{E}\left[\sum_{j=1}^{b} R_{j,i}^2 h_i\right] + \mathbb{E}\left[\sum_{j=1}^{b}\sum_{l\in[n]\setminus i} R_{j,l}R_{j,i}h_l\right] \\
&= h_i + 0 \\
&= h_i
\end{aligned}$$

Secondly, we prove the variance is small

$$\begin{aligned}
\mathbb{E}[(R^\top Rh_i)^2] &= \mathbb{E}[\langle R, R_{*,i}h^\top\rangle^2] \\
&= \mathbb{E}\left[\left(\sum_{j=1}^{b}\sum_{l=1}^{n} R_{j,l}R_{j,i}h_l\right)^2\right] \\
&= \mathbb{E}\left[\left(\sum_{j=1}^{b} R_{j,i}^2 h_i + \sum_{j=1}^{b}\sum_{l\in[n]\setminus i} R_{j,l}R_{j,i}h_l\right)^2\right] \\
&= \mathbb{E}\left[\left(\sum_{j=1}^{b} R_{j,i}^2 h_i\right)^2\right] + 2\,\mathbb{E}\left[\sum_{j'=1}^{b} R_{j',i}^2 h_i \sum_{j=1}^{b}\sum_{l\in[n]\setminus i} R_{j,l}R_{j,i}h_l\right] \\
&\quad + \mathbb{E}\left[\left(\sum_{j=1}^{b}\sum_{l\in[n]\setminus i} R_{j,l}R_{j,i}h_l\right)^2\right] \\
&= C_1 + C_2 + C_3,
\end{aligned}$$

where the last step follows from defining those terms to be C_1, C_2 and C_3. For the term C_1,

we have

$$C_1 = h_i^2 \, \mathbb{E}\left[\left(\sum_{j=1}^{b} R_{j,i}^2\right)^2\right] = h_i^2 \, \mathbb{E}\left[\sum_{j=1}^{b} R_{j,i}^4 + \sum_{j' \neq j} R_{j,i}^2 R_{j',i}^2\right] = h_i^2 \left(b \cdot \frac{1}{b^2} + b(b-1) \cdot \frac{1}{b^2}\right) = h_i^2$$

For the second term C_2,

$$C_2 = 0.$$

For the third term C_3,

$$\begin{aligned} C_3 = & \ \mathbb{E}\left[\left(\sum_{j=1}^{b} \sum_{l \in [n] \setminus i} R_{j,l} R_{j,i} h_l\right)^2\right] \\ = & \ \mathbb{E}\left[\sum_{j=1}^{b} \sum_{l \in [n] \setminus i} R_{j,l}^2 R_{j,i}^2 h_l^2\right] + \mathbb{E}\left[\sum_{j=1}^{b} \sum_{l \in [n] \setminus i} R_{j,l} R_{j,i} h_l \sum_{j' \in [b] \setminus j} \sum_{l' \in [n] \setminus i \setminus l} R_{j',l'} R_{j',i} h_{l'}\right] \\ = & \sum_{j=1}^{b} \sum_{l \in [n] \setminus i} \frac{1}{b} \frac{1}{b} h_l^2 + 0 \leq \frac{1}{b} \|h\|_2^2 \end{aligned}$$

Therefore, we have

$$\mathbb{E}[(R^\top R h)_i^2] \leq C_1 + C_2 + C_3 \leq h_i^2 + \frac{1}{b} \|h\|_2^2.$$

Third, we prove the worst case bound with high probability. We can write $(R^\top R h)_i -$

h_i as follows

$$\begin{aligned}
(R^\top Rh)_i - h_i &= \langle R, R_{*,i}h^\top \rangle - h_i \\
&= \sum_{j=1}^{b}\sum_{l=1}^{n} R_{j,l}\cdot R_{j,i}\cdot h_l - h_i \\
&= \sum_{j=1}^{b} R_{j,i}^2 h_i - h_i + \sum_{j=1}^{b}\sum_{l\in[n]\backslash i} R_{j,l}R_{j,i}\cdot h_l \\
&= \sum_{j=1}^{b}\sum_{l\in[n]\backslash i} R_{j,l}R_{j,i}\cdot h_l && \text{by } R_{j,i}^2 = 1/b \\
&= \sum_{l\in[n]\backslash i} h_l \langle R_{*,l}, R_{*,i}\rangle \\
&= \sum_{l\in[n]\backslash i} h_l \cdot \langle \sigma_l \overline{R}_{*,l}, \sigma_i \overline{R}_{*,i}\rangle && \text{by } R_{*,l} = \sigma_l \overline{R}_{*,l}
\end{aligned}$$

First, we apply Khintchine's inequality, we have

$$\Pr\left[\left|\sum_{l\in[n]\backslash i} h_l\cdot\sigma_l\cdot\langle\overline{R}_{*,l},\sigma_i\overline{R}_{*,i}\rangle\right| \geq Ct\left(\sum_{l\in[n]\backslash i} h_l^2(\langle\overline{R}_{*,l},\sigma_i\overline{R}_{*,i}\rangle)^2\right)^{1/2}\right] \leq \exp(-C't^2)$$

and choose $t = \sqrt{\log(n/\delta)}$.

For each $l \neq i$, using [LDFU13] we have

$$\Pr\left[|\langle\overline{R}_{*,l},\overline{R}_{*,i}\rangle| \geq \frac{\sqrt{\log(n/\delta)}}{\sqrt{b}}\right] \leq \delta/n.$$

Taking a union bound over all $l \in [n]\backslash i$, we have

$$|(R^\top Rh)_i - h_i| \leq \|h\|_2 \frac{\log(n/\delta)}{\sqrt{b}}$$

with probability $1-\delta$. □

Chapter 4

Algorithmic Theory of ODEs

Sampling logconcave functions arising in statistics and machine learning has been a subject of intensive study. Recent developments include analyses for Langevin dynamics and Hamiltonian Monte Carlo (HMC). While both approaches have dimension-independent bounds for the underlying *continuous* processes under sufficiently strong smoothness conditions, the resulting discrete algorithms have complexity and number of function evaluations growing with the dimension. Motivated by this problem, in this chapter, we give a general algorithm for solving multivariate ordinary differential equations whose solution is close to the span of a known basis of functions (e.g., polynomials or piecewise polynomials). The resulting algorithm has polylogarithmic depth and essentially tight runtime — it is nearly linear in the size of the representation of the solution.

We apply this to the sampling problem to obtain a nearly linear implementation of HMC for a broad class of smooth, strongly logconcave densities, with the number of iterations (parallel depth) and gradient evaluations being *polylogarithmic* in the dimension (rather than polynomial as in previous work). This class includes the widely-used loss function for logistic regression with incoherent weight matrices and has been subject of much study recently. We also give a faster algorithm with *polylogarithmic depth* for the more general and standard class of strongly convex functions with Lipschitz gradient. These results are based on (1)

an improved contraction bound for the exact HMC process and (2) logarithmic bounds on the degree of polynomials that approximate solutions of the differential equations arising in implementing HMC.

4.1 Introduction

The complexity of sampling a high-dimensional density of the form $e^{-f(x)}$ where f is a convex function is a fundamental problem with many applications [LS90, LS92, LS93, LV06a, LV06b, Dal17, DK17, DRD18, DCWY18]. The focus of this chapter is to give very fast, i.e., nearly linear time algorithms, for a large subclass of such densities. A motivating and important case is the loss function for logistic regression, widely used in machine learning applications [Ber44, Paa00, NJ02, HJLS13, Bou14]:

$$\sum_{i=1}^{n} \phi_i(a_i^\top x)$$

where ϕ_i are convex functions; a popular choice is $\phi(t) = \log(1 + e^{-t})$. Sampling according to e^{-f} for this choice of f corresponds to sampling models according to their KL-divergence, a natural and effective choice for classification problems [HJLS13].

A general approach to sampling is by an ergodic Markov chain whose stationary distribution is designed to have the desired density. Traditionally, this is done via a Metropolis filter, which accepts a proposed (random) next step y from the current point x with probability $\min\{1, \frac{f(y)}{f(x)}\}$. While very general, one downside of this approach is the possibility of high rejection probabilities, which typically force local steps to be very small. Nevertheless, for arbitrary logconcave functions (including nonsmooth ones), this approach has the current best guarantees [LV06b].

Another family of algorithms is derived from an underlying *continuous* stochastic process with the desired stationary density. A classic example of such a continuous process is Brownian motion. To sample a convex body for example, one could use Brownian motion

with a boundary reflection condition. This is written as the stochastic equation:

$$\mathrm{d}X_t = \mathrm{d}W_t$$

with reflection at the boundary of the domain, and dW_t being infinitesimal Brownian motion. To sample from the density proportional to $e^{-f(x)}$, one can use the stochastic differential equation,

$$\mathrm{d}X_t = -\nabla f(X_t)\mathrm{d}t + \sqrt{2}\mathrm{d}W_t.$$

By the classical Fokker-Planck equation, under mild assumptions on f, the stationary density of this process is proportional to $e^{-f(x)}$.

How can we turn these continuous processes into algorithms? One approach is to take small rather than infinitesimal steps, and this leads to the Langevin dynamics, of which there are multiple flavors [Dal17, DK17, ZLC17, RRT17, DRD18, CCBJ18, CCAY+18, CFM+18]. Starting with Dalalyan [Dal17], it has been established that these dynamics converge in polynomial (in dimension) time for strongly logconcave functions, with the underdamped version converging in $O(\sqrt{d})$ iterations (and polynomial dependences on appropriate condition numbers) [CCBJ18]. The dependence on dimension seems unavoidable in the discretized algorithm, even though the continuous process has no such dependence.

Hamiltonian Monte Carlo. HMC is a random process that maintains a position x and velocity pair v. To sample according to e^{-f}, we define a Hamiltonian $H(x, v) = f(x) + \frac{1}{2}\|v\|^2$. At each step v is chosen randomly from $N(0, I)$ and x is updated using the following Ordinary Differential Equation (ODE) for a some fixed time interval.

$$\frac{\mathrm{d}x(t)}{\mathrm{d}t} = v(t), \quad \frac{\mathrm{d}v(t)}{\mathrm{d}t} = -\nabla f(x(t)).$$

This process has the particularly nice property that it conserves the value of H, and as a result there is no need to apply a Metropolis filter. HMC has been studied in many works [MS17, MV18, LV18]. Mangoubi and Smith [MS17] gave the following guarantee for strongly logconcave densities.

Theorem 4.1.1 ([MS17])**.** *Let f be a smooth, strongly convex function s.t. for all y*

$$m_2 \cdot I \preceq \nabla^2 f(y) \preceq M_2 \cdot I.$$

Then, HMC converges to the density proportional to e^{-f} in $\widetilde{O}((M_2/m_2)^2)$ iterations with each iteration being the exact solution of an ODE.

For the resulting algorithm presented in [MS17], which needs to approximate the solution of the ODE, the number of function evaluations and overall time grow as square-root of the dimension (and a higher polynomial of the condition number). Table 4.1 summarizes related work on sampling logconcave functions with various structural assumptions. In all these cases, even with higher-order smoothness and incoherence assumptions, the number of gradient/function evaluations grows as a polynomial in d. A special case of much interest is Bayesian logistic regression. To address this [MV18] define an incoherence parameter and achieve the previously best dependence on the dimension of $d^{1/4}$ for functions with bounded incoherence. They note that this is nearly optimal for the leapfrog implementation of HMC they use. Improving the complexity further, and in particular the dependence on the dimension d is an important open problem. This brings us to our main motivating question:

For what class of functions can we avoid polynomial dependence on dimension (in an algorithm)? Can we do this for the logistic loss function?

Table 4.1: Summary of results, d is the dimension, κ is the condition number of $\nabla^2 f$. "Iters" denotes "the number of iterations / parallel depth". "Gra/Iter" denotes the "the number of gradients per iteration". We use the parallel depth of the algorithm as the number of iterations. We suppress polylogarithmic terms and dependence on the error parameter. Ball walk/hit-and-run apply to general logconcave distributions, the rest assume strongly logconcave with Lipschitz gradient and possibly more. "B./H." denotes "Ball Walk/Hit-and-run". "DL" denotes "Damped Langevin". In all previous work, for simplicity, we report the most favorable bounds by making various assumptions such as $\kappa \ll d$.

4.1.1 Results

We begin with an informal statement of our result for sampling from a class that includes the logistic loss function.

Theorem 4.1.2 (Informal version of Theorem 4.5.6)**.** *Let* $A = [a_1; a_2; \cdots; a_n] \in \mathbb{R}^{n \times d}$, $\phi_i : \mathbb{R} \to \mathbb{R}$ *with its* k*-th derivatives bounded by* $O(1)^k$ *and*

$$f(x) = \sum_{i=1}^{n} \phi_i(a_i^\top x) + \frac{m_2}{2}\|x\|^2.$$

Suppose that $\nabla^2 f$ *has condition number* κ *and* $\tau = \|AA^\top\|_{\infty\to\infty}$. *Then we can find a random point* X *whose Wasserstein distance to* Y *drawn from the density proportional to* e^{-f} *satisfies*

$$W_2(X, Y) \le \frac{\epsilon}{\sqrt{m_2}}$$

using $\widetilde{O}(\kappa^{1.5} + \frac{\tau}{m_2})$ *iterations, where each iteration takes* $\widetilde{O}(d)$ *time and* $\widetilde{O}(1)$ *evaluations of* ∇f.

Remark 4.1.1. The $\frac{1}{\sqrt{m_2}}$ term in the error is needed to make the statement invariant under scaling of f.

For the logistic loss[1] $\phi(t) = \log(1 + e^{-t})$, we have $\phi'(t) = -\frac{1}{1+e^t}$, and it has Cauchy estimate $M = 1$ with radius $r = 1$ (See Lemma 4.9.2). The above result has the following application,

Corollary 4.1.3 (Logistic loss sampling)**.** *Let* $f(x) = \sum_{i=1}^n \phi_i(a_i^\top x) + \frac{m_2}{2}\|x\|^2$ *with* $\phi(t) = \log(1 + e^{-t})$. *Let* $\tau = \|AA^\top\|_{\infty\to\infty}$ *and suppose that* $\nabla^2 f(x) \preceq M_2 \cdot I$ *for all* x. *Starting at the minimum* $x^{(0)}$ *of* f, *we can find a random point* X *whose Wasserstein distance to* Y *drawn from the density proportional to* e^{-f} *satisfies*

$$W_2(X, Y) \le \frac{\epsilon}{\sqrt{m_2}}$$

using $\widetilde{O}(\frac{\tau}{m_2} + \kappa^{1.5})$ *iterations with* $\kappa = \frac{M_2}{m_2}$. *Each iteration takes* $\widetilde{O}(d)$ *time and* $\widetilde{O}(1)$ *matrix-vector multiplications for* A *and* $A^\top$.

Remark 4.1.2. Lemma 4.6.1 shows that $\|AA^\top\|_{\infty\to\infty} = \Theta(\lambda_{\max}(AA^\top))$ for sparse enough matrix $AA^\top$. Since $\lambda_{\max}(AA^\top)$ usually has the same order as M_2, the number of iterations is dominated by the $\kappa^{1.5}$ term.

[1]The logistic function is $g(t) = \frac{1}{1+e^{-t}}$ and the logistic loss is $-\log(g(t)) = \log(1 + e^{-t})$.

The above results extend and improve previous work substantially. First, in all previous algorithms, the number of functions calls was polynomial in the dimension d, while the dependence here is polylogarithmic. Second, our incoherence assumption for logistic regression is simpler and milder. Third, due to the nature of how we implement each step, the parallel depth of the algorithm is just the number of iterations, i.e., polylogarithmic in the dimension and $\widetilde{O}(1)$ when the condition numbers are bounded. Fourth, the runtime and depth of our algorithm depends polynomially in $\log(1/\epsilon)$ while all previous (nearly) linear time algorithms depends polynomially in $1/\epsilon$.

We also give an improved bound on the complexity of sampling from e^{-f} when f is strongly convex and has a Lipschitz gradient (no further smoothness assumptions).

Theorem 4.1.4. (Strongly Convex)**.** Given a function f such that $0 \prec m_2 \cdot I \preceq \nabla^2 f(x) \preceq M_2 \cdot I$ for all $x \in \mathbb{R}^d$ and $0 < \epsilon < \sqrt{d}$. Starting $x^{(0)}$ at the minimum of f, we can find a random point X whose Wasserstein distance to Y drawn from the density proportional to e^{-f} satisfies

$$W_2(X, Y) \leq \frac{\epsilon}{\sqrt{m_2}}$$

using $O(\kappa^{1.5} \log(\frac{d}{\epsilon}))$ iterations where $\kappa = \frac{M_2}{m_2}$. Each iteration takes $O\left(\frac{\kappa^{\frac{1}{4}} d^{\frac{3}{2}}}{\epsilon} \log\left(\frac{\kappa d}{\epsilon}\right)\right)$ time and $O\left(\frac{\kappa^{\frac{1}{4}} d^{\frac{1}{2}}}{\epsilon} \log\left(\frac{\kappa d}{\epsilon}\right)\right)$ evaluations of ∇f, amortized over all iterations.

The previous best bound was $\kappa^2\sqrt{d}$ iterations [CCBJ18]. This result is one of the key surprises of this chapter. Although this problem has been studied extensively with specifically-designed algorithms and analysis, we show how to get a better result by a general ODE algorithm and a general analysis which works for any ODE. Furthermore, *our algorithm is the first to achieve polylogarithmic depth dependence on the dimension, which seemed impossible in prior work.*

The above results are based on three ingredients: (1) a new contraction rate for HMC of $\kappa^{1.5}$, improving on the previous best bound of κ^2 (2) a proof that a solution to ODE's arising from HMC applied to the above problem are approximated by (piecewise) low-degree polynomials and (3) a fast (nearly linear time and polylog parallel depth) algorithm for solving multivariate second-order ODEs.

We next present the multivariate high-order ODE guarantee. This generalizes and improves on the guarantee from [LV17]. While we state it below for the case of the piecewise polynomial basis of functions, it applies to any basis of functions. This is a general result about solving ODE efficiently, independent of the application to sampling. The only assumptions needed are that the ODE function is Lipschitz and that the solution is close to the span of small number of basis of functions. These natural assumptions suffice to get around the worst-case complexity lower bounds for solving such general ODEs [KF82, Ko83, Ko10, Kaw10, KC12].

Theorem 4.1.5 (Informal version of Theorem 4.2.4 for 1st order ODE)**.** *Let $x^*(t) \in \mathbb{R}^d$ be the solution of the ODE*

$$\frac{\mathrm{d}}{\mathrm{d}t}x(t) = F(x(t), t), x(0) = v$$

where $F : \mathbb{R}^{d+1} \to \mathbb{R}^d$, $x(t) \in \mathbb{R}^d$ and $v \in \mathbb{R}^d$. Given some L and $\epsilon > 0$ such that

1. There exists a piece-wise polynomial $q(t)$ such that $q(t)$ on $[T_{j-1}, T_j]$ is a degree D_j polynomial with

$$0 = T_0 < T_1 < \cdots < T_n = T$$

and that

$$\left\| q(t) - \frac{\mathrm{d}}{\mathrm{d}t} x^*(t) \right\| \leq \frac{\epsilon}{T}, \forall t \in [0, T]$$

2. *The algorithm knows about the intervals* $[T_{j-1}, T_j]$ *and the degree* D_j *for all* $j \in [n]$.

3. *For any* $y, z \in \mathbb{R}^d$,

$$\|F(y,t) - F(z,t)\| \leq L\|y - z\|, \forall t \in [0, T].$$

Assume $LT \leq 1/16000$. *Then, we can find a piece-wise polynomial* $x(t)$ *such that*

$$\max_{t \in [0,T]} \|x(t) - x^*(t)\| \lesssim \epsilon.$$

using $\widetilde{O}\left(\sum_{i=1}^n (1 + D_i)\right)$ *evaluations of* F *and* $\widetilde{O}\left(d \sum_{i=1}^n (1 + D_i)\right)$ *time.*

We suspect these methods will be useful in many other settings beyond the focus application of this chapter. Moreover, the result is nearly optimal. Roughly speaking, it says that the complexity of solving the ODE is nearly the same as the complexity of representing the solution. The assumption that $LT < 1$ is essential, as otherwise after longer time, the solution can blow up exponentially. Also, the assumption on the piece-wise polynomial approximation has a certain universality since this is how one implicitly represents a function using any iterative method. Finally, each iteration of the ODE algorithm, the collocation method, can be fully parallelized; as a result the parallel time complexity of the sampling algorithms in this chapter are polylogarithmic in the dimension.

4.1.2 HMC and improved contraction rate

We give an improved contraction rate for HMC, stated explicitly as Algorithm 4.1. We

Algorithm 4.1 Hamiltonian Monte Carlo Algorithm

procedure HMC($x^{(0)}, f, \epsilon, h$) ▷ Theorem 4.3.2

Suppose that f is m_2 strongly convex with M_2 Lipschitz gradient on $\mathbb{R}^d$.

Assume that the step size $h \leq \frac{m_2^{1/4}}{2M_2^{3/4}}$.

Let the number of iterations $N = \frac{1}{\theta} \cdot \log\left(\frac{4}{\epsilon^2}\left(\frac{\|\nabla f(x^{(0)})\|_2^2}{m_2} + d\right)\right)$ with $\theta = \frac{m_2 h^2}{8}$.

For $k = 1, 2, \cdots, N$ **do**

Generate a Gaussian random direction $v \sim \mathcal{N}(0, I_d)$.

Let $x(t)$ be the HMC defined by

$$\frac{\mathrm{d}^2 x}{\mathrm{d}t^2} = -\nabla f(x), \frac{\mathrm{d}x}{\mathrm{d}t}(0) = v, x(0) = x^{(k-1)}.$$

Find a point $x^{(k)}$ such that ▷ Theorem 4.2.4

$$\|x^{(k)} - x(h)\|_2 \leq \bar{\epsilon} := \frac{\theta \cdot \epsilon}{2\sqrt{m_2}}.$$

end for

return $x^{(N)}$.

end procedure

give two contraction bounds for the ideal HMC. The first bound is $(\frac{m_2}{M_2})^{1.5}$ using $T \sim \frac{m_2^{1/4}}{M_2^{3/4}}$. The second bound shows that there is a T that gives the optimal contraction bound $\frac{m_2}{M_2}$. However, as we will see this part cannot be used to bound the overall mixing time, because the time T depends on the point we use for coupling, which is unknown to the algorithm. We keep this as evidence for a possible $\frac{m_2}{M_2}$ bound. The improvement is from κ^2 in previous work to $\kappa^{1.5}$.

Lemma 4.1.6 (Contraction bound for HMC)**.** *Let $x(t)$ and $y(t)$ be the solution of HMC dynamics on e^{-f} starts at $x(0)$ and $y(0)$ with initial direction $x'(0) = y'(0) = v$ for some vector v. Suppose that f is m_2 strongly convex with M_2 Lipschitz gradient., i.e., $m_2 \cdot I \preceq \nabla^2 f(x) \preceq M_2 \cdot I$ for all x. Then, for $0 \leq t \leq \frac{m_2^{1/4}}{2M_2^{3/4}}$, we have that*

$$\|x(t) - y(t)\|_2^2 \leq \left(1 - \frac{m_2}{4}t^2\right) \|x(0) - y(0)\|_2^2.$$

Furthermore, there is $t \geq 0$ depending on $f, x(0), y(0)$, and v such that

$$\|x(t) - y(t)\|_2^2 \leq \left(1 - \frac{1}{16}\frac{m_2}{M_2}\right) \|x(0) - y(0)\|_2^2.$$

4.1.3 Techniques

In this chapter we give bounds on the Collocation Method for solving ODEs. To ensure the algorithm is applicable to the ODE's that arise in the sampling application, we need to show that the solution of the ODE is close to a low-rank basis. Given only bounds on the Hessian of a function, we do this by approximating the solution of the ODE with a piecewise degree two polynomial. For smooth functions, we can use low-degree polynomials.

The proofs of the degree bounds go via the Cauchy-Kowalevsky method, by showing bounds on all derivatives at the initial point. To do this for multivariate ODE's, we use

the method of majorants, and reduce the problem to bounding the radius of convergence of one-variable ODEs.

The improved convergence guarantees for exact HMC are also based on better analysis of the underlying ODE, showing that a larger step size than previously known is possible.

For many optimization and sampling methods, there are corresponding customized versions that deal with decomposable functions by sampling terms of the functions. These algorithms usually take nearly linear time with the number of iterations being polynomial in the dimension. Often, an improvement in the general case would lead to an improvement in the decomposable case. To limit the length of this chapter, we focus only on results with polylogarithmic depth. Therefore, in Table 4.1, we do not list algorithms that involve sampling each term in decomposable functions [BFR16, DSM+16, DRW+16, BFFN17, DK17, CWZ+17, NDH+17, CFM+18]. We expect our techniques can be further improved for decomposable functions by sampling individual terms.

Outline of chapter. Then we give the main ODE algorithm and guarantees in Section 4.2. We give the proof of the improved convergence bound for HMC in Section 4.3. We use both parts to obtain improved guarantees for sampling strongly logconcave functions with Lipschitz gradients in Section 4.4 and smooth functions, including logistic loss in Section 4.5.

Some preliminaries including standard definitions and well-known theorems about ODEs are in an appendix. Remaining proofs about ODEs are in Appendix 4.7. In Appendix 4.8, we present some useful tools for Cauchy estimates. Appendix 4.9 shows how to calculate the Cauchy estimates of some function which are extensively used in practice.

4.2 ODE Solver for any basis

In this section, we analyze the collocation method for solving ODEs [Ise09]. This method is classical in numerical analysis. The goal of this section is provide an introduction of this method and provide a non-asymptotic bounds for this method. In [LV17, LV18], we applied this method to obtain faster algorithms for sampling on polytopes. Unfortunately, the particular version of collocation method we used assume the solution can be approximated by a low-degree polynomial, which heavily restrict the set of functions we can sample.

To give an intuition for the collocation method, we first consider the following first-order ODE

$$\frac{\mathrm{d}}{\mathrm{d}t}x(t) = F(x(t), t), \quad \forall 0 \leq t \leq T,$$
$$x(0) = v.$$

where $F : \mathbb{R}^{d+1} \to \mathbb{R}$. The collocation method is partly inspired by the Picard-Lindelöf theorem, a constructive existence proof for a large class of ODE. Therefore, we will first revisit the proof of Picard-Lindelöf theorem for first-order ODE.

4.2.1 Picard-Lindelöf theorem

In general, we can rewritten the first-order ODE as an integral equation

$$x(t) = v + \int_0^t F(x(s), s)\mathrm{d}s \quad \text{for all } 0 \leq t \leq T.$$

To simplify the notation, we use $\mathcal{C}([0, T], \mathbb{R}^d)$ to denote $\mathbb{R}^d$-valued functions on $[0, T]$. We define the operator $\mathcal{T}$ from $\mathcal{C}([0, T], \mathbb{R}^d)$ to $\mathcal{C}([0, T], \mathbb{R}^d)$ by

$$\mathcal{T}(x)(t) = v + \int_0^t F(x(s), s)\mathrm{d}s \quad \text{for all } 0 \leq t \leq T. \tag{4.1}$$

Therefore, the integral equation is simply $x = \mathcal{T}(x)$.

Banach fixed point theorem shows that the integral equation $x = \mathcal{T}(x)$ has a unique solution if there is a norm, and $j \in \mathbb{N}$ such that the map $\mathcal{T}^{\circ j}$ has Lipschitz constant less than 1. Recall that $\mathcal{T}^{\circ j}$ is the composition of j many $\mathcal{T}$, i.e.,

$$\mathcal{T}^{\circ j}(x) = \underbrace{\mathcal{T}(\mathcal{T}(\cdots \mathcal{T}}_{j \text{ many } \mathcal{T}}(x)\cdots)).$$

Picard-Lindelöf theorem shows that if F is Lipschitz in x, then the map $\mathcal{T}^{\circ j}$ has Lipschitz constant less than 1 for some positive integer j.

Lemma 4.2.1. *Given any norm $\|\cdot\|$ on $\mathbb{R}^d$. Let L be the Lipschitz constant of F in x, i.e.*

$$\|F(x,s) - F(y,s)\| \le L\|x - y\| \quad \textit{for all } x, y \in \mathbb{R}^d, s \in [0,T].$$

For any $x \in \mathcal{C}([0,T], \mathbb{R}^d)$, we define the corresponding norm

$$\|x\| \stackrel{\text{def}}{=} \max_{0 \le t \le T} \|x(t)\|.$$

Then, the Lipschitz constant of $\mathcal{T}^{\circ j}$ in this norm is upper bounded by $(LT)^j/j!$.

Proof. We prove this lemma with a stronger induction statement

$$\|(\mathcal{T}^{\circ j}\, x)(h) - (\mathcal{T}^{\circ j}\, y)(h)\| \le \frac{L^j h^j}{j!}\|x - y\| \quad \text{for all } 0 \le h \le T.$$

The base case $j = 0$ is trivial. For the induction case j, we can upper bound the term

as follows

$$
\begin{aligned}
&\| \mathcal{T}^{\circ j} x(h) - \mathcal{T}^{\circ j} y(h)\| \\
&= \| \mathcal{T}\, \mathcal{T}^{\circ (j-1)} x(h) - \mathcal{T}\, \mathcal{T}^{\circ (j-1)} y(h)\| \\
&\leq \int_0^h \|F(\mathcal{T}^{\circ (j-1)} x(s), s) - F(\mathcal{T}^{\circ (j-1)} y(s), s)\| \mathrm{d}s \\
&\leq L \int_0^h \| \mathcal{T}^{\circ (j-1)} x(s) - \mathcal{T}^{\circ (j-1)} y(s)\| \mathrm{d}s && \text{by } f \text{ is } L \text{ Lipschitz} \\
&\leq L \int_0^h \frac{L^{j-1} s^{j-1}}{(j-1)!} \|x - y\| \mathrm{d}s && \text{by the induction statement} \\
&= \frac{L^j}{j!} h^j \|x - y\|.
\end{aligned}
$$

This completes the induction. □

4.2.2 Intuition of collocation method

To make the Picard-Lindelöf theorem algorithmic, we need to discuss how to represent a function in $\mathcal{C}([0, T], \mathbb{R}^d)$. One standard way is to use a polynomial $p_i(t)$ in t for each coordinate $i \in [d]$. In this section, we assume that there is a basis $\{\varphi_j\}_{j=1}^D \subset \mathcal{C}([0, T], \mathbb{R})$ such that for all $i \in [d]$, $\frac{\mathrm{d}x_i}{\mathrm{d}t}$ is approximated by some linear combination of $\varphi_j(t)$.

For example, if $\varphi_j(t) = t^{j-1}$ for $j \in [d]$, then our assumption is simply saying $\frac{\mathrm{d}x_i}{\mathrm{d}t}$ is approximated by a degree $D - 1$ polynomial. Other possible basis are piecewise-polynomial and Fourier series. By Gram-Schmidt orthogonalization, we can always pick nodes point $\{c_i\}_{j=1}^D$ such that

$$\varphi_j(c_i) = \delta_{i,j} \quad \text{for } i, j \in [D].$$

The benefit of such basis is that for any $f \in \mathrm{span}(\varphi_j)$, we have that $f(t) = \sum_{j=1}^D f(c_j)\varphi_j(t)$.

For polynomials, the resulting basis are the Lagrange polynomials

$$\varphi_j(t) = \prod_{i \in [D] \setminus \{j\}} \frac{t - c_i}{c_j - c_i} \quad \text{for } j \in [D].$$

The only assumption we make on the basis is that its integral is bounded.

Definition 4.2.1. Given a D dimensional subspace $\mathcal{V} \subset \mathcal{C}([0,T], \mathbb{R})$ and node points $\{c_j\}_{j=1}^D \subset [0,T]$. For any $\gamma_\varphi \geq 1$, we call a basis $\{\varphi_j\}_{j=1}^D \subset \mathcal{V}$ is γ_φ bounded if $\varphi_j(c_i) = \delta_{i,j}$ and we have

$$\sum_{j=1}^{D} \left| \int_0^t \varphi_j(s) \mathrm{d}s \right| \leq \gamma_\varphi T \quad \text{for } t \in [0,T].$$

Note that if the constant function $1 \in \mathcal{V}$, then we have

$$1 = \sum_{j=1}^{D} 1(c_j)\varphi_j(t) = \sum_{j=1}^{D} \varphi_j(t).$$

Hence, we have

$$T = \int_0^T 1 \mathrm{d}s \leq \sum_{j=1}^{D} \left| \int_0^T \varphi_j(s) \mathrm{d}s \right| \leq \gamma_\varphi T.$$

Therefore, $\gamma_\varphi \geq 1$ for most of the interesting basis. This is the reason why we simply put it as an assumption to shorten some formulas.

In the section 4.2.5, we prove that for the space of low degree polynomial and piecewise low degree polynomial, there is a basis on the Chebyshev nodes that is $O(1)$ bounded.

Assuming that $\frac{dx}{dt}$ can be approximated by some element in $\mathcal{V}$, we have that

$$\frac{\mathrm{d}x}{\mathrm{d}t}(t) \sim \sum_{j=1}^{D} \frac{\mathrm{d}x}{\mathrm{d}t}(c_j)\varphi_j(t) = \sum_{j=1}^{D} F(x(c_j), c_j)\varphi_j(t).$$

Integrating both sides, we have

$$x(t) \approx v + \int_0^t \sum_{j=1}^{D} F(x(c_j), c_j)\varphi_j(s)\mathrm{d}s. \tag{4.2}$$

This inspires us to consider the following operator from $\mathcal{C}([0,T], \mathbb{R}^d)$ to $\mathcal{C}([0,T], \mathbb{R}^d)$:

$$\mathcal{T}_\varphi(x)(t)_i = v_i + \int_0^t \sum_{j=1}^{D} F(x(c_j), c_j)_i\varphi_j(s)\mathrm{d}s \quad \text{for } i \in [d]. \tag{4.3}$$

Equation (4.2) can be written as $x \approx \mathcal{T}_\varphi(x)$. To find x to satisfies this, naturally, one can apply the fix point iteration and this is called the collocation method.

4.2.3 Collocation method

From the definition of (4.3), we note that $\mathcal{T}_\varphi(x)$ depends only on $x(t)$ at $t = c_j$. Therefore, we can only need to calculate $\mathcal{T}_\varphi(x)(t)$ at $t = c_j$. To simplify the notation, for any $x \in \mathcal{C}([0,T], \mathbb{R}^d)$, we define a corresponding matrix $[x] \in \mathbb{R}^{d\times D}$ by $[x]_{i,j} = x_i(c_j)$. For any $d \times D$ matrix X, we define $F(X, c)$ as an $d \times D$ matrix

$$F(X, c)_{i,j} = F(X_{*,j}, c_j)_i. \tag{4.4}$$

where $X_{*,j}$ is the j-th column of X. Finally, we define A_φ as a $D \times D$ matrix

$$(A_\varphi)_{i,j} = \int_0^{c_j} \varphi_i(s)\mathrm{d}s. \tag{4.5}$$

By inspecting the definition of (4.3), (4.4) and (4.5), we have that

$$[\mathcal{T}_\varphi(x)] = v \cdot 1_D^\top + F([x], c)A_\varphi$$

where 1_D is a column of all 1 vector of length D. Hence, we can apply the map $\mathcal{T}_\varphi$ by simply multiply $F([x], c)$ by a pre-compute $D \times D$ matrix A_φ. For the basis we considered

Algorithm 4.2 Collocation Method

procedure CollocationMethod(F, v, T, φ, c) ▷ Theorem 4.2.3

  return $x^{(N)}$
end procedure

in this chapter, each iteration takes only $\widetilde{O}(dD)$ which is nearly linear to the size of our representation of the solution.

We state our guarantee for a first-order ODE (Algorithm 4.2).

Theorem 4.2.2 (First order ODE)**.** *Let $x^*(t)$ be the solution of an d dimensional ODE*

$$x(0) = v, \frac{\mathrm{d}x(t)}{\mathrm{d}t} = F(x(t), t) \quad \textit{for all } 0 \le t \le T.$$

We are given a D dimensional subspace $\mathcal{V} \subset \mathcal{C}([0,T], \mathbb{R})$, node points $\{c_j\}_{j=1}^D \subset [0,T]$ and a γ_φ bounded basis $\{\varphi_j\}_{j=1}^D \subset \mathcal{V}$ (Definition 4.2.1). Given some L and $\epsilon > 0$ such that

1. *There exists a function $q \in \mathcal{V}$ such that*

$$\left\| q(t) - \frac{\mathrm{d}}{\mathrm{d}t}x^*(t) \right\| \le \frac{\epsilon}{T}, \forall t \in [0,T].$$

2. *For any $y, z \in \mathbb{R}^d$,*

$$\|F(y,t) - F(z,t)\| \le L\|y - z\|, \forall t \in [0,T].$$

Assume $\gamma_\varphi LT \le 1/2$. Then the algorithm CollocationMethod *(Algorithm 4.2) outputs a function $x^{(N)} \in \mathcal{V}$ such that*

$$\max_{t\in[0,T]} \|x^{(N)}(t) - x^*(t)\| \le 20\gamma_\varphi \epsilon.$$

The algorithm takes $O\left(D \log\left(\frac{T}{\epsilon} \max_{s\in[0,T]} \|F(v,s)\|\right)\right)$ evaluations of F.

Next we state the general result for a k-th order ODE. We prove this via a reduction from higher order ODE to first-order ODE. See the proof in Appendix 4.7.

Theorem 4.2.3 (k-th order ODE)**.** *Let $x^*(t) \in \mathbb{R}^d$ be the solution of the ODE*

$$\frac{\mathrm{d}^k}{\mathrm{d}t^k} x(t) = F\left(\frac{\mathrm{d}^{k-1}}{\mathrm{d}t^{k-1}} x(t), \cdots, x(t), t\right)$$
$$\frac{\mathrm{d}^i}{\mathrm{d}t^i} x(0) = v_i, \forall i \in \{k-1, \cdots, 1, 0\}.$$

where $F : \mathbb{R}^{kd+1} \to \mathbb{R}^d$, $x(t) \in \mathbb{R}^d$, and $v_0, v_1, \cdots, v_{k-1} \in \mathbb{R}^d$.

We are given a D dimensional subspace $\mathcal{V} \subset \mathcal{C}([0,T], \mathbb{R})$, node points $\{c_j\}_{j=1}^D \subset [0,T]$ and a γ_φ bounded basis $\{\varphi_j\}_{j=1}^D \subset \mathcal{V}$ (Definition 4.2.1). Given some L and $\epsilon > 0$ such that

1. *For $i \in [k]$, there exists a function $q^{(i)} \in \mathcal{V}$ such that*

$$\left\| q^{(i)}(t) - \frac{\mathrm{d}^i}{\mathrm{d}t^i} x^*(t) \right\| \le \frac{\epsilon}{T^i}, \forall t \in [0,T].$$

2. *For any $y, z \in \mathbb{R}^{kd}$,*

$$\|F(y,t) - F(z,t)\| \le \sum_{i=1}^k L_i \|y_i(t) - z_i(t)\|, \forall t \in [0,T].$$

Assume $\gamma_\varphi LT \le 1/8$ *with* $L = \sum_{i=1}^k L_i^{1/i}$. *Then, we can find functions* $\{q^{(i)}\}_{i\in\{0,1,\cdots,k-1\}} \subset \mathcal{V}$ *such that*

$$\max_{t\in[0,T]} \left\| q^{(i)}(t) - \frac{\mathrm{d}^i}{\mathrm{d}t^i} x^*(t) \right\|_p = 20(1+2k)\gamma_\varphi \frac{\epsilon}{T^i}, \forall i \in \{0,1,\cdots,k-1\}.$$

The algorithm takes $O(D\log(C/\epsilon))$ *evaluations of* F *where*

$$C = (4\gamma_\varphi T)^k \cdot \max_{s\in[0,T]} \|F(v_{k-1}, v_{k-2}, \cdots, v_0, s)\| + \sum_{i=1}^{k-1} (4\gamma_\varphi T)^i \|v_i\|.$$

Note that the statement is a bit awkward. Instead of finding a function whose derivatives are same as the derivatives of x^*, the algorithm approximates the derivatives of x^* individually. This is because we do not know if derivatives/integrals of functions in $\mathcal{V}$ remain in $\mathcal{V}$. For piece-wise polynomials, we can approximate the j-th derivative of the solution by taking $(k-j)$-th iterated integral of $q^{(k)}$, which is still a piece-wise polynomial.

In section 4.2.5, we give a basis for piece-wise polynomials (Lemma 4.2.8). Using this basis, we have the following Theorem.

Theorem 4.2.4. (k-th order ODE) Let $x^*(t) \in \mathbb{R}^d$ be the solution of the ODE

$$\frac{\mathrm{d}^k}{\mathrm{d}t^k} x(t) = F\left(\frac{\mathrm{d}^{k-1}}{\mathrm{d}t^{k-1}} x(t), \cdots, x(t), t\right)$$
$$\frac{\mathrm{d}^i}{\mathrm{d}t^i} x(0) = v_i, \forall i \in \{k-1, \cdots, 1, 0\}.$$

where $F : \mathbb{R}^{kd+1} \to \mathbb{R}^d$, $x(t) \in \mathbb{R}^d$, and $v_0, v_1, \cdots, v_{k-1} \in \mathbb{R}^d$. Given some L and $\epsilon > 0$ such that

1. There exists a piece-wise polynomial $q(t)$ such that $q(t)$ on $[T_{j-1}, T_j]$ is a degree D_j polynomial with

$$0 = T_0 < T_1 < \cdots < T_n = T$$

and that

$$\left\| q(t) - \frac{\mathrm{d}^k}{\mathrm{d}t^k} x^*(t) \right\| \leq \frac{\epsilon}{T^k}, \forall t \in [0, T]$$

2. The algorithm knows about the intervals $[T_{j-1}, T_j]$ and the degree D_j for all $j \in [n]$.

3. For any $y, z \in \mathbb{R}^{kd}$,

$$\|F(y,t) - F(z,t)\| \leq \sum_{i=1}^{k} L_i \|y_i - z_i\|, \forall t \in [0, T].$$

Assume $LT \leq 1/16000$ with $L = \sum_{i=1}^{k} L_i^{1/i}$. Then, we can find a piece-wise polynomial $x(t)$ such that

$$\max_{t \in [0,T]} \left\| \frac{\mathrm{d}^i}{\mathrm{d}t^i} x(t) - \frac{\mathrm{d}^i}{\mathrm{d}t^i} x^*(t) \right\|_p \lesssim \frac{\epsilon k}{T^i}, \forall i \in \{0, 1, \cdots, k-1\}.$$

using $O(D \log(C/\epsilon))$ evaluations of F with the size of basis $D = \sum_{i=1}^{n} (1 + D_i)$ and

$$O\left(d \min\left(\sum_{i=1}^{n} (1 + D_i)^2, D \log(CD/\epsilon) \right) \log(C/\epsilon) \right)$$

time where

$$C = O(T)^k \cdot \max_{s \in [0,T]} \|F(v_{k-1}, v_{k-2}, \cdots, v_0, s)\| + \sum_{i=1}^{k-1} O(T)^i \|v_i\|.$$

Remark 4.2.1. The two different runtime come from two different ways to the integrate of basis in Lemma 4.2.8. The first one is an navie method which is good enough for all our application. The second one follows from multipole method which gives an nearly linear time to the size of the basis with an extra log dependence on the accuracy.

In the rest of this section, we prove the first-order guarantee, Theorem 4.2.2

4.2.4 Proof of first order ODE

First, we bound the Lipschitz constant of the map $\mathcal{T}_\varphi$. Unlike the Picard-Lindelöf theorem, we are not able to get an improved bound of the Lipschitz constant of the composite of $\mathcal{T}_\varphi$. Fortunately, the Lipschitz constant of the map $\mathcal{T}_\varphi$ is good enough for all applications in this chapter.

Lemma 4.2.5. *Given any norm $\|\cdot\|$ on $\mathbb{R}^d$. Let L be the Lipschitz constant of F in x, i.e.*

$$\|F(x,s) - F(y,s)\| \le L\|x-y\| \quad \textit{for all } x,y \in \mathbb{R}^d, s \in [0,T].$$

Then, the Lipschitz constant of $\mathcal{T}_\varphi$ in this norm is upper bounded by $\gamma_\varphi LT$.

Proof. For any $0 \le t \le T$,

$$\begin{aligned}
\|\mathcal{T}_\varphi(x)(t) - \mathcal{T}_\varphi(y)(t)\| &= \left\| \int_0^t \sum_{j=1}^D F(x(c_j),c_j)\varphi_j(s)\mathrm{d}s - \int_0^t \sum_{j=1}^D F(y(c_j),c_j)\varphi_j(s)\mathrm{d}s \right\| \\
&\le \sum_{j=1}^D \left| \int_0^t \varphi_j(s)\mathrm{d}s \right| \cdot \max_{t\in[0,T]} \|F(x(t),t) - F(y(t),t)\| \\
&\le \gamma_\varphi LT \cdot \max_{s\in[0,t]} \|x(t) - y(t)\| \\
&\le \gamma_\varphi LT \|x-y\|.
\end{aligned}$$

where the third step follows by $\sum_{j=1}^D |\int_0^t \varphi_j(s)\mathrm{d}s| \le \gamma_\varphi T$ for all $0 \le t \le T$. □

For the rest of the proof, let x_φ^* denote the fixed point of $\mathcal{T}_\varphi$, i.e., $\mathcal{T}_\varphi(x_\varphi^*) = x_\varphi^*$. The Banach fixed point theorem and Lemma 4.2.5 shows that x_φ^* uniquely exists if $T \le \frac{1}{L\gamma_\varphi}$.

Let x^* denote the solution of the ODE, i.e., the fixed point of $\mathcal{T}$, with $\mathcal{T}(x^*) = x^*$. Let $x^{(0)}$ denote the initial solution given by $x^{(0)}(t) = v$ and $x^{(N)}$ denote the solution obtained by

applying operator $\mathcal{T}_\varphi$ for N times. Note that $x^{(N)}(t)$ is the output of CollocationMethod in Algorithm 4.2.

Let $q \in \mathcal{V}$ denote an approximation of $\frac{\mathrm{d}}{\mathrm{d}t}x^*$ such that

$$\left\| q(t) - \frac{\mathrm{d}}{\mathrm{d}t}x^*(t) \right\| \leq \frac{\epsilon}{T}. \forall t \in [0, T]$$

The next lemma summarizes how these objects are related and will allow us to prove the main guarantee for first-order ODEs.

Lemma 4.2.6. *Let $L^{(j)}$ be the Lipschitz constant of the map $\mathcal{T}_\varphi^{\circ j}$. Assume that $L^{(N)} \leq 1/2$. Then, we have*

$$\begin{aligned}
\|x^{(N)} - x^*\| &\leq L^{(N)}\|x^{(0)} - x^*\| + 2\|x^*_\varphi - x^*\|, && (4.6)\\
\|x^*_\varphi - x^*\| &\leq 2 \cdot \| \mathcal{T}_\varphi^{\circ N}(x^*) - x^*\|, && (4.7)\\
\|x^* - \mathcal{T}_\varphi^{\circ N}(x^*)\| &\leq \sum_{i=0}^{N-1} L^{(i)} \cdot \|x^* - \mathcal{T}_\varphi(x^*)\|, && (4.8)\\
\|x^* - \mathcal{T}_\varphi(x^*)\| &\leq 2\gamma_\varphi \cdot \epsilon. && (4.9)
\end{aligned}$$

Proof. We prove the claims in order.

For the first claim,

$$\begin{aligned}
\|x^{(N)} - x^*\| &\leq \|x^{(N)} - x^*_\varphi\| + \|x^*_\varphi - x^*\| && \text{by triangle inequality}\\
&= \| \mathcal{T}_\varphi^{\circ N}(x^{(0)}) - \mathcal{T}_\varphi^{\circ N}(x^*_\varphi)\| + \|x^*_\varphi - x^*\|\\
&\leq L^{(N)}\|x^{(0)} - x^*_\varphi\| + \|x^*_\varphi - x^*\|\\
&\leq L^{(N)}\|x^{(0)} - x^*\| + L^{(N)}\|x^* - x^*_\varphi\| + \|x^*_\varphi - x^*\|\\
&\leq L^{(N)}\|x^{(0)} - x^*\| + 2\|x^*_\varphi - x^*\|
\end{aligned}$$

where the last step follows by $L^{(N)} \leq 1$.

For the second claim,

$$\begin{aligned}
\|x_\varphi^* - x^*\| &= \| \mathcal{T}_\varphi^{\circ N}(x_\varphi^*) - x^*\| && \text{by } x_\varphi^* = \mathcal{T}_\varphi^{\circ N}(x_\varphi^*) \\
&\leq \| \mathcal{T}_\varphi^{\circ N}(x_\varphi^*) - \mathcal{T}_\varphi^{\circ N}(x^*)\| + \| \mathcal{T}_\varphi^{\circ N}(x^*) - x^*\| && \text{by triangle inequality} \\
&\leq L^{(N)} \cdot \|x_\varphi^* - x^*\| + \| \mathcal{T}_\varphi^{\circ N}(x^*) - x^*\| && \text{by the definition of } L^{(N)} \\
&\leq \frac{1}{2}\|x_\varphi^* - x^*\| + \| \mathcal{T}_\varphi^{\circ N}(x^*) - x^*\| && \text{by } L^{(N)} \leq 1/2
\end{aligned}$$

For the third claim,

$$\begin{aligned}
\|x^* - \mathcal{T}_\varphi^{\circ N}(x^*)\| &\leq \sum_{i=0}^{N-1} \| \mathcal{T}_\varphi^{\circ i}(x^*) - \mathcal{T}_\varphi^{\circ (i+1)}(x^*)\| \\
&\leq \sum_{i=0}^{N-1} L^{(i)} \cdot \|x^* - \mathcal{T}_\varphi(x^*)\|
\end{aligned}$$

For the last claim,

$$
\begin{aligned}
&\|x^*(t) - \mathcal{T}_\varphi(x^*)(t)\| \\
=& \|\mathcal{T}(x^*)(t) - \mathcal{T}_\varphi(x^*)(t)\| \\
=& \left\| \int_0^t F(x^*(s), s)\mathrm{d}s - \int_0^t \sum_{j=1}^D F(x^*(c_j), c_j)\varphi_j(s)\mathrm{d}s \right\| \\
=& \left\| \int_0^t \frac{\mathrm{d}}{\mathrm{d}t}x^*(s)\mathrm{d}s - \int_0^t \sum_{j=1}^D \frac{\mathrm{d}}{\mathrm{d}t}x^*(c_j)\varphi_j(s)\mathrm{d}s \right\| \\
\leq& \left\| \int_0^t (\frac{\mathrm{d}}{\mathrm{d}t}x^*(s) - q(s))\mathrm{d}s - \int_0^t \sum_{j=1}^D (\frac{\mathrm{d}}{\mathrm{d}t}x^*(c_j) - q(c_j))\varphi_j(s)\mathrm{d}s \right\| \\
+& \left\| \int_0^t q(s)\mathrm{d}s - \int_0^t \sum_{j=1}^D q(c_j)\varphi_j(s)\mathrm{d}s \right\| \\
\leq& \int_0^t \left\| \frac{\mathrm{d}}{\mathrm{d}t}x^*(s) - q(s) \right\| \mathrm{d}s + \sum_{j=1}^D \left\| \frac{\mathrm{d}}{\mathrm{d}t}x^*(c_j) - q(c_j) \right\| \left| \int_0^t \varphi_j(s)\mathrm{d}s \right| + 0 \\
\leq& (1 + \gamma_\varphi) \cdot \epsilon + 0
\end{aligned}
$$

where the first step follows by $\mathcal{T}(x^*) = x^*$, the second step follows by the definition of $\mathcal{T}$ and $\mathcal{T}_\varphi$, the third step follows by $x^*(t)$ is the solution of ODE, the fourth step follows by triangle inequality, the second last step follows by $q \in \mathcal{V}$, and the last step follows by $\|\frac{\mathrm{d}}{\mathrm{d}t}x^* - q\| \leq \frac{\epsilon}{T}$ and the definition of γ_φ. □

Now, we are ready to prove Theorem 4.2.2.

Proof. Using Lemma 4.2.6, we have

$$\begin{aligned}
\|x^{(N)} - x^*\| &\le L^{(N)}\|x^{(0)} - x^*\| + 2\|x^*_\varphi - x^*\| && \text{by Eq. (4.6)} \\
&\le L^{(N)}\|x^{(0)} - x^*\| + 4\|\mathfrak{T}^{\circ N}_\varphi(x^*) - x^*\| && \text{by Eq. (4.7)} \\
&\le L^{(N)}\|x^{(0)} - x^*\| + 4\sum_{i=0}^{N-1} L^{(i)} \cdot \|x^* - \mathfrak{T}_\varphi(x^*)\| && \text{by Eq. (4.8)} \\
&\le L^{(N)}\|x^{(0)} - x^*\| + 8\sum_{i=0}^{N-1} L^{(i)} \cdot \gamma_\varphi \cdot \epsilon. && \text{by Eq. (4.9)}
\end{aligned}$$

Using the assumption that $\gamma_\varphi LT \le \frac{1}{2}$, Lemma 4.2.5 shows that $L^{(1)} \le \frac{1}{2}$ and hence $L^{(j)} \le \frac{1}{2^j}$. Therefore, we have

$$\|x^{(N)} - x^*\| \le \frac{1}{2^N}\|x^{(0)} - x^*\| + 16\gamma_\varphi \cdot \epsilon = \frac{1}{2^N}\|x^* - x^*(0)\| + 16\gamma_\varphi \cdot \epsilon \tag{4.10}$$

To bound $\|x^* - x^*(0)\|$, for any $0 \le t \le T$

$$x^*(t) = x^*(0) + \int_0^t F(x^*(s), s)\mathrm{d}s.$$

Hence, we have that

$$\begin{aligned}
\|x^*(t) - x^*(0)\| &\le \left\|\int_0^T F(x^*(0), s)\mathrm{d}s\right\| + \left\|\int_0^t \left(F(x^*(s), s) - F(x^*(0), s)\right)\mathrm{d}s\right\| \\
&\le \left\|\int_0^T F(x^*(0), s)\mathrm{d}s\right\| + L\int_0^t \|x^*(s) - x^*(0)\|\mathrm{d}s.
\end{aligned}$$

Solving this integral inequality (see Lemma 4.6.3), we have that

$$\|x^*(t) - x^*(0)\| \le e^{Lt}\left\|\int_0^T F(x^*(0), s)\mathrm{d}s\right\|.$$

Now, we use $LT \le \frac{1}{2}$ and get

$$\|x^*(t) - x^*(0)\| \le 2\left\|\int_0^T F(x^*(0), s)\mathrm{d}s\right\|.$$

Picking $N = \left\lceil \log_2 \left(\frac{T}{\epsilon} \max_{s\in[0,T]} \|F(x^*(0), s)\| \right) \right\rceil$, (4.10) shows that the error is less than $20\gamma_\varphi \epsilon$.

□

4.2.5 A basis for piece-wise polynomials

In this section, we discuss how to construct a bounded basis for low-degree piece-wise polynomials. We are given n intervals $\{[I_{i-1}, I_i]\}_{i=1}^n$ where $I_0 = 0$ and $I_n = T$. In the i^{th} interval $[I_{i-1}, I_i]$, we represent the function by a degree D_i polynomial. Formally, we define the function subspace by

$$\mathcal{V} \stackrel{\text{def}}{=} \bigoplus_{i=1}^n \mathcal{V}_i \quad \text{with} \quad \mathcal{V}_i \stackrel{\text{def}}{=} \left\{ \left(\sum_{j=0}^{D_i} \alpha_j t^j \right) \cdot 1_{[I_{i-1}, I_i]} : \alpha_j \in \mathbb{R} \right\}. \tag{4.11}$$

The following Lemma shows we can construct the basis for $\mathcal{V}$ by concatenating the basis for $\mathcal{V}_i$.

Lemma 4.2.7. *For $i \in [n]$, we are given a γ_i bounded basis $\{\varphi_{j,i}\}_{j=0}^{D_i}$ for the subspace $\mathcal{V}_i \subset \mathcal{C}([I_{i-1}, I_i], \mathbb{R})$ on nodes point $\{c_{j,i}\}_{j=0}^{D_i}$. Then, $\{\varphi_{j,i}\}_{i,j}$ is a $\sum_{i=1}^n \gamma_i (I_i - I_{i-1})$ bounded basis for the subspace $\bigoplus_{i=1}^n \mathcal{V}_i \subset \mathcal{C}([I_0, I_n], \mathbb{R})$.*

Proof. For any $t \geq 0$, we have

$$\begin{aligned} \sum_{i=1}^n \sum_{j=0}^{D_i} \left| \int_{I_0}^t \varphi_{i,j}(s) \mathrm{d}s \right| &\leq \sum_{i=1}^n \left(\sum_{j=0}^{D_i} \left| \int_{I_{i-1}}^t \varphi_{i,j}(s) \mathrm{d}s \right| 1_{t \geq I_{i-1}} \right) \\ &\leq \sum_{i=1}^n \gamma_i (I_i - I_{i-1}) \end{aligned}$$

where we used that $\varphi_{i,j}$ is supported on $[I_{i-1}, I_i]$ in the first inequality. □

Next, we note that the boundedness for basis is shift and scale invariant. Hence, we will focus on obtaining a basis for $(t-1)$-degree polynomial on $[-1,1]$ for notation convenience.

For $[-1,1]$, we choose the node points $c_j = \cos(\frac{2j-1}{2t}\pi)$ and the basis are

$$\varphi_j(x) = \frac{\sqrt{1-c_j^2}\cos(t\cos^{-1}x)}{t(x-c_j)}.$$

It is easy to see that $\varphi_j(c_i) = \delta_{i,j}$. To bound the integral, Lemma 91 in [LV17] shows that

$$\left|\int_{-1}^{y}\varphi_j(x)dx\right| \le \frac{2000}{t} \text{ for all } y \in [-1,1].$$

Summing it over t basis functions, we have that $\gamma_\varphi \le 2000$. Together with Lemma 4.2.7, we have the following result:

Lemma 4.2.8. *Let $\mathcal{V}$ be a subspace of piecewise polynomials on $[0,T]$ with fixed nodes. Then, there is a 2000 bounded basis $\{\varphi\}$ for $\mathcal{V}$. Furthermore, for any vector v, it takes $O(\sum_{i=1}^{n}(1+D_i)^2)$ time to compute $v^\top A_\varphi$ where D_i is the maximum degree of the i-th piece.*

Alternatively, one can find u such that $\|u - v^\top A_\varphi\| \le \epsilon T\|v\|_\infty$ in time

$$O\left(\operatorname{rank}(\mathcal{V})\log(\frac{\operatorname{rank}(\mathcal{V})}{\epsilon})\right).$$

Proof. The bound follows from previous discussion. For the computation cost, note that

$$(v^\top A_\varphi)_{(i,j)} = \sum_{i',j'}\int_0^{c_{(i,j)}} v_{(i',j')}\varphi_{(i',j')}(s)\mathrm{d}s.$$

where (i,j) is the j-th node at the i-th piece. For any $i \neq i'$, the support of $\varphi_{(i',j')}(s)$ is either disjoint from $[0,c_{(i,j)}]$ (if $i' > i$) or included in $[0,c_{(i,j)}]$ (if $i' < i$). Hence, we have that

$$\int_0^{c_{(i,j)}}\varphi_{(i',j')}(s)\mathrm{d}s = \begin{cases} 0 & \text{if } i' > i \\ \int_{-\infty}^{\infty}\varphi_{(i',j')}(s)\mathrm{d}s & \text{if } i' < i \end{cases}.$$

Therefore, we have

$$(v^\top A_\varphi)_{(i,j)} = \sum_{i'<i,j'} v_{(i',j')} \cdot \int_{-\infty}^{\infty} \varphi_{(i',j')}(s)\mathrm{d}s + \sum_{j'} v_{(i,j')} \cdot \int_{0}^{c_{(i,j)}} \varphi_{(i,j')}(s)\mathrm{d}s.$$

Note that $\int_0^{c_{(i,j)}} \varphi_{(i',j')}(s)\mathrm{d}s$ can precomputed. Since there are $\sum_{i=1}^n (1+D_i)$ many pairs of (i,j), the first term can be computed in $\sum_{i=1}^n (1+D_i)$ time. Since there are $\sum_{i=1}^n (1+D_i)^2$ many pairs of (i,j,j'), the second term can be computed in $\sum_{i=1}^n (1+D_i)^2$ time.

Theorem 4.2.9 gives another way to compute the integration and its runtime is

$$O\left(\mathrm{rank}(\mathcal{V}) \log(\frac{\mathrm{rank}(\mathcal{V})}{\epsilon})\right).$$

□

Remark 4.2.2. Experiment seems to suggest the basis we proposed is 1 bounded.

Here is the theorem we used above to compute the Lagrange polynomials.

Theorem 4.2.9 ([DGR96, Section 5])**.** *Let ϕ_i be the Lagrange basis polynomials on the Chebyshev nodes $c_j = \cos(\frac{2j-1}{2t}\pi)$ for $j \in [t]$, namely, $\phi_i(s) = \prod_{j\neq i} \frac{s-c_j}{c_i-c_j}$. Given a polynomial $p(s) = \sum_{j=1}^t \alpha_j \phi_j(s)$ represented by $\{\alpha_j\}_{j=1}^t$, one can compute $\{\ell_i\}_{i=1}^t$ such that*

$$\left|\ell_i - \int_0^{c_i} p(s)ds\right| \leq \epsilon \|\alpha\|_\infty$$

in time $O(t\log(\frac{t}{\epsilon}))$.

4.3 Improved Contraction Bound for HMC

In this section, we give an improved contraction bound for HMC (Algorithm 4.1). Each iteration of Algorithm 4.1 solve the HMC dynamics approximately. In the later sections, we will discuss how to solve this ODE.

To give a contraction bound for the noisy HMC, we first analyze the contraction of the ideal HMC. We reduce the problem of bounding the contraction rate of the ideal HMC to the following lemma involving a matrix ODE.

Lemma 4.3.1. *Given a symmetric matrix $H(t)$ such that $0 \prec m_2 \cdot I \preceq H(t) \preceq M_2 \cdot I$ for all $t \geq 0$. Consider the ODE*

$$u''(t) = -H(t) \cdot u(t),$$
$$u'(0) = 0.$$

Let $\alpha(t) = \frac{1}{\|u(0)\|_2} \int_0^t (t-s) \cdot \|H(s)u(0)\|_2 \mathrm{d}s$. For any $0 \leq T \leq \frac{1}{2\sqrt{M_2}}$ such that $\alpha(T) \leq \frac{1}{8}\sqrt{\frac{m_2}{M_2}}$, we have that

$$\|u(T)\|_2^2 \leq \left(1 - \max\left(\frac{1}{4}m_2 T^2, \frac{1}{2}\sqrt{\frac{m_2}{M_2}} \cdot \alpha(T)\right)\right) \cdot \|u(0)\|_2^2.$$

Using this lemma, we prove both parts of the main contraction bound, Lemma 4.1.6.

Proof of Lemma 4.1.6. Let error function $e(t) = y(t) - x(t)$. The definition of HMC shows that

$$e''(t) = -(\nabla f(y(t)) - \nabla f(x(t))) = -H(t) \cdot e(t)$$

where $H(t) = \int_0^1 \nabla^2 f(x(t) + s(y(t) - x(t)))\mathrm{d}s$. By the strong convexity and the Lipschitz gradient of f, we have that

$$m_2 \cdot I \preceq H(t) \preceq M_2 \cdot I.$$

Hence, we can apply Lemma 4.3.1.

To get the first bound, we bound the $\alpha(t)$ defined in Lemma 4.3.1 as follows

$$\alpha(t) = \frac{1}{\|e(0)\|_2} \int_0^t (t-s) \cdot \|H(s)e(0)\|_2 \mathrm{d}s \leq M_2 \int_0^t (t-s)\mathrm{d}s = M_2 \frac{t^2}{2}.$$

Therefore, for $0 \leq t \leq \frac{m_2^{1/4}}{2M_2^{3/4}}$, we have that $\alpha(t) \leq \frac{1}{8}\sqrt{\frac{m_2}{M_2}}$ and hence Lemma 4.3.1 gives the first bound.

To get the second bound, we note that $\alpha(t)$ is increasing and hence there is t such that $\alpha(t) = \frac{1}{8}\sqrt{\frac{m_2}{M_2}}$. Using such t in Lemma 4.3.1 gives the second bound. □

Now, we prove the main technical lemma of this section, a contraction estimate for matrix ODE. We note that not all matrix ODEs come from some HMC and hence it might be possible to get a better bound by directly analyzing the HMC.

Proof of Lemma 4.3.1. Let e_1 denote the basis vector that it is 1 in the first coordinate and 0 everywhere else.

Without loss of generality, we can assume $\|u(0)\|_2 = 1$ and $u(0) = e_1$.

The proof involves first getting a crude bound on $\|u(t)\|_2$. Then, we boast the bound by splitting the movement of $u(t)$ into one parallel to e_1 and one orthogonal to e_1.

Crude bound on $\|u(t)\|_2$:

Integrating both sides of $u''(t) = -H(t) \cdot u(t)$ twices and using $u'(0) = 0$ gives

$$u(t) = u(0) - \int_0^t (t-s)H(s)u(s)\mathrm{d}s. \tag{4.12}$$

We take the norm on both sides and use $0 \preceq H(s) \preceq M_2 \cdot I$ to get

$$\|u(t)\|_2 \leq 1 + M_2 \cdot \int_0^t (t-s)\|u(s)\|_2 \mathrm{d}s.$$

Applying Lemma 4.6.2 to this equation and using $t \leq \frac{1}{2\sqrt{M_2}}$ gives

$$\|u(t)\|_2 \leq \cosh(\sqrt{M_2}t) \leq \frac{6}{5}$$

Putting it back to (4.12) gives

$$\|u(t) - e_1\|_2 \leq \int_0^t (t-s)\|H(s) \cdot u(s)\|_2 \mathrm{d}s = \int_0^t (t-s) \cdot M_2 \cdot \frac{6}{5} \mathrm{d}s = \frac{6}{10} M_2 t^2.$$

In particular, for any $0 \leq t \leq \frac{1}{2\sqrt{M_2}}$, we have that

$$\frac{5}{6} \leq u_1(t) \leq \frac{7}{6}. \tag{4.13}$$

Improved bound on $\|u(t)\|_2$:

Let P_1 be the orthogonal projection to the first coordinate and $P_{-1} = I - P_1$. We write $u(t) = u_1(t) + u_{-1}(t)$ with $u_1(t) = P_1 u(t)$ and $u_{-1}(t) = P_{-1} u(t)$, namely, $u_1(t)$ is parallel to e_1 and $u_{-1}(t)$ is orthogonal to e_1.

Fix any $0 \leq t \leq T$. Let $\beta(t) = e_1^\top u(t)$. By the definition of u, we have

$$u''(t) = -\beta(t) \cdot H(t) e_1 - H(t) u_{-1}(t). \tag{4.14}$$

Integrating both sides twice and using $u_{-1}(0) = 0$, we have

$$\begin{aligned} u_{-1}(t) &= \int_0^t (t-s) P_{-1} u''(s) \mathrm{d}s \\ &= -\int_0^t (t-s) \cdot \beta(s) \cdot P_{-1} H(s) e_1 \mathrm{d}s - \int_0^t (t-s) P_{-1} H(s) u_{-1}(s) \mathrm{d}s. \end{aligned}$$

Taking norm on both sides and using that $0 \preceq H(t) \preceq M_2 \cdot I$ and $\frac{5}{6} \leq \beta(s) \leq \frac{7}{6}$, we have that

$$\begin{aligned}
\|u_{-1}(t)\|_2 &\leq \int_0^t (t-s) \cdot \beta(s) \cdot \|H(s)e_1\|_2 \mathrm{d}s + M_2 \cdot \int_0^t (t-s) \cdot \|u_{-1}(s)\|_2 \mathrm{d}s \\
&\leq \frac{7}{6} \int_0^t (t-s) \cdot \|H(s)e_1\|_2 \mathrm{d}s + M_2 \cdot \int_0^t (t-s) \cdot \|u_{-1}(s)\|_2 \mathrm{d}s \\
&\leq \frac{7}{6}\alpha(T) + M_2 \cdot \int_0^t (t-s) \cdot \|u_{-1}(s)\|_2 \mathrm{d}s \qquad (4.15)
\end{aligned}$$

where $\alpha(T) \stackrel{\text{def}}{=} \int_0^T (T-s) \cdot \|H(s)e_1\|_2 \mathrm{d}s$. Solving this integral inequality (Lemma 4.6.2), we get

$$\|u_{-1}(t)\|_2 \leq \frac{7}{6}\alpha(T) \cdot \cosh(\sqrt{M_2}t) \leq \frac{7}{6}\alpha(T) \cdot \cosh(1/2) \leq \frac{4}{3}\alpha(T) \qquad (4.16)$$

where the second step follows from $t \leq \frac{1}{2\sqrt{M_2}}$, and the last step follows from $\cosh(1/2) \leq \frac{8}{7}$.

Next, we look at the first coordinate of (4.14) and get

$$\begin{aligned}
\beta''(t) &= -\beta(t) \cdot e_1^\top H(t) e_1 - e_1^\top H(t) u_{-1}(t) \\
&\leq -\frac{5}{6} e_1^\top H(t) e_1 + \|H(t)e_1\|_2 \cdot \|u_{-1}(t)\|_2. \qquad (4.17)
\end{aligned}$$

To bound the last term, we note that

$$\begin{aligned}
\|H(t)e_1\|_2 &= \sqrt{e_1^\top H^2(t) e_1} \\
&\leq \sqrt{M_2 \cdot e_1^\top H(t) e_1} && \text{by } H^2(t) \preceq M_2 \cdot H(t) \\
&= \sqrt{\frac{M_2}{m_2}} \sqrt{\frac{m_2}{e_1^\top H(t) e_1}} e_1^\top H(t) e_1 \\
&\leq \sqrt{\frac{M_2}{m_2}} \cdot e_1^\top H(t) e_1 && \text{by } m_2 \leq e_1^\top H(t) e_1. \qquad (4.18)
\end{aligned}$$

Using this into (4.17) and $\alpha(T) \leq \frac{1}{8}\sqrt{\frac{m_2}{M_2}}$, we have

$$\beta''(t) \leq -e_1^\top H(t) e_1 \cdot \left(\frac{5}{6} - \frac{4}{3}\sqrt{\frac{M_2}{m_2}}\alpha(T) \right) \leq -\frac{2}{3} e_1^\top H(t) e_1.$$

Hence, we have that

$$\beta(t) \leq 1 - \frac{2}{3}\int_0^t (t-s)\cdot e_1^\top H(s)e_1 \mathrm{d}s. \tag{4.19}$$

Using (4.19), $\beta(t) \geq \frac{5}{6}$ and (4.16) gives

$$\begin{aligned}
\|u(t)\|_2^2 &= \beta^2(t) + \|u_{-1}(t)\|_2^2 \\
&\leq 1 - \int_0^t (t-s)\cdot e_1^\top H(s)e_1 \mathrm{d}s + \left(\frac{4}{3}\int_0^T (T-s)\cdot \|H(s)e_1\|_2 \mathrm{d}s\right)^2 \\
&\leq 1 - \int_0^t (t-s)\cdot e_1^\top H(s)e_1 \mathrm{d}s + 2\sqrt{\frac{M_2}{m_2}}\int_0^T (T-s)\cdot e_1^\top H(s)e_1 \mathrm{d}s \cdot \alpha(T) \\
&= 1 - \int_0^t (t-s)\cdot e_1^\top H(s)e_1 \mathrm{d}s \left(1 - 2\sqrt{\frac{M_2}{m_2}}\alpha(T)\right) \\
&\leq 1 - \frac{1}{2}\int_0^t (t-s)\cdot e_1^\top H(s)e_1 \mathrm{d}s
\end{aligned}$$

where we used (4.18) at the second inequality and $\alpha(T) \leq \frac{1}{8}\sqrt{\frac{m_2}{M_2}}$ at the end.

Finally, we bound the last term in two way. One way simply uses $e_1^\top H(s)e_1 \geq m_2$ and get

$$\int_0^t (t-s)\cdot e_1^\top H(s)e_1 \mathrm{d}s \geq \frac{m_2}{2}t^2$$

which implies

$$\|u(t)\|_2^2 \leq 1 - \frac{m_2}{4}t^2.$$

For the other way, we apply (4.18) to get that

$$\int_0^t (t-s)\cdot e_1^\top H(s)e_1 \mathrm{d}s \geq \int_0^t (t-s)\cdot \|H(t)e_1\|_2 \sqrt{\frac{m_2}{M_2}}\mathrm{d}s = \sqrt{\frac{m_2}{M_2}}\cdot\alpha(T).$$

where the last step follows by the definition of $\alpha(T)$. Thus, we have

$$\|u(t)\|_2^2 \leq 1 - \frac{1}{2}\sqrt{\frac{m_2}{M_2}}\alpha(T).$$

□

Finally, we analyze the contraction of the noisy HMC.

Theorem 4.3.2 (Contraction of noisy HMC)**.** *Suppose f is m_2 strongly convexity with M_2 Lipschitz gradient. For any step-size $h \leq \frac{m_2^{1/4}}{2M_2^{3/4}}$, let $X \sim \mathrm{HMC}(x^{(0)}, f, \epsilon, h)$ and $Y \sim e^{-f}$. Then, we have that*

$$W_2(X, Y) \leq \frac{\epsilon}{\sqrt{m_2}}.$$

In addition, the number of iterations is

$$N = O\left(\frac{1}{m_2 h^2}\right) \cdot \log\left(\frac{\|\nabla f(x^{(0)})\|_2^2/m_2 + d}{\epsilon}\right).$$

Proof. To prove the W_2 distance, we let $x^{(k)}$ be the iterates of the algorithm HMC. Let $y^{(k)}$ be the k-th step of the ideal HMC starting from a random point $y^{(0)} \sim e^{-f}$ with the random initial direction identical to the algorithm HMC. Let $x^{*(k)}$ be the 1 step ideal HMC starting from $x^{(k-1)}$ with the same initial direction as $y^{(k)}$. Lemma 4.1.6 shows that

$$\|x^{*(k)} - y^{(k)}\|_2^2 \leq \left(1 - \frac{m_2 h^2}{4}\right)\|x^{(k-1)} - y^{(k-1)}\|_2^2.$$

Let $\theta = \frac{m_2 h^2}{8}$, then $\theta \leq \frac{1/(4\kappa^{3/4})}{8} \leq 1/32$. By the assumption of the noise, we have $\|x^{(k)} -$

$x^{*(k)}\|_2 \leq \frac{\epsilon\theta}{2\sqrt{m_2}}$. Hence, we have

$$\begin{aligned}
\|x^{(k)} - y^{(k)}\|_2^2 &= \|(x^{*(k)} - y^{(k)}) + (x^{(k)} - x^{*(k)})\|_2^2 \\
&\leq (1+\theta)\,\|x^{*(k)} - y^{(k)}\|_2^2 + (1+1/\theta)\|x^{(k)} - x^{*(k)}\|_2^2 \\
&\leq (1+\theta)\,(1-2\theta)\|x^{(k-1)} - y^{(k-1)}\|_2^2 + (1+1/\theta)\|x^{(k)} - x^{*(k)}\|_2^2 \\
&\leq (1-\theta)\,\|x^{(k-1)} - y^{(k-1)}\|_2^2 + (1+1/\theta)\|x^{(k)} - x^{*(k)}\|_2^2 \\
&\leq (1-\theta)\,\|x^{(k-1)} - y^{(k-1)}\|_2^2 + (2/\theta)\cdot\frac{\epsilon^2\theta^2}{4m_2}.
\end{aligned}$$

where the second step follows by $(a+b)^2 \leq (1+\theta)a^2 + (1+1/\theta)b^2$, the third step follows by $\|x^{*(k)} - y^{(k)}\|_2^2 \leq (1-2\theta)\|x^{(k-1)} - y^{(k-1)}\|_2^2$, the fourth step follows by $(1+\theta)(1-2\theta) \leq (1-\theta)$, the fifth step follow by $\theta \leq 1/4$ and $\|x^{(k)} - x^{*(k)}\|_2 \leq \frac{\epsilon\theta}{2\sqrt{m_2}}$.

Applying this bound iteratively gives

$$\|x^{(k)} - y^{(k)}\|_2^2 \leq (1-\theta)^k\,\|x^{(0)} - y^{(0)}\|_2^2 + \frac{\epsilon^2}{2m_2}. \tag{4.20}$$

Let $x^{(\min)}$ be the minimum of f. Then, we have

$$\|x^{(0)} - y^{(0)}\|_2^2 \leq 2\|x^{(0)} - x^{(\min)}\|_2^2 + 2\|y^{(0)} - x^{(\min)}\|_2^2. \tag{4.21}$$

For the first term, the strong convexity of f shows that

$$\|x^{(0)} - x^{(\min)}\|_2^2 \leq \frac{1}{m^2}\|\nabla f(x^{(0)})\|_2^2. \tag{4.22}$$

For the second term, Theorem 1 in [DM16] shows that

$$\mathbb{E}\left[\|y^{(0)} - x^{(\min)}\|_2^2\right] \leq \frac{d}{m_2}. \tag{4.23}$$

Combining (4.20), (4.21), (4.22) and (4.23), we have

$$\mathbb{E}\left[\|x^{(k)} - y^{(k)}\|_2^2\right] \leq (1-\theta)^k\left(\frac{2\|\nabla f(x^{(0)})\|_2^2}{m_2^2} + \frac{2d}{m_2}\right) + \frac{\epsilon^2}{2m_2}.$$

Picking

$$k = \frac{1}{\theta} \cdot \log\left(\frac{\frac{2\|\nabla f(x^{(0)})\|_2^2}{m_2^2} + \frac{2d}{m_2}}{\frac{\epsilon^2}{2m_2}}\right) = \frac{1}{\theta} \cdot \log\left(\frac{4}{\epsilon^2}\left(\frac{\|\nabla f(x^{(0)})\|_2^2}{m_2} + d\right)\right),$$

we have that

$$\mathbb{E}\left[\|x^{(k)} - y^{(k)}\|_2^2\right] \leq \frac{\epsilon^2}{m_2}.$$

This proves that $W_2(X, Y) \leq \frac{\epsilon}{\sqrt{m_2}}$. □

4.4 Strongly Convex functions with Lipschitz Gradient

In this section, we give a faster sampling algorithm for strongly convex functions with Lipschitz gradient. The purpose of this section is to illustrate that our contraction bound and ODE theorem are useful even for functions that are not infinitely differentiable. We believe that our bound can be beaten by algorithms designed for this specific setting.

4.4.1 Bounding the ODE solution

First, we prove that the HMC dynamic for these functions can be well approximated by piece-wise degree-2 polynomials. Note that this only requires that the Hessian has bounded eigenvalues.

Lemma 4.4.1 (Smoothness implies the existence of degree-2 polynomial approximation)**.** *Let f be a twice-differentiable function such that $-M_2 \cdot I \preceq \nabla^2 f(x) \preceq M_2 \cdot I$ for all $x \in \mathbb{R}^d$. Let $0 \leq h \leq \frac{1}{2\sqrt{M_2}}$. Consider the HMC dynamic*

$$\begin{aligned} \frac{\mathrm{d}^2 x}{\mathrm{d}t^2}(t) &= -\nabla f(x(t)) \text{ for } 0 \leq t \leq h, \\ \frac{\mathrm{d}x}{\mathrm{d}t}(0) &= v_1, \\ x(0) &= v_0. \end{aligned}$$

For any integer k, there is a continuously differentiable k-piece degree 2 polynomial q such that $q(0) = v_0$, $\frac{\mathrm{d}q}{\mathrm{d}t}(0) = v_1$ and $\left\| \frac{\mathrm{d}^2 q}{\mathrm{d}t^2}(t) - \frac{\mathrm{d}^2 x}{\mathrm{d}t^2}(t) \right\|_2 \leq \frac{\epsilon}{h^2}$ for $0 \leq t \leq h$ with

$$\epsilon = \frac{2M_2 h^3}{k} \left(\|v_1\|_2 + \|\nabla f(v_0)\|_2 \cdot h \right).$$

Proof. Let $x(t)$ be the solution of the ODE. We define a continuously differentiable k-piece

degree-2 polynomial q by

$$q(0) = v_0 \text{ and } q'(t) = \frac{\mathrm{d}x(t_{\text{pre}})}{\mathrm{d}t} \cdot \frac{t_{\text{next}} - t}{t_{\text{next}} - t_{\text{pre}}} + \frac{\mathrm{d}x(t_{\text{next}})}{\mathrm{d}t} \cdot \frac{t_{\text{pre}} - t}{t_{\text{next}} - t_{\text{pre}}}$$

with $t_{\text{pre}} = \left\lfloor \frac{t}{h/k} \right\rfloor \cdot \frac{h}{k}$ and $t_{\text{next}} = t_{\text{pre}} + \frac{h}{k}$. Clearly, we have that $q(0) = x(0) = v_0$ and $\frac{\mathrm{d}q}{\mathrm{d}t}(0) = \frac{\mathrm{d}x}{\mathrm{d}t}(0) = v_1$. Also, we have that

$$\left\| \frac{\mathrm{d}^2 q}{\mathrm{d}t^2}(t) - \frac{\mathrm{d}^2 x}{\mathrm{d}t^2}(t) \right\|_2 = \left\| \int_{t_{\text{pre}}}^{t_{\text{next}}} \frac{\mathrm{d}^2 x}{\mathrm{d}t^2}(s) ds - \frac{\mathrm{d}^2 x}{\mathrm{d}t^2}(t) \right\|_2 \leq \frac{h}{k} \max_{0 \leq t \leq h} \left\| \frac{\mathrm{d}^3 x}{\mathrm{d}t^3}(t) \right\|_2 \leq \frac{M_2 h}{k} \max_{0 \leq t \leq h} \left\| \frac{\mathrm{d}x}{\mathrm{d}t}(t) \right\| \tag{4.24}$$

where we used that $\frac{\mathrm{d}^3 x}{\mathrm{d}t^3}(t) = -\nabla^2 f(x(t)) \frac{\mathrm{d}x}{\mathrm{d}t}(t)$ at the end.

Therefore, it suffices to bound the term $\max_{0 \leq t \leq h} \left\| \frac{\mathrm{d}x}{\mathrm{d}t}(t) \right\|$. Using again that $\frac{\mathrm{d}^3 x}{\mathrm{d}t^2}(t) = -\nabla^2 f(x(t)) \frac{\mathrm{d}x}{\mathrm{d}t}(t)$, we have that

$$\begin{aligned} \frac{\mathrm{d}x}{\mathrm{d}t}(t) &= \frac{\mathrm{d}x}{\mathrm{d}t}(0) + \frac{\mathrm{d}^2 x}{\mathrm{d}t^2}(0) \cdot t + \int_0^t (t - s) \cdot \frac{\mathrm{d}^3 x}{\mathrm{d}t^3}(s) ds \\ &= v_1 - \nabla f(v_0) \cdot t - \int_0^t (t - s) \cdot \nabla^2 f(x(s)) \frac{\mathrm{d}x}{\mathrm{d}t}(s) ds. \end{aligned}$$

Hence, for $0 \leq t \leq h$, we have that

$$\left\| \frac{\mathrm{d}x}{\mathrm{d}t}(t) \right\|_2 \leq \|v_1\|_2 + \|\nabla f(v_0)\|_2 \cdot h + M_2 \cdot \int_0^t (t - s) \left\| \frac{\mathrm{d}x}{\mathrm{d}t}(t) \right\|_2 ds.$$

Solving this integral inequality, Lemma 4.6.2 shows that

$$\max_{0 \leq t \leq h} \left\| \frac{\mathrm{d}x}{\mathrm{d}t}(t) \right\| \leq (\|v_1\|_2 + \|\nabla f(v_0)\|_2 \cdot h) \cdot \cosh(\sqrt{M_2} \cdot h) \leq 2 (\|v_1\|_2 + \|\nabla f(v_0)\|_2 \cdot h)$$

where we used that $h \leq \frac{1}{2\sqrt{M_2}}$. Applying this in (4.24) gives this result. □

The precise runtime depends on how accurate we need to solve the ODE, namely, the parameter ϵ in Lemma 4.4.1. The term $\|v_1\|_2$ can be upper bounded by $O(\sqrt{d})$ with

high probability since v_1 is sampled from normal distribution. The term $\|\nabla f(v_0)\|_2$ is much harder to bound. Even for a random v_0 e^{-f}, the worst case bound we can give is

$$\|\nabla f(v_0)\|_2 = \|\nabla f(v_0) - \nabla f(x^*)\|_2 \leq M_2\|v_0 - x^*\|_2 \lesssim \sqrt{\kappa M_2 d}$$

where we used that $\|v_0 - x^*\|_2 \lesssim \sqrt{d/m_2}$ for random v_0 e^{-f} [DM16]. This is not enough for improving existing algorithms, as we would need $\sqrt{\kappa d}$ time per iteration. The crux of this section is to show that $\|\nabla f(v_0)\|_2 = O(\sqrt{M_2 d})$ for most of the iterations in the HMC walk if the process starts at the minimum of f. This is tight for quadratic f.

Lemma 4.4.2 (Smoothness implies expected gradient is upper bounded)**.** *Let f be a function such that $-M_2 \cdot I \preceq \nabla^2 f(x) \preceq M_2 \cdot I$ for all $x \in \mathbb{R}^d$. Let $x^{(k)}$ be the starting point of the k^{th} step in* $\mathrm{HMC}(x^{(0)}, f, \epsilon, h)$ *(Algorithm 4.1) with step size $h \leq \frac{1}{8\sqrt{M_2}}$. Then, we have that*

$$\frac{1}{N}\mathbb{E}\left[\sum_{k=0}^{N-1}\|\nabla f(x^{(k)})\|_2^2\right] \leq O\left(\frac{f(x^{(0)}) - \min_x f(x)}{h^2 N} + M_2 d + \frac{\bar{\epsilon}^2}{h^4}\right)$$

$\bar{\epsilon}$ is the error in solving the HMC defined in Algorithm 4.1.

Proof. Consider one step of the HMC dynamic. Note that

$$\frac{\mathrm{d}}{\mathrm{d}t} f(x(t)) = \nabla f(x(t))^\top \frac{\mathrm{d}x}{\mathrm{d}t}.$$

Hence, we have

$$\begin{aligned}
\frac{\mathrm{d}^2}{\mathrm{d}t^2} f(x(t)) &= \frac{\mathrm{d}x}{\mathrm{d}t}^\top \nabla^2 f(x(t)) \frac{\mathrm{d}x}{\mathrm{d}t} + \nabla f(x(t))^\top \frac{\mathrm{d}^2 x}{\mathrm{d}t^2} \\
&= \frac{\mathrm{d}x}{\mathrm{d}t}^\top \nabla^2 f(x(t)) \frac{\mathrm{d}x}{\mathrm{d}t} - \|\nabla f(x(t))\|^2 && \text{by } \frac{\mathrm{d}^2 x}{\mathrm{d}t^2} = -\nabla f(x(t)) \\
&\leq M_2 \cdot \|\frac{\mathrm{d}x}{\mathrm{d}t}\|_2^2 - \|\nabla f(x(t))\|^2. && \text{by } \nabla^2 f(x(t)) \preceq M_2 \cdot I \qquad (4.25)
\end{aligned}$$

In Lemma 4.4.1, we proved that $\|\frac{\mathrm{d}x}{\mathrm{d}t}\|_2 \leq 2\left(\|\frac{\mathrm{d}x}{\mathrm{d}t}(0)\|_2 + \|\nabla f(x(0))\|_2 \cdot h\right)$ for all $0 \leq t \leq h$. Using this, we have that

$$\begin{aligned}\|\nabla f(x(t)) - \nabla f(x(0))\| &\leq M_2\|x(t) - x(0)\|_2 \\ &\leq M_2 \int_0^t \|\frac{\mathrm{d}x}{\mathrm{d}t}(t)\|_2 \mathrm{d}t \\ &\leq 2M_2 h \cdot \left(\|\frac{\mathrm{d}x}{\mathrm{d}t}(0)\|_2 + \|\nabla f(x(0))\|_2 \cdot h\right)\end{aligned}$$

which implies

$$\|\nabla f(x(t))\| = \|\nabla f(x(0))\| \pm 2M_2 h \left(\|\frac{\mathrm{d}x}{\mathrm{d}t}(0)\| + \|\nabla f(x(0))\| \cdot h\right). \tag{4.26}$$

Using our choice of h, we have that $\|\nabla f(x(t))\| \geq \frac{1}{2}\|\nabla f(x(0))\| - 2M_2 h \cdot \|\frac{\mathrm{d}x}{\mathrm{d}t}(0)\|_2$. Putting these estimates into (4.25) gives

$$\begin{aligned}&\frac{\mathrm{d}^2}{\mathrm{d}t^2} f(x(t)) \\ &\leq 2M_2 \left(\|\frac{\mathrm{d}x}{\mathrm{d}t}(0)\|^2 + \|\nabla f(x(0))\|^2 h^2\right) - \frac{1}{4}\|\nabla f(x(0))\|^2 + 2M_2 h \cdot \|\nabla f(x(0))\| \cdot \|\frac{\mathrm{d}x}{\mathrm{d}t}(0)\| \\ &\leq 2M_2 \left(\|\frac{\mathrm{d}x}{\mathrm{d}t}(0)\|^2 + \|\nabla f(x(0))\|^2 h^2\right) - \frac{1}{4}\|\nabla f(x(0))\|^2 + 2 \cdot (\frac{1}{8}\|\nabla f(x(0))\|)^2 + 2 \cdot (16M_2 h\|\frac{\mathrm{d}x}{\mathrm{d}t}(0)\|)^2 \\ &= (2M_2 + 512M_2^2 h^2)\|\frac{\mathrm{d}x}{\mathrm{d}t}(0)\|^2 - (\frac{1}{4} - 2M_2 h^2 - \frac{1}{32})\|\nabla f(x(0))\|^2 \\ &\leq 10M_2 \cdot \|\frac{\mathrm{d}x}{\mathrm{d}t}(0)\|^2 - \frac{1}{8}\|\nabla f(x(0))\|^2\end{aligned}$$

where we used that $h \leq \frac{1}{8\sqrt{M_2}}$ at the last two equations.

Since $\frac{\mathrm{d}x}{\mathrm{d}t}(0)$ is sampled from normal distribution, we have that

$$\begin{aligned}\mathbb{E}[f(x(h))] &\leq f(x(0)) + \int_0^h (h-t)\frac{\mathrm{d}^2}{\mathrm{d}t^2} f(x(t))\mathrm{d}t \\ &= f(x(0)) + 5M_2 \cdot h^2 \cdot \mathbb{E}\left[\|\frac{\mathrm{d}x}{\mathrm{d}t}x(0)\|^2\right] - \frac{h^2}{16}\|\nabla f(x(0))\|^2 \\ &= f(x(0)) + 5M_2 \cdot h^2 \cdot d - \frac{h^2}{16}\|\nabla f(x(0))\|^2\end{aligned}$$

where the last step follows from $\mathbb{E}[\|\frac{\mathrm{d}x}{\mathrm{d}t}(0)\|^2] = d$.

For the ODE starting from $x^{(k)}$, we have that

$$\mathbb{E}[f(x(h))] \le f(x^{(k)}) - \frac{h^2}{16}\|\nabla f(x^{(k)})\|^2 + O(M_2 \cdot d \cdot h^2).$$

To compare $f(x(h))$ and $f(x^{(k+1)})$, we note that the distance between $x^{(k+1)}$ and $x(h)$ is less than $\bar{\epsilon}$ in ℓ_2 norm. Using (4.26) and the fact $\nabla^2 f \preceq M_2 I$, the function value changed by at most

$$\bar{\epsilon} \cdot \|\nabla f(x^{(k+1)})\| + M_2 \cdot \bar{\epsilon}^2 = 2\bar{\epsilon} \cdot \|\nabla f(x^{(k)})\| + O(\bar{\epsilon} M_2 \sqrt{d} h + \bar{\epsilon}^2 M_2)$$

with high probability. Hence, we have

$$\begin{aligned}
\mathbb{E}[f(x^{(k+1)})] &\le f(x^{(k)}) + 2\bar{\epsilon}\|\nabla f(x^{(k)})\| - \frac{h^2}{16}\|\nabla f(x^{(k)})\|^2 + O(\bar{\epsilon} M_2 \sqrt{d} h + \bar{\epsilon}^2 M_2 + M_2 d h^2) \\
&\le f(x^{(k)}) + 2\bar{\epsilon}\|\nabla f(x^{(k)})\| - \frac{h^2}{16}\|\nabla f(x^{(k)})\|^2 + O(\bar{\epsilon}^2 M_2 + M_2 d h^2) \\
&\le f(x^{(k)}) + 2\bar{\epsilon}\|\nabla f(x^{(k)})\| - \frac{h^2}{16}\|\nabla f(x^{(k)})\|^2 + O(\frac{\bar{\epsilon}^2}{h^2} + M_2 d h^2) \\
&\le f(x^{(k)}) - \frac{h^2}{32}\|\nabla f(x^{(k)})\|^2 + O(\frac{\bar{\epsilon}^2}{h^2} + M_2 d h^2)
\end{aligned}$$

where the step follows from $2ab \le a^2 + b^2$, the third step follows from our choice of h, the second last step follows by $2\bar{\epsilon}\|\nabla f(x^{(k)})\| \le \frac{h^2}{64}\|\nabla f(x^{(k)})\|^2 + 64\frac{\bar{\epsilon}^2}{h^2}$.

Summing k from 0 to $N-1$, we have

$$\sum_{k=0}^{N-1} \mathbb{E}\left[f(x^{(k+1)}) - f(x^{(k)}) + \frac{h^2}{32}\|\nabla f(x^{(k)})\|^2\right] \le N \cdot O\left(\frac{\bar{\epsilon}^2}{h^2} + M_2 d h^2\right)$$

Using $f(x^{(N)}) \ge \min_x f(x)$ and reorganizing the terms gives the desired result.

□

Remark 4.4.1. Both Lemma 4.4.1 and Lemma 4.4.2 do not need convexity.

4.4.2 Sampling

Now, we can apply our algorithm for second-order ODEs to the HMC dynamic. To control the gradient of the initial point in a simple way, we start at the algorithm at a local minimum of f.

Theorem 4.1.4. (Strongly Convex)**.** Given a function f such that $0 \prec m_2 \cdot I \preceq \nabla^2 f(x) \preceq M_2 \cdot I$ for all $x \in \mathbb{R}^d$ and $0 < \epsilon < \sqrt{d}$. Starting $x^{(0)}$ at the minimum of f, we can find a random point X whose Wasserstein distance to Y drawn from the density proportional to e^{-f} satisfies

$$W_2(X, Y) \leq \frac{\epsilon}{\sqrt{m_2}}$$

using $O(\kappa^{1.5} \log(\frac{d}{\epsilon}))$ iterations where $\kappa = \frac{M_2}{m_2}$. Each iteration takes $O\left(\frac{\kappa^{\frac{1}{4}} d^{\frac{3}{2}}}{\epsilon} \log\left(\frac{\kappa d}{\epsilon}\right)\right)$ time and $O\left(\frac{\kappa^{\frac{1}{4}} d^{\frac{1}{2}}}{\epsilon} \log\left(\frac{\kappa d}{\epsilon}\right)\right)$ evaluations of ∇f, amortized over all iterations.

Proof. The number of iterations follows from Theorem 4.3.2 with

$$h = \frac{m_2^{1/4}}{16000 M_2^{3/4}}. \tag{4.27}$$

To approximate the HMC dynamic, we apply the ODE algorithm (Theorem 4.2.4). Now, we estimate the parameters in Theorem 4.2.4. Note that $L_1 = 0$, $L_2 = M_2$, $L = \sqrt{M_2}$, $T = h$, $LT \leq 1/16000$, $\epsilon_{\text{ODE}} = \frac{\epsilon \cdot \sqrt{m_2} h^2}{16}$. Hence, if the solution is approximated by a k-piece degree 2 polynomial, we can find it in $O(dk) \cdot \log(\frac{C}{\epsilon_{\text{ODE}}})$ time and $O(k) \cdot \log(\frac{C}{\epsilon_{\text{ODE}}})$ evaluations where

$$C = O(h^2) \|\nabla f(v_0)\| + h \|v_1\|$$

with v_0 and v_1 are the initial point and initial velocity of the dynamic.

Finally, Lemma 4.4.1 shows that the ODE can be approximated using a

$$k \stackrel{\text{def}}{=} \frac{2 \cdot M_2 h^3 \left(\|v_1\|_2 + \|\nabla f(v_0)\|_2 \cdot h \right)}{\epsilon / (\sqrt{m_2} \cdot \kappa^{3/2})}$$

piece degree 2 polynomials where v_0 is the initial point and v_1 is the initial velocity. Since v_1 is sampled from normal distribution, we have that

$$k \lesssim \frac{1}{\epsilon} \left(\kappa^{\frac{1}{4}} \sqrt{d} + \frac{\|\nabla f(v_0)\|_2}{\sqrt{M_2}} \right).$$

in expectation.

Now, we apply Lemma 4.4.2 with $\bar{\epsilon} = \sqrt{m_2} h^2 \epsilon / 16$ and use the fact that $f(x^{(0)}) - \min_x f(x) \leq \frac{\|\nabla f(x^{(0)})\|_2^2}{m_2}$, we have

$$\begin{aligned}
\mathbb{E}\left[\frac{1}{N} \sum_{k=0}^{N-1} \|\nabla f(x^{(k)})\|_2^2 \right] &\lesssim \frac{\|\nabla f(x^{(0)})\|_2^2}{m_2 h^2 N} + M_2 d + \frac{\bar{\epsilon}^2}{h^4} \\
&\lesssim \frac{\|\nabla f(x^{(0)})\|_2^2}{m_2 h^2 N} + M_2 d + m_2 \epsilon^2 \\
&\lesssim \|\nabla f(x^{(0)})\|_2^2 + M_2 d + m_2 \epsilon^2 \\
&\lesssim \|\nabla f(x^{(0)})\|_2^2 + M_2 d
\end{aligned}$$

where the third step follows from $N \geq \frac{1}{m_2 h^2}$, our choice of h and ϵ (i.e., Eq. (4.27)), and we used that $\epsilon \leq \sqrt{d}$ at the end. Hence, the expected number of evaluations per each HMC iterations (amortized over all HMC iterations) is

$$\begin{aligned}
O(k) \cdot \log(\frac{C}{\epsilon_{\text{ODE}}}) &\lesssim \frac{1}{\epsilon} \left(\kappa^{\frac{1}{4}} \sqrt{d} + \frac{\|\nabla f(x^{(0)})\| + \sqrt{M_2 d}}{\sqrt{M_2}} \right) \log \left(\frac{h^2 (\|\nabla f(x^{(0)})\| + \sqrt{M_2 d}) + h\sqrt{d}}{\epsilon_{\text{ODE}}} \right) \\
&\lesssim \frac{1}{\epsilon} \left(\kappa^{\frac{1}{4}} \sqrt{d} + \frac{\|\nabla f(x^{(0)})\|}{\sqrt{M_2}} \right) \log \left(\frac{1}{\epsilon} \left(\frac{\|\nabla f(x^{(0)})\|}{\sqrt{m_2}} + \kappa^{3/4} \sqrt{d} \right) \right)
\end{aligned}$$

where the last step follows from our choice of $\epsilon_{\text{ODE}} = \frac{\epsilon \cdot \sqrt{m_2} h^2}{16}$ and our choice of $h = \frac{m_2^{1/4}}{16000 M_2^{3/4}}$. Since we start at the minimum of f, $\|\nabla f(x^{(0)})\| = 0$ and this gives the expected number of evaluations.

Similarly, we have the bound for expected time. This completes the proof. □

4.5 Sampling from Incoherent Logistic Loss Functions and More

In this section we prove Theorem 4.5.6. Since the function

$$f(x) = \sum_{i=1}^{n} \phi_i(a_i^\top x) + \frac{m_2}{2}\|x\|_2^2,$$

the HMC dynamic for sampling $e^{-f(x)}$ is given by

$$\frac{\mathrm{d}^2}{\mathrm{d}t^2}x(t) = -\nabla f(x(t)) = -A^\top \phi'(Ax) - m_2 x$$

where the i^{th} row of $A \in \mathbb{R}^{n\times d}$ is $a_i^\top$, $\forall i \in [n]$ and $\phi' : \mathbb{R}^n \to \mathbb{R}^n$ is defined by

$$\phi'(s) = \left(\frac{\mathrm{d}}{\mathrm{d}s_1}\phi_1(s_1), \frac{\mathrm{d}}{\mathrm{d}s_2}\phi_2(s_2), \cdots, \frac{\mathrm{d}}{\mathrm{d}s_n}\phi_n(s_n)\right).$$

To simplify the proof, we let $s(t) = Ax(t)$. Then, s satisfies the equation

$$\frac{\mathrm{d}^2}{\mathrm{d}t^2}s(t) = F(s(t)) \quad \text{where} \quad F(s) = -AA^\top \phi'(s) - m_2 s. \tag{4.28}$$

Ignoring the term $m_2 s$, F consists of two parts the first part $-AA^\top$ is linear and the second part is decoupled in each variable. This structure allows us to study the dynamic s easily. In this section, we discuss how to approximate the solution of (4.28) using the collocation method.

The proof consists of (a) bounding $\|s(t)\|_\infty$, (b) bounding Lipschitz constant of F and (c) showing that $s(t)$ can be approximated by a polynomial.

4.5.1 ℓ_∞ bound of the dynamic

Lemma 4.5.1 (ℓ_∞ bound of the dynamic)**.** *Let $x^{(j)}$ be the j^{th} iteration of the HMC dynamic defined in Algorithm 4.1 with*

$$f(x) = \sum_{i=1}^{n} \phi_i(a_i^\top x) + \frac{m_2}{2}\|x\|_2^2.$$

Assume that $m_2 \cdot I \preceq \nabla^2 f(x) \preceq M_2 \cdot I$ *for all* x, $|\phi'(s)| \leq M$ *for all* s, *and that* $\tau = \|AA^\top\|_{\infty\to\infty}$. *Let* $s^{(j)} = Ax^{(j)}$. *Suppose that the step size* $T \leq \frac{1}{2\sqrt{m_2}}$, *we have that*

$$\max_{j\in[N]} \|s^{(j)} - s^{(0)}\|_\infty = O\left(\sqrt{\frac{\tau}{m_2}} + \frac{\tau M}{m_2}\right) \cdot \log(dN/\eta)$$

with probability at least $1 - \eta$.

Proof. We ignore the index of iteration (j) and focus on how s changes within each ODE first.

For any $0 \leq t \leq T$ and for any i, we have that

$$s_i(t) = s_i(0) + s_i'(0)t - \int_0^t (t-\ell)(AA^\top \phi'(s(\ell)))_i \mathrm{d}\ell - m_2 \int_0^t (t-\ell) s_i(\ell) \mathrm{d}\ell. \tag{4.29}$$

Using $\tau = \|AA^\top\|_{\infty\to\infty}$ and $|\phi'(s)| \leq M$, we have

$$\begin{aligned}
|s_i(t) - s_i(0)| &\leq T \cdot |s_i'(0)| + \int_0^T (T-\ell)\cdot\tau\cdot M \mathrm{d}\ell + m_2 \int_0^t (t-\ell)|s_i(\ell) - s_i(0)|\mathrm{d}\ell + \frac{1}{2} m_2 T^2 |s_i(0)| \\
&= \frac{1}{2} m_2 T^2 \cdot |s_i(0)| + T \cdot |s_i'(0)| + \frac{1}{2} T^2 \cdot \tau M + m_2 \int_0^t (t-\ell)|s_i(\ell) - s_i(0)|\mathrm{d}\ell.
\end{aligned}$$

Solving this integral inequality (Lemma 4.6.2), we get

$$\begin{aligned}
|s_i(t) - s_i(0)| &\leq \left(\frac{1}{2} m_2 T^2 \cdot |s_i(0)| + T \cdot |s_i'(0)| + \frac{1}{2} T^2 \cdot \tau M\right) \cdot \cosh(\sqrt{m_2} t) \\
&\leq \frac{1}{4}|s_i(0)| + 2T \cdot |s_i'(0)| + T^2 \cdot \tau M
\end{aligned} \tag{4.30}$$

where we used that $t \leq T \leq \frac{1}{2\sqrt{m_2}}$.

Using this estimate back to (4.29), we have

$$\begin{aligned}
&\left|s_i(T) - s_i(0) - s_i'(0)T + \frac{1}{2}m_2T^2s_i(0)\right| \\
\leq\ & \int_0^T (T-\ell)|AA^\top\phi'(s(\ell))_i|\mathrm{d}\ell + m_2\int_0^T (T-\ell)|s_i(\ell)-s_i(0)|\mathrm{d}\ell \\
\leq\ & \int_0^T (T-\ell)\tau M\mathrm{d}\ell + m_2\int_0^T (T-\ell)\left(\frac{1}{4}|s_i(0)| + 2T\cdot|s_i'(0)| + T^2\cdot\tau M\right)\mathrm{d}\ell \\
=\ & \frac{1}{2}T^2\cdot\tau M + \frac{1}{2}m_2T^2\cdot\left(\frac{1}{4}|s_i(0)| + 2T\cdot|s_i'(0)| + T^2\cdot\tau M\right) \\
\leq\ & \frac{1}{2}T^2\cdot\tau M + \frac{1}{2}m_2T^2\cdot\left(\frac{1}{4}|s_i(0)| + \frac{1}{\sqrt{m_2}}\cdot|s_i'(0)| + \frac{1}{4m_2}\cdot\tau M\right) \\
=\ & \frac{5}{8}T^2\cdot\tau M + \frac{1}{8}m_2T^2|s_i(0)| + \frac{1}{2}\sqrt{m_2}T^2\cdot|s_i'(0)|
\end{aligned}$$

where the second step follows from $|AA^\top\phi'(s(\ell))_i| \leq \tau M$ and (4.30), the third step follows from $\int_0^T (T-\ell)\mathrm{d}\ell = \frac{1}{2}T^2$, the fourth step follows from $T \leq \frac{1}{2\sqrt{m_2}}$.

Note that we bounded how much each iteration of the HMC dynamic can change the solution. Writing it differently, we have

$$s_i^{(j+1)} = (1 - \frac{1}{2}m_2T^2)s_i^{(j)} + s_i^{(j)'}(0)\cdot T + \beta$$

where

$$|\beta| \leq \frac{1}{4}m_2T^2|s_i^{(j)}(0)| + \sqrt{m_2}T^2\cdot|s_i^{(j)'}(0)| + \tau M\cdot T^2.$$

Note that $s_i^{(j)'}(0) \sim \mathcal{N}(0, (A^\top A)_i)$ and that

$$\lambda_{\max}(A^\top A) = \lambda_{\max}(AA^\top) \leq \|AA^\top\|_{\infty\to\infty} = \tau.$$

Therefore, $s_i^{(j)'}(0)T \sim \alpha_i\cdot\mathcal{N}(0,1)$ with $0 \leq \alpha_i \leq \sqrt{\tau}T$. Now, we simplify the dynamic to

$$s_i^{(j+1)} = (1-\delta)s_i^{(j)} + \alpha_iN^{(j)} + \beta$$

where $\delta := \frac{1}{2}m_2T^2$, $\alpha_i \le a := \sqrt{\tau}T$, and

$$|\beta| \le \frac{\delta}{2}|s_i^{(j)}(0)| + b|N^{(j)}| + c$$

with $b := \sqrt{m_2\tau}T^2$ and $c := \tau M \cdot T^2$.

Applying Lemma 4.5.2, we have that

$$\Pr\left[\max_{j\in[N]}|s_i^{(j)} - s_i^{(0)}| \ge C \cdot \left(\frac{a}{\sqrt{\delta}} + \frac{c+b}{\delta}\right)\log(N/\epsilon)\right] \le \epsilon$$

for some constant C. Taking union bound over $i \in [d]$, the bound follows from the calculation

$$\frac{a}{\sqrt{\delta}} + \frac{c+b}{\delta} = \frac{\sqrt{2\tau}T}{\sqrt{m_2}T} + \frac{\tau M \cdot T^2 + \sqrt{m_2\tau}\cdot T^2}{2m_2T^2} \gtrsim \sqrt{\frac{\tau}{m_2}} + \frac{\tau M}{m_2}.$$

□

Lemma 4.5.2 (Bounding the Martingale)**.** *Let $X^{(i)}$ be a sequence of random variable such that*

$$X^{(i+1)} = (1-\delta)X^{(i)} + \alpha_i N^{(i)} + \beta$$

where $N^{(i)} \sim \mathcal{N}(0,1)$ are independent, $\alpha_i \le a$, $\beta \le \frac{\delta}{2}|X^{(i)}| + b|N^{(i)}| + c$ with positive a, b, c and $0 < \delta \le 1$. For some constant universal $C > 0$, we have that

$$\Pr\left[\max_{i\in[k]}|X^{(i)} - X^{(0)}| \ge C \cdot \left(\frac{a}{\sqrt{\delta}} + \frac{c+b}{\delta}\right)\log(k/\epsilon)\right] \le \epsilon$$

for any $0 < \epsilon < 1$.

Proof. We will first show that $X^{(i)}$ cannot grow to large. The proof of the other direction is similar. Consider the potential $\Phi^{(i)} = \mathbb{E}\left[e^{\lambda X^{(i)}}\right]$. Note that

$$\begin{aligned}\Phi^{(i+1)} &\le \mathbb{E}\left[e^{\lambda((1-\delta)X^{(i)} + \alpha_i N^{(i)} + b|N^{(i)}| + c + \frac{\delta}{2}|X^{(i)}|)}\right] \\ &\le e^{\lambda c}\,\mathbb{E}\left[e^{\lambda(1-\delta)X^{(i)} + \frac{\delta}{2}|X^{(i)}|}\right]\mathbb{E}\left[e^{\lambda(\alpha_i N^{(i)} + b|N^{(i)}|)}\right],\end{aligned}$$

where we used that $N^{(i)}$ are independent. Picking $\lambda \leq \frac{1}{a+b}$ and using $N^{(i)} \sim \mathcal{N}(0,1)$ and $|\alpha_i| \leq a$, we have that

$$\mathbb{E}\left[e^{\lambda(\alpha_i N^{(i)} + b|N^{(i)}|)}\right] \leq e^{O(\lambda b + \lambda^2 a^2)}.$$

Therefore, for any $\eta > 0$, we have

$$\begin{aligned}
\Phi^{(i+1)} &\leq e^{O(\lambda c + \lambda b + \lambda^2 a^2)} \cdot \left(\mathbb{E}\left[e^{\lambda(1-\delta)X^{(i)} + \frac{\delta}{2}|X^{(i)}|} 1_{X^{(i)} \leq \eta}\right] + \mathbb{E}\left[e^{\lambda(1-\frac{\delta}{2})X^{(i)}} 1_{X^{(i)} > \eta}\right]\right) \\
&\leq e^{O(\lambda c + \lambda b + \lambda^2 a^2)} \cdot \left(e^{\lambda\eta} + \mathbb{E}\left[e^{\lambda X^{(i)} - \frac{\lambda}{2}\delta\eta}\right]\right) \\
&\leq e^{O(\lambda c + \lambda b + \lambda^2 a^2 + \lambda\eta)} + e^{O(\lambda c + \lambda b + \lambda^2 a^2) - \frac{\lambda}{2}\delta\eta} \Phi^{(i)}.
\end{aligned}$$

Choose $\eta = \Theta(\frac{c+b+\lambda a^2}{\delta})$ such that $O(\lambda c + \lambda b + \lambda^2 a^2) - \frac{\lambda}{2}\delta\eta \leq 0$. Hence, we have

$$\Phi^{(i+1)} \leq e^{O(\lambda c + \lambda b + \lambda^2 a^2 + \lambda\eta)} + \Phi^{(i)} \leq e^{O(\frac{\lambda c + \lambda b + \lambda^2 a^2}{\delta})} + \Phi^{(i)}.$$

Picking an appropriate λ, we have the result. □

4.5.2 Lipschitz constant of F

Now, we bound the Lipschitz constant of function F.

Lemma 4.5.3 (Lipschitz bound of function F)**.** *Let $L_{\phi'}$ be the Lipschitz constant of ϕ', i.e.,*

$$\|\phi'(s_1) - \phi'(s_2)\|_\infty \leq L_{\phi'} \|s_1 - s_2\|_\infty, \forall s_1, s_2.$$

The function F defined in (4.28) has Lipschitz constant $(L_{\phi'}\tau + m_2)$ in ℓ_∞ norm where $\tau = \|AA^\top\|_{\infty\to\infty}$.

Proof. Note that

$$\begin{aligned}\|F(s_1) - F(s_2)\|_\infty &= \|AA^\top(\phi'(s_1) - \phi'(s_2))\|_\infty + m_2\|s_1 - s_2\|_\infty \\ &\le \tau \cdot \|\phi'(s_1) - \phi'(s_2)\|_\infty + m_2\|s_1 - s_2\|_\infty \\ &\le (\tau \cdot L_{\phi'} + m_2) \cdot \|s_1 - s_2\|_\infty,\end{aligned}$$

where the second step follows by $\|AA^\top\|_{\infty\to\infty} = \tau$, and second step follows by ϕ' is $L_{\phi'}$-Lipschitz function.

□

Remark 4.5.1. If we think of the role of F in our second order ODE (4.28), then F is in fact independent of $\frac{\mathrm{d}s}{\mathrm{d}t}$. Therefore $L_1 = 0$ and $L_2 = L_{\phi'}\tau + m_2$.

4.5.3 Existence of low-degree solutions

Next, we establish bounds on the radius up to which the solution to the ODE (4.28) have a low-degree polynomial approximation.

Lemma 4.5.4 (Low-degree polynomial approximation)**.** *Assume that $\|AA^\top\|_{\infty\to\infty} = \tau$ and that for all i, ϕ_i' has Cauchy estimate M with radius r, i.e.,*

$$\forall l \ge 0, \forall a \in \mathbb{R}, |(\phi_i)^{(l+1)}(a)| \le M \cdot l! \cdot r^{-l}.$$

Let $s^*(t) \in \mathbb{R}^n$ denote the solution of the ODE (4.28).

For any

$$0 \le T \le \frac{r}{4}\left((M\tau r + m_2 r(r + \|s(0)\|_\infty))^{1/2} + \|s'(0)\|_\infty\right)^{-1}$$

and any $0 < \epsilon < 1$*, there is a degree* $D = 2\lceil 4 + \log_2(1/\epsilon)\rceil$ *polynomial* $q : \mathbb{R} \to \mathbb{R}^n$ *such that*

$$q(0) = s^*(0), q'(0) = s^{*\prime}(0), \text{ and } \left\| \frac{\mathrm{d}^2}{\mathrm{d}t^2} q(t) - \frac{\mathrm{d}^2}{\mathrm{d}t^2} s^*(t) \right\|_\infty \leq \frac{\epsilon \cdot r}{T^2}, \forall t \in [0, T]$$

First, we verify the condition in Lemma 4.6.6.

Lemma 4.5.5. (Bounding derivatives of F)**.** Under the same assumptions in Lemma 4.5.4, we have

$$\|D^k F(s)[\Delta_1, \Delta_2, \cdots, \Delta_k]\|_\infty \leq g^{(k)}(0) \cdot \prod_{j=1}^{k} \|\Delta_j\|_\infty, \forall k \geq 0, \forall \Delta_1, \cdots, \Delta_k.$$

where

$$g(x) = \frac{\tau \cdot M + m_2 \cdot (r + \|s\|_\infty)}{1 - r^{-1}x}.$$

Proof. Recall that $\phi'(x) = (\phi_1'(x_1), \phi_2'(x_2), \cdots, \phi_n'(x_n))$, $\forall x \in \mathbb{R}^n$. We have

$$\begin{aligned}
&\|AA^\top D^k \phi'(s)[\Delta_1, \Delta_2, \cdots, \Delta_k]\|_\infty \\
\leq\ & \tau \cdot \|D^k \phi'(s)[\Delta_1, \Delta_2, \cdots, \Delta_k]\|_\infty && \text{by } \|AA^\top\|_{\infty\to\infty} = \tau \\
\leq\ & \tau \cdot \max_{i\in[n]} |\phi_i^{(k+1)}| \cdot |\Delta_{1,i}| \cdot |\Delta_{2,i}| \cdots |\Delta_{k,i}| \\
\leq\ & \tau \cdot \max_{i\in[n]} |\phi_i^{(k+1)}| \prod_{j=1}^{k} \|\Delta_j\|_\infty \\
\leq\ & \tau \cdot M \cdot k! \cdot r^{-k} \cdot \prod_{j=1}^{k} \|\Delta_j\|_\infty.
\end{aligned}$$

Next, the derivatives of the $m_2 s$ term in $F(s) = -AA^\top \phi'(s) - m_2 s$ can be bounded by the derivatives of $x \to m_2(\|s\|_\infty + x)$, which then can be bounded by the derivatives of $x \to m_2(r + \|s\|_\infty)/(1 - r^{-1}x)$. This explains the second part of the function g. □

Proof of Lemma 4.5.4. Theorem 4.6.4 and Lemma 4.5.5 shows that

$$\|s^{*(k)}(0)\|_\infty \le \frac{k!\alpha^k}{r^{-1}} = r \cdot k! \cdot \alpha^k \tag{4.31}$$

where

$$\alpha = \max\left(\left(\frac{4}{3} \cdot (M\tau + m_2(r + \|s(0)\|_\infty)) \cdot r^{-1}\right)^{1/2}, 2 \cdot \|s'(0)\|_\infty r^{-1}\right).$$

Since s^* is real analytic at 0 (Theorem 4.6.4), around $t = 0$, we have

$$s^*(t) = \sum_{k=0}^{\infty} \frac{s^{*(k)}(0)}{k!} t^k.$$

Apply Theorem 4.6.4 repeatedly at every t such that $s^*(t)$ is defined, we can show that the above equation holds as long as the right hand side converges.

Let $q(t) = \sum_{k=0}^{D} s^{*(k)}(0)t^k$. Then, we have that

$$\begin{aligned}
\left\|\frac{\mathrm{d}^2}{\mathrm{d}t^2}q(t) - \frac{\mathrm{d}^2}{\mathrm{d}t^2}s^*(t)\right\|_\infty &\le \left\|\sum_{k=D+1}^{\infty} \frac{s^{*(k)}(0)}{(k-2)!} t^{k-2}\right\|_\infty \\
&\le r \cdot \sum_{k=D+1}^{\infty} \frac{k!}{(k-2)!}\alpha^k t^{k-2} \\
&\le \frac{r}{T^2} \cdot \sum_{k=D+1}^{\infty} \frac{(k-1)k}{2^k} \\
&= \frac{r}{T^2} \cdot 2^{-D}(D^2 + 3D + 4) \\
&\le 16\frac{2^{-D/2}r}{T^2}
\end{aligned}$$

where we used (4.31) at the second inequality, $\alpha T \le \frac{1}{2}$ at the third inequality, and $D \ge 1$ at the fourth inequality. □

4.5.4 Main result

Theorem 4.5.6 (Formal version of Theorem 4.1.2)**.** *Let* $A = [a_1; a_2; \cdots; a_n] \in \mathbb{R}^{n \times d}$, $\phi_i : \mathbb{R} \to \mathbb{R}$ *be a function, and*

$$f(x) = \sum_{i=1}^{n} \phi_i(a_i^\top x) + \frac{m_2}{2}\|x\|^2.$$

Let $\tau = \|AA^\top\|_{\infty \to \infty}$ *and suppose that*

1. *f has M_2 Lipschitz gradient, i.e., $\nabla^2 f(x) \preceq M_2 \cdot I$ for all x,*

2. *ϕ_i' has Cauchy estimate M with radius r, i.e., $\forall i \in [n], \ell \geq 1, s \in \mathbb{R}$, $|\phi_i^{(l+1)}(s)| \leq M \cdot l! \cdot r^{-l}$.*

Starting at $x^{(0)}$, we can output a random point X such that

$$\mathop{\mathbb{E}}_{Y \propto e^{-f}} \left[\|X - Y\|_2^2\right] \leq \frac{\epsilon}{\sqrt{m_2}}$$

using $N \lesssim k \log\left(\frac{k}{\epsilon}\left(\frac{\|\nabla f(x^{(0)})\|^2}{m_2} + d\right)\right)$ iterations with

$$k \lesssim \kappa^{1.5} + \frac{M\tau}{m_2 r}\log(dN) + \frac{\tau}{m_2 r^2}\log^2(dN) \quad \text{with} \quad \kappa = \frac{M_2}{m_2}.$$

Each iteration takes $O(d \log^3(\frac{1}{\delta}))$ time and $O(\log^2(\frac{1}{\delta}))$ evaluations to the function ϕ' and the matrix vector multiplications for A and $A^\top$, with

$$\delta = \Omega(\frac{1}{r})\sqrt{\frac{\lambda_{\min}(A^\top A)}{n \cdot m_2}} \cdot \frac{\epsilon}{k}.$$

Proof. The proof consists of bounding the cost of each HMC step in Algorithm 4.1 and bounding the number of steps.

Cost per iteration:

Parameters	Value	Source
k	2	Eq. (4.28)
L_1	0	Lemma 4.5.3 and Remark 4.5.1
L_2	$\frac{M\tau}{r} + m_2$	Lemma 4.5.3 and Remark 4.5.1
D	$O(\log(1/\delta))$	Lemma 4.5.4
C	$O(r)$	Eq. (4.34)
ϵ_{ODE}	$O(\delta r)$	Eq. (4.33)

Table 4.2: Summary of parameters of Theorem 4.2.4

As we discussed in this section, we consider the ODE (4.28) instead. We will use Theorem 4.2.4 to solve the ODE (4.28). Hence, we need to bound the parameters of Theorem 4.2.4, which are summarized in Table 4.2.

Parameters D and ϵ_{ODE}: Let s denote its solution. Lemma 4.5.4 shows that if

$$h \le \frac{r}{4}\left((M\tau \cdot r + m_2 r(r + \|s(0)\|_\infty))^{1/2} + \|s'(0)\|_\infty\right)^{-1}, \tag{4.32}$$

for any $\delta > 0$, there is a degree $O(\log(1/\delta))$ polynomial q such that

$$q(0) = s(0), \quad q'(0) = s'(0), \quad \text{and} \quad \left\|\frac{\mathrm{d}^2}{\mathrm{d}t^2}q(t) - \frac{\mathrm{d}^2}{\mathrm{d}t^2}s(t)\right\|_\infty \le \frac{\delta \cdot r}{T^2} \text{ for } t \in [0, h]. \tag{4.33}$$

Parameter C: To apply Theorem 4.2.4, we first show parameter $C \le O(r)$ as follows:

$$\begin{aligned}
C &\lesssim h \cdot (h\|F(s(0))\|_\infty + \|s'(0)\|_\infty) \\
&\le h \cdot \left(h\left(\left\|AA^\top \phi'(s(0))\right\|_\infty + \|m_2 s(0)\|_\infty\right) + \|s'(0)\|_\infty\right) \\
&\le h^2\tau \|\phi'(s(0))\|_\infty + h^2 m_2 \|s(0)\|_\infty + h\|s'(0)\|_\infty \\
&\le h^2\tau M + h^2 m_2 \|s(0)\|_\infty + h\|s'(0)\|_\infty \\
&\le \frac{r}{16} + \frac{r}{16} + \frac{r}{4} \le r.
\end{aligned} \tag{4.34}$$

where the second step follows from (4.28) and triangle inequality, the third step follows from $\|AA^\top\|_{\infty\to\infty} = \tau$, the fourth step follows from ϕ' has Cauchy estimate M with radius r, and the last step follows from (4.32).

Now, Theorem 4.2.4 shows that if h satisfies (4.32) and that

$$h \le \frac{1}{16000}\frac{1}{L} = \frac{1}{16000}\frac{1}{L_1 + \sqrt{L_2}} = \frac{1}{16000}\sqrt{\frac{r}{M\tau + m_2 r}}, \tag{4.35}$$

then, we can find p such that

$$\|s(h) - p\|_\infty \le O(\delta \cdot r) \tag{4.36}$$

using $O(\log(\frac{1}{\delta})\log(\frac{C}{\delta\cdot r})) = O(\log^2(\frac{1}{\delta}))$ evaluations of ϕ_i' and $O(d\log^2(\frac{1}{\delta})\log(\frac{C}{\delta\cdot r})) = O(d\log^3(\frac{1}{\delta}))$ time.

To understand the condition in Eq. (4.32), we note that $s'(0) = Av$ where $v \sim \mathcal{N}(0, I)$. Hence, $s^{*\prime}(0) \sim \mathcal{N}(0, A^\top A)$. Note that $\lambda_{\max}(A^\top A) = \lambda_{\max}(AA^\top) \le \|AA^\top\|_{\infty\to\infty} = \tau$. Hence, we have that

$$\|s'(0)\|_\infty = O(1) \cdot \sqrt{\tau \cdot \log(dN/\eta)}$$

with probability at least $1 - \eta$ probability for all N iterations. In Lemma 4.5.1, we proved that

$$\|s(0)\|_\infty = O\left(\sqrt{\frac{\tau}{m_2}} + \frac{\tau M}{m_2}\right) \cdot \log(dN/\eta)$$

with probability at least $1 - \eta$ for all N iterations.

Putting the bound on $\|s'(0)\|$ and $\|s(0)\|$ into the right hand side of Eq. (4.32) gives

$$\begin{aligned}
&\frac{1}{r}\left(\sqrt{M\tau\cdot r + m_2 r(r+\|s(0)\|_\infty)} + \|s'(0)\|_\infty\right) \qquad (4.37)\\
&\lesssim \sqrt{\frac{M\tau}{r}} + \sqrt{m_2} + \sqrt{\frac{m_2}{r}\left(\sqrt{\frac{\tau}{m_2}} + \frac{\tau M}{m_2}\right)\log(dN/\eta)} + \frac{\sqrt{\tau}}{r}\sqrt{\log(dN/\eta)}\\
&\leq \frac{M_2^{3/4}}{m_2^{1/4}} + \left(\frac{(\tau m_2)^{1/4}}{r^{1/2}} + \sqrt{\frac{M\tau}{r}} + \frac{\sqrt{\tau}}{r}\right)\sqrt{\log(dN/\eta)}\\
&\leq \frac{M_2^{3/4}}{m_2^{1/4}} + \left(\frac{\sqrt{\tau}}{r}\sqrt{\log(dN/\eta)} + \frac{\sqrt{m_2}}{\sqrt{\log(dN/\eta)}} + \sqrt{\frac{M\tau}{r}} + \frac{\sqrt{\tau}}{r}\right)\sqrt{\log(dN/\eta)}\\
&\lesssim \frac{M_2^{3/4}}{m_2^{1/4}} + \frac{\sqrt{\tau}}{r}\log(dN/\eta) + \sqrt{\frac{M\tau}{r}}\sqrt{\log(dN/\eta)}
\end{aligned}$$

where the second step follows by Eq. (4.32), the third step follows by $\sqrt{m_2} \leq \frac{M_2^{3/4}}{m_2^{1/4}}$ and $\sqrt{\log(dN/\eta)} \geq 1$, the fourth step follows by $ab \leq a^2 + b^2$, the fifth step follows by $\sqrt{\log(dN/\eta)} \geq 1$ and $\sqrt{m_2} \leq \frac{M_2^{3/4}}{m_2^{1/4}}$.

Therefore,

$$h = \Theta\left(\sqrt{\frac{M\tau}{r}}\sqrt{\log(dN/\eta)} + \frac{\sqrt{\tau}}{r}\log(dN/\eta) + \frac{M_2^{3/4}}{m_2^{1/4}}\right)^{-1} \qquad (4.38)$$

satisfies the condition in Eq. (4.32) and Eq. (4.35). It also satisfies the condition in Theorem 4.3.2 ($h \leq \frac{m_2^{1/4}}{2M_2^{3/4}}$).

Next, we note that the corresponding HMC dynamic $x^*(h)$ is given by

$$x^*(h) = (A^\top A)^{-1}A^\top s^*(h).$$

Let p be the approximate of $s^*(h)$ we find using Theorem 4.3.2 and $q = (A^\top A)^{-1}A^\top p$, then,

we have

$$\begin{aligned}\|x^*(h) - q\|_2 &= \|(A^\top A)^{-1}A^\top s^*(h) - (A^\top A)^{-1}Ap\|_2 \\ &\leq \|(A^\top A)^{-1}A^\top\|_{2\to 2} \cdot \|s^*(h) - p\|_2 \\ &\leq \|(A^\top A)^{-1}A^\top\|_{2\to 2} \cdot O(\sqrt{n} \cdot r \cdot \delta) \\ &\leq (\lambda_{\min}(A^\top A))^{-\frac{1}{2}} \cdot O(\sqrt{n} \cdot r \cdot \delta),\end{aligned}$$

where the first step follows by definition of $x^*(h)$ and q, the second step follows by definition of $\|\|_{2\to 2}$ norm, the third step follows from $\|s^*(h) - p\|_2 \leq O(\sqrt{n}r\delta)$ (implied by (4.36) and $\|\|_2 \leq \sqrt{n}\|\|_\infty$).

Using such q as an approximation of $x^*(h)$ in Algorithm 4.1, Theorem 4.3.2 shows that the W_2 error of the sampled point is bounded by

$$O\left((\lambda_{\min}(A^\top A))^{-\frac{1}{2}} \cdot \sqrt{n} \cdot r \cdot \delta\right) \leq \frac{\epsilon \cdot \theta}{2\sqrt{m_2}}.$$

where $\theta = \frac{m_2 h^2}{8}$ and the last step follows from picking

$$\delta = c \cdot \frac{1}{r}\sqrt{\frac{\lambda_{\min}(A^\top A)}{n \cdot m_2}} \cdot \epsilon \cdot \theta$$

for some small enough c. The cost of each iteration follows from Theorem 4.2.4 and all parameters we pick.

Number of iterations:

Theorem 4.3.2 shows that the number of iterations is

$$O\left(\frac{1}{\theta}\right) \cdot \left(\log\left(\frac{1}{\theta \cdot \epsilon}\right) + \log\left(\frac{\|\nabla f(x^{(0)})\|^2}{m_2} + d\right)\right).$$

Finally, we bound the term $1/\theta$ as follows

$$\begin{aligned}\frac{1}{\theta} &\lesssim \frac{1}{m_2}\left(\frac{M\tau}{r}\log\left(\frac{dN}{\eta}\right)+\frac{\tau}{r^2}\log^2\left(\frac{dN}{\eta}\right)+\frac{M_2^{3/2}}{\sqrt{m_2}}\right)\\ &= \kappa^{1.5}+\frac{M\tau}{m_2 r}\log\left(\frac{dN}{\eta}\right)+\frac{\tau}{m_2 r^2}\log^2\left(\frac{dN}{\eta}\right).\end{aligned}$$

where we used $\kappa = M_2/m_2$ and (4.38). □

4.6 Preliminaries

4.6.1 Notation

For any function f, we define $\widetilde{O}(f)$ to be $f \cdot \log^{O(1)}(f)$. In addition to $O(\cdot)$ notation, for two functions f, g, we use the shorthand $f \lesssim g$ (resp. $\gtrsim$) to indicate that $f \leq Cg$ (resp. $\geq$) for an absolute constant C.

Definition 4.6.1 ($p \to q$ norm)**.** Given matrix $A \in \mathbb{R}^{n \times d}$, we define $\|\|_{p \to q}$ norm as follows

$$\|A\|_{p \to q} = \max_{x \in \mathbb{R}^d} \frac{\|Ax\|_q}{\|x\|_p}.$$

$\|A\|_{\infty \to \infty}$ is a special case where $p = \infty$ and $q = \infty$.

Definition 4.6.2 (Wasserstein distance)**.** The k-th Wasserstein distance between two probability measure μ and ν is

$$W_k(\mu, \nu) = \left(\inf_{(X,Y) \in \mathcal{C}(\mu,\nu)} \mathbb{E}\left[\|X - Y\|^k \right] \right)^{1/k},$$

where $\mathcal{C}(\mu, \nu)$ is the set of all couplings of μ and ν.

Definition 4.6.3 (Cauchy's estimates)**.** We say function ϕ has Cauchy estimate M and radius of convergence r, if for all $x \in \mathbb{R}$ and for all integers $l \geq 0$

$$|\phi^{(l)}(x)| \leq M \cdot l! \cdot r^{-l}.$$

Lemma 4.6.1. *If the number of non-zeros for each row of $AA^\top$ is bounded by s, then*

$$\lambda_{\max}(AA^\top) \leq \|AA^\top\|_{\infty \to \infty} \leq \sqrt{s} \cdot \lambda_{\max}(AA^\top).$$

Proof. Let v be the maximum eigenvalue of $AA^\top$. Then, we have that

$$AA^\top v = \lambda_{\max}(AA^\top) \cdot v.$$

Since $\|AA^\top\|_{\infty\to\infty} = \max_{\|v\|_\infty=1} \|AA^\top v\|_\infty$, we have that $\lambda_{\max}(AA^\top) \le \|AA^\top\|_{\infty\to\infty}$.

For the another direction,

$$\begin{aligned}\|AA^\top\|_{\infty\to\infty} &= \max_i \sum_j |AA^\top|_{ij} \le \max_i \sqrt{s} \cdot \sqrt{\sum_j (AA^\top)_{ij}^2} \\ &\le \sqrt{s} \cdot \max_i \max_{\|v\|_2=1} e_i^\top AA^\top v = \sqrt{s} \cdot \lambda_{\max}(AA^\top).\end{aligned}$$

□

4.6.2 Simple ODEs

We prove two helper lemmas (Lemma 4.6.2 and 4.6.3) for the later use.

Lemma 4.6.2. *Given a continuous function $v(t)$ and positive scalars β, γ such that*

$$0 \le v(t) \le \beta + \gamma \int_0^t (t-s)v(s)\mathrm{d}s.$$

We have that $v(t) \le \beta \cosh(\sqrt{\gamma}t)$ for all $t \ge 0$.

Proof. Let $\overline{v}(t)$ be the solution of the integral equation $\overline{v}(t) = \beta + \gamma \int_0^t (t-s)\overline{v}(s)\mathrm{d}s$. Note that $\overline{v}$ satisfies the ODE

$$\overline{v}''(t) = \gamma \overline{v}(t), \quad \overline{v}'(0) = 0, \quad \overline{v}(0) = \beta.$$

Solving it, we have $\overline{v}(t) = \beta \cosh(\sqrt{\gamma}t)$. Hence, it suffices to prove that $v(t) \le \overline{v}(t)$ for all $t \ge 0$.

Fix any $\epsilon > 0$. We let T be the supremum such that $(1+\epsilon)\overline{v}(t) \geq v(t)$ for all $0 \leq t \leq T$. Suppose $T < +\infty$. Then, we have that

$$v(T) \leq \beta + \gamma \int_0^T (T-s)v(s)\mathrm{d}s \leq \beta + (1+\epsilon)\gamma \int_0^T (T-s)\overline{v}(s)\mathrm{d}s < (1+\epsilon)\overline{v}(T).$$

By the continuity of v and $\overline{v}$, we show that T is not the supremum. This is a contradiction. Therefore, $T = +\infty$ for any $\epsilon > 0$. □

Lemma 4.6.3. *Given a continuous function $v(t)$ and positive scalars β, γ such that*

$$0 \leq v(t) \leq \beta + \gamma \int_0^t v(s)\mathrm{d}s.$$

We have that $v(t) \leq \beta e^{\gamma t}$ for all $t \geq 0$.

Proof. The proof is identical to Lemma 4.6.2.

Let $\overline{v}(t)$ be the solution of the integral equation $\overline{v}(t) = \beta + \gamma \int_0^t \overline{v}(s)\mathrm{d}s$. Note that $\overline{v}$ satisfies the ODE

$$\overline{v}''(t) = \gamma \overline{v}(t), \quad \overline{v}'(0) = 0, \quad \overline{v}(0) = \beta.$$

Solving it, we have $\overline{v}(t) = \beta \exp(\gamma t)$. Hence, it suffices to prove that $v(t) \leq \overline{v}(t)$ for all $t \geq 0$.

Fix any $\epsilon > 0$. We let T be the supremum such that $(1+\epsilon)\overline{v}(t) \geq v(t)$ for all $0 \leq t \leq T$. Suppose $T < +\infty$. Then, we have that

$$v(T) \leq \beta + \gamma \int_0^T v(s)\mathrm{d}s \leq \beta + (1+\epsilon)\gamma \int_0^T \overline{v}(s)\mathrm{d}s < (1+\epsilon)\overline{v}(T).$$

By the continuity of v and $\overline{v}$,we show that T is not the supremum. This is a contradiction. Therefore, $T = +\infty$ for any $\epsilon > 0$. □

4.6.3 Cauchy Estimates and Method of Majorants

In order to prove the solution of the HMC dynamic can be approximated by a low degree polynomial, we first give a general bound the k^{th} derivative of the second order ODE $u''(t) = F(u(t))$, by reducing it to bounding derivatives of a one-variable ODE. The low degree result then follows from: first, we take the Taylor expansion of the original function; second, truncate it at a certain degree; finally we can claim that the low-degree truncation provides a good approximation to the original function.

Theorem 4.6.4. *Given vectors $v_1, v_0 \in \mathbb{R}^d$ and any norm $\|\cdot\|$ on $\mathbb{R}^d$. Let $U \subset \mathbb{R}^d$ be a neighborhood of v_0 and that $F : U \to \mathbb{R}^d$ is real analytic near v_0. Suppose that*

$$\|D^{(k)}F(v_0)[\Delta_1, \Delta_2, \cdots, \Delta_k]\| \leq k! \cdot a \cdot c^k \prod_{j=1}^{k} \|\Delta_j\| \text{ for all } k \geq 0.$$

Then, the ODE

$$\frac{\mathrm{d}^2}{\mathrm{d}t^2}u(t) = F(u(t)), \frac{\mathrm{d}}{\mathrm{d}t}u(0) = v_1, u(0) = v_0 \tag{4.39}$$

has a unique real analytic solution around $t = 0$. Furthermore, we have

$$\|u^{(k)}(0)\| \leq \frac{k!\alpha^k}{c} \quad \forall k \geq 1$$

with $\alpha = \max(\sqrt{\frac{4}{3}ac}, 2\|v_1\|c)$.

Theorem 4.6.4 involves two steps. The first step (Lemma 4.6.6) involves bounding the derivatives of the solution of the multivariate ODE (4.39) by its scalar version. The second step (Lemma 4.6.7) involves bounding the scalar ODE directly.

The first step follows directly from the majorization proof of Cauchy–Kowalevski theorem. See [vdH03] for an introduction of the method of majorants. This theorem usually

stated qualitatively without an explicit bound. For completeness, we include a proof for the first step.

Theorem 4.6.5 (Cauchy–Kowalevski theorem [Cau42, Kow75, Kro83, Nak94])**.** *Given vectors* $v_{k-1}, v_{k-2}, \cdots, v_0 \in \mathbb{R}^d$*. Let* $U \subset \mathbb{R}^{kd+1}$ *be a neighborhood of* $z \stackrel{\text{def}}{=} (v_{k-1}, v_{k-2}, \cdots, v_0, 0)$ *and that* $F : U \to \mathbb{R}^d$ *is a real analytic near* z*. Then, the ODE*

$$\frac{d^k}{\mathrm{d}t^k} x(t) = F\left(\frac{\mathrm{d}^{k-1}}{\mathrm{d}t^{k-1}} x(t), \cdots, x(t), t\right),$$
$$\frac{d^i}{\mathrm{d}t^i} x(0) = v_i, \forall i \in \{k-1, \cdots, 1, 0\}$$

has a unique real analytic solution around $t = 0$*.*

Lemma 4.6.6. (Bounding multivariate ODE by scalar ODE)**.** Given vectors $v_1, v_0 \in \mathbb{R}^d$ and any norm $\|\cdot\|$ on $\mathbb{R}^d$. Let $U \subset \mathbb{R}^d$ be a neighborhood of v_0 and that $F : U \to \mathbb{R}^d$ is a real analytic near v_0. Suppose that

$$\|D^{(k)} F(v_0)[\Delta_1, \Delta_2, \cdots, \Delta_k]\| \leq f^{(k)}(0) \prod_{j=1}^{k} \|\Delta_j\| \text{ for all } k \geq 0$$

for some real analytic function f around 0. Then the ODE (4.39) has a unique real analytic solution around $t = 0$. Furthermore, for any $b \geq \|v_1\|$, we have

$$\|u^{(k)}(0)\| \leq \psi^{(k)}(0) \quad \forall k \geq 1$$

where ψ is the solution of the ODE

$$\psi''(t) = f(\psi(t)), \psi'(0) = b, \psi(0) = 0.$$

For many functions F, including the HMC dynamic or complex analytic F, we can pick bound the derivatives of F by the function $f(x) = \frac{a}{1-cx}$ for some a and c in Lemma 4.6.6. Therefore, we only need to give a bound on the scalar ODE for this function f.

Lemma 4.6.7. (Bounding scalar ODE) Let $f(x) = \frac{a}{1-cx}$ with positive a and c. Let $\psi(t)$ denote the solution of the ODE

$$\psi''(t) = f(\psi(t)), \psi'(0) = b, \psi(0) = 0$$

with $b \geq 0$. Then,

$$\psi^{(k)}(0) \leq \frac{k!\alpha^k}{c} \quad \forall k \geq 1$$

with $\alpha = \max(\sqrt{\frac{4}{3}ac}, 2bc)$.

Finally, we note that Theorem 4.6.4 follows from Lemma 4.6.6 and Lemma 4.6.7 with $f(x) = \frac{a}{1-cx}$.

4.7 Deferred Proof for ODE (Section 4.2)

4.7.1 Proof of general k-th order ODE

The goal of this section is to prove Theorem 4.2.3.

Proof. We define $\overline{x}(t) \in \mathbb{R}^{kd}$,

$$\overline{x}(t) = (\overline{x}_1(t), \overline{x}_2(t), \cdots, \overline{x}_k(t)) = \left(c_1 \frac{\mathrm{d}^{k-1}}{\mathrm{d}t^{k-1}} x(t), c_2 \frac{\mathrm{d}^{k-2}}{\mathrm{d}t^{k-2}} x(t), \cdots, c_k x(t) \right),$$

where $\overline{x}_1(t) \in \mathbb{R}^d$, $\overline{x}_2(t) \in \mathbb{R}^d$, $\cdots$, $\overline{x}_k(t) \in \mathbb{R}^d$. We define the norm on $\mathbb{R}^{kd}$ by $\|\overline{x}\| = \sum_{i=1}^k \|\overline{x}_i\|$.

Then we have

$$\frac{\mathrm{d}}{\mathrm{d}t}\overline{x}(t) = \left(c_1 \frac{\mathrm{d}^k}{\mathrm{d}t^k} x(t), c_2 \frac{\mathrm{d}^{k-1}}{\mathrm{d}t^{k-1}} x(t), \cdots, c_k \frac{\mathrm{d}}{\mathrm{d}t} x(t) \right).$$

In order to have $\overline{F}(\overline{x}(t), t) = \frac{\mathrm{d}}{\mathrm{d}t}\overline{x}(t)$, we let

$$\overline{F}(\overline{x}(t), t) = \left(c_1 F\left(c_1^{-1}\overline{x}_1(t), c_2^{-1}\overline{x}_2(t), \cdots, c_k^{-1}\overline{x}_k(t), t \right), c_2 c_1^{-1}\overline{x}_1(t), c_3 c_2^{-1}\overline{x}_2(t), \cdots, c_k c_{k-1}^{-1}\overline{x}_{k-1}(t) \right).$$

Now, we check that indeed

$$\begin{aligned}
\frac{\mathrm{d}}{\mathrm{d}t}\overline{x}(t) = & \left(c_1 \frac{\mathrm{d}^k}{\mathrm{d}t^k} x(t), c_2 \frac{\mathrm{d}^{k-1}}{\mathrm{d}t^{k-1}} x(t), \cdots, c_k \frac{\mathrm{d}}{\mathrm{d}t} x(t) \right) \\
= & \left(c_1 F\left(\frac{\mathrm{d}^{k-1}}{\mathrm{d}t^{k-1}} x(t), \frac{\mathrm{d}^{k-2}}{\mathrm{d}t^{k-2}} x(t), \cdots, x(t), t \right), c_2 \frac{\mathrm{d}^{k-1}}{\mathrm{d}t^{k-1}} x(t), \cdots, c_k \frac{\mathrm{d}}{\mathrm{d}t} x(t) \right) \\
= & \left(c_1 F\left(c_1^{-1}\overline{x}_1(t), c_2^{-1}\overline{x}_2(t), \cdots, c_k^{-1}\overline{x}_k(t), t \right), c_2 c_1^{-1}\overline{x}_1(t), c_3 c_2^{-1}\overline{x}_2(t), \cdots, c_k c_{k-1}^{-1}\overline{x}_{k-1}(t) \right) \\
& \overline{F}(\overline{x}(t), t).
\end{aligned}$$

We bound the Lipschitz constant of function $\overline{F}$ by

$$\begin{aligned}\|\overline{F}(y(t),t)-\overline{F}(z(t),t)\| &\le c_1\sum_{i=1}^{k} L_i c_i^{-1}\|y_i(t)-z_i(t)\| + \sum_{i=1}^{k-1} c_{i+1}c_i^{-1}\|y_i(t)-z_i(t)\| \\ &= \sum_{i=1}^{k-1}(c_1 L_i c_i^{-1} + c_{i+1}c_i^{-1})\|y_i(t)-z_i(t)\| + c_1 L_k c_k^{-1}\|y_k(t)-z_k(t)\|.\end{aligned}$$

We choose $c_1 = 1$, $c_i = \sum_{j=i}^{k} L_j^{(i-1)/j} + \frac{1}{\overline{T}^{i-1}}$, $\forall i \in \{2,\cdots,k\}$ where $\overline{T} = 4\gamma_\varphi T$. Then we can calculate for each $i \in [k-1]$,

$$\begin{aligned}c_1 L_i c_i^{-1} + c_{i+1}c_i^{-1} &= \frac{L_i}{\sum_{j=i}^{k} L_j^{(i-1)/j} + \frac{1}{\overline{T}^{i-1}}} + \frac{\sum_{j=i+1}^{k} L_j^{i/j} + \frac{1}{\overline{T}^{i}}}{\sum_{j=i}^{k} L_j^{(i-1)/j} + \frac{1}{\overline{T}^{i-1}}} \\ &= \frac{L_i}{L_i^{(i-1)/i} + \sum_{j=i+1}^{k} L_j^{(i-1)/j} + \frac{1}{\overline{T}^{i-1}}} + \frac{\sum_{j=i+1}^{k} L_j^{i/j} + \frac{1}{\overline{T}^{i}}}{\sum_{j=i}^{k} L_j^{(i-1)/j} + \frac{1}{\overline{T}^{i-1}}} \\ &\le L_i^{1/i} + \sum_{j=i+1}^{k} L_j^{1/j} + \frac{1}{\overline{T}} \\ &= \sum_{j=i}^{k} L_j^{1/j} + \frac{1}{\overline{T}}\end{aligned}$$

For $i = k$, we have

$$c_1 L_k c_k^{-1} = \frac{L_k}{L_k^{(k-1)/k} + \frac{1}{\overline{T}^{k-1}}} \le L_k^{1/k}.$$

Thus,

$$\|\overline{F}(y(t),t)-\overline{F}(z(t),t)\| \le \left(\sum_{j=1}^{k} L_j^{1/j} + \frac{1}{\overline{T}}\right)\cdot\sum_{i=1}^{k}\|y_i(t)-z_i(t)\| = \left(\sum_{j=1}^{k} L_j^{1/j} + \frac{1}{\overline{T}}\right)\|y(t)-z(t)\|.$$

It gives the following Claim:

Claim 4.7.1. *Function $\overline{F}$ has Lipschitz constant $\overline{L} = \sum_{j=1}^{k} L_j^{1/j} + \frac{1}{\overline{T}}$.*

Then, we consider the following first order ODE,

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t}\overline{x}(t) &= \overline{F}(\overline{x}(t), t),\\ \overline{x}(0) &= (c_1 v_{k-1}, c_2 v_{k-2}, \cdots, c_k v_0)\end{aligned}$$

Let $\overline{x}^*(t) \in \mathbb{R}^{kd}$ denote the optimal solution, then

$$\overline{x}^*(t) = \left(c_1 \frac{\mathrm{d}^{k-1}}{\mathrm{d}t^{k-1}} x^*(t), c_2 \frac{\mathrm{d}^{k-2}}{\mathrm{d}t^{k-2}} x^*(t), \cdots, c_k x^*(t)\right).$$

Now, we prove that $\frac{\mathrm{d}}{\mathrm{d}t}\overline{x}^*(t)$ is approximate by some element in $\mathcal{V}^d$. Let $\overline{q} : \mathbb{R} \to \mathbb{R}^{kd}$ be defined as follows

$$\overline{q}(t) = \left(c_1 q^{(k)}(t), c_2 q^{(k-1)}(t), \cdots, c_k q^{(1)}(t)\right).$$

Then,

$$\begin{aligned}&\left\|\overline{q}(t) - \frac{\mathrm{d}}{\mathrm{d}t}\overline{x}^*(t)\right\|\\ =& \left\|\left(c_1 q^{(k)}(t), c_2 q^{(k-1)}(t), \cdots, c_k q^{(1)}(t)\right) - \left(c_1 \frac{\mathrm{d}^k}{\mathrm{d}t^k} x^*(t), c_2 \frac{\mathrm{d}^{k-1}}{\mathrm{d}t^{k-1}} x^*(t), \cdots, c_k \frac{\mathrm{d}}{\mathrm{d}t} x^*(t)\right)\right\|\\ =& \sum_{i=1}^{k} c_i \left\|q^{(k+1-i)}(t) - \frac{\mathrm{d}^{k+1-i}}{\mathrm{d}t^{k+1-i}} x^*(t)\right\|\\ \leq& \sum_{i=1}^{k} c_i \frac{\epsilon}{\overline{T}^{k+1-i}} = \frac{1}{\overline{T}} \underbrace{\epsilon \sum_{i=1}^{k} \frac{c_i}{\overline{T}^{k-i}}}_{\overline{\epsilon}}.\end{aligned}$$

By the assumption on T, we have that $\gamma_\varphi \overline{L} T \leq 1/2$ and hence theorem 4.2.2 finds

$$\overline{x}^{(N)}(t) = (\overline{x}_1^{(N)}(t), \overline{x}_2^{(N)}(t), \cdots, \overline{x}_k^{(N)}(t)) \in \mathbb{R}^{kd}$$

such that

$$\|\overline{x}^{(N)}(t) - \overline{x}^*(t)\| \leq 20\gamma_\varphi \overline{\epsilon} \tag{4.40}$$

This implies that

$$\left\| c_i^{-1}\overline{x}^{(N)}(t) - \frac{\mathrm{d}^{k-i}}{\mathrm{d}t^{k-i}} x^*(t) \right\| \leq 20 c_i^{-1}\gamma_\varphi \overline{\epsilon}, \forall i \in [k]. \tag{4.41}$$

To bound the last term, we show the following Claim:

Claim 4.7.2. *Let* $\overline{\epsilon} = \epsilon \sum_{i=1}^{k} \frac{c_i}{\overline{T}^{k-i}}$. *If we choose* $c_1 = 1$ *and* $c_i = \sum_{j=i}^{k} L_j^{(i-1)/j} + \frac{1}{\overline{T}^{i-1}}$, $\forall i \in \{2, \cdots, k\}$, *then*

$$c_i^{-1}\overline{\epsilon} \leq \frac{\epsilon}{\overline{T}^{k-i}}(2k+1).$$

Proof. For each $i \in [k]$,

$$c_i^{-1}\overline{\epsilon} = c_i^{-1}\epsilon \sum_{j=1}^{k} \frac{c_j}{\overline{T}^{k-j}} = \frac{\epsilon}{\overline{T}^{k-i}} \sum_{j=1}^{k} \frac{c_j c_i^{-1}}{\overline{T}^{i-j}}$$

We can lower bound the term $\frac{c_j c_i^{-1}}{\overline{T}^{i-j}}$ as follows,

$$\begin{aligned}
\frac{c_j c_i^{-1}}{\overline{T}^{i-j}} &= \frac{\sum_{l=j}^{k} L_l^{(j-1)/l} + \frac{1}{\overline{T}^{j-1}}}{\overline{T}^{i-j}(\sum_{l=i}^{k} L_l^{(i-1)/l} + \frac{1}{\overline{T}^{i-1}})} \\
&= \frac{\sum_{l=j}^{k} L_l^{(j-1)/l} + \frac{1}{\overline{T}^{j-1}}}{\sum_{l=i}^{k} \overline{T}^{i-j} L_l^{(i-1)/l} + \frac{1}{\overline{T}^{j-1}}} \\
&\leq \frac{\sum_{l=j}^{k} L_l^{(j-1)/l} + \frac{1}{\overline{T}^{j-1}}}{\frac{1}{\overline{T}^{j-1}}} \\
&= 1 + \sum_{l=j}^{k} (L_l^{1/l}\overline{T})^{j-1}
\end{aligned}$$

Therefore, we have

$$\begin{aligned} c_i^{-1}\overline{\epsilon} &= \frac{\epsilon}{\overline{T}^{k-i}} \sum_{j=1}^{k} \frac{c_j c_i^{-1}}{\overline{T}^{i-j}} \\ &\leq \frac{\epsilon}{\overline{T}^{k-i}} \sum_{j=1}^{k} \left(1 + \sum_{l=j}^{k} (L_l^{1/l}\overline{T})^{j-1} \right) \\ &\leq \frac{\epsilon}{\overline{T}^{k-i}} \left(2k + \sum_{j=1}^{k} \left(\sum_{l=1}^{k} L_l^{1/l}\overline{T} \right)^j \right) \\ &\leq \frac{\epsilon}{\overline{T}^{k-i}} \left(2k + \sum_{j=1}^{k} (1/2)^j \right) \end{aligned}$$

where we used $\gamma_\varphi LT \leq 1/8$ at the end. Thus we complete the proof of Claim. □

Now, using the claim to (4.41), we have the error is

$$20(2k+1)\gamma_\varphi \frac{\epsilon}{\overline{T}^{k-i}} \leq 20(2k+1)\gamma_\varphi \frac{\epsilon}{T^{k-i}}.$$

To bound the number of iterations needed in the log term in Theorem 4.2.2, we note that

$$\begin{aligned} \int_0^T \|\overline{F}(\overline{x}(0), s)\| ds &= c_1 \left\| \int_0^T F(c_1^{-1}\overline{x}_1(0), c_2^{-1}\overline{x}_2(0), \cdots, c_k^{-1}\overline{x}_k(0), s) ds \right\| + T \cdot \sum_{i=1}^{k-1} c_{i+1} c_i^{-1} \|\overline{x}_i(t)\| \\ &= \left\| \int_0^T F(\frac{d^{k-1}}{dt^{k-1}}x(0), \frac{d^{k-2}}{dt^{k-2}}x(0), \cdots, x(0), s) ds \right\| + T \cdot \sum_{i=1}^{k-1} c_{i+1} \left\| \frac{d^{k-i}}{dt^{k-i}}x(0) \right\|. \end{aligned}$$

Note that

$$c_{i+1} \leq \sum_{j=1}^{k} L_j^{i/j} + \frac{1}{\overline{T}^i} \leq L^i + \frac{1}{\overline{T}^i} \leq \frac{2}{\overline{T}^i}$$

where we used $L\overline{T} \leq \frac{1}{2}$. Hence, the number of iterations we need is

$$O\left(D\log\left(\frac{1}{\overline{\epsilon}}\left(\left\|\int_0^T F(v_{k-1}, v_{k-2}, \cdots, v_0, s)ds\right\| + \sum_{i=1}^{k-1}\frac{\|v_i\|}{\overline{T}^{k-i-1}}\right)\right)\right)$$
$$= O\left(D\log\left(\frac{1}{\epsilon}\left(\overline{T}^{k-1}\cdot\left\|\int_0^T F(v_{k-1}, v_{k-2}, \cdots, v_0, s)ds\right\| + \sum_{i=1}^{k-1}\overline{T}^{i}\|v_i\|\right)\right)\right)$$

where we used $\overline{\epsilon} \geq \epsilon \cdot c_k \geq \frac{\epsilon}{\overline{T}^{k-1}}$. □

4.8 Deferred Proof for Cauchy Estimates (Section 4.6.3)

In this section, we provide the proofs of some core Lemmas/Claims used for proving Theorem 4.6.4.

Lemma 4.6.6. (Bounding multivariate ODE by scalar ODE). Given vectors $v_1, v_0 \in \mathbb{R}^d$ and any norm $\|\cdot\|$ on $\mathbb{R}^d$. Let $U \subset \mathbb{R}^d$ be a neighborhood of v_0 and that $F : U \to \mathbb{R}^d$ is a real analytic near v_0. Suppose that

$$\|D^{(k)}F(v_0)[\Delta_1, \Delta_2, \cdots, \Delta_k]\| \leq f^{(k)}(0) \prod_{j=1}^{k} \|\Delta_j\| \text{ for all } k \geq 0$$

for some real analytic function f around 0. Then the ODE (4.39) has a unique real analytic solution around $t = 0$. Furthermore, for any $b \geq \|v_1\|$, we have

$$\|u^{(k)}(0)\| \leq \psi^{(k)}(0) \quad \forall k \geq 1$$

where ψ is the solution of the ODE

$$\psi''(t) = f(\psi(t)), \psi'(0) = b, \psi(0) = 0.$$

Proof. Theorem 4.6.5 shows that the solution u uniquely exists and is real analytic around 0. Therefore, we can take derivatives on both sides of $u''(t) = F(u(t))$ and get

$$\begin{aligned}
u^{(3)}(t) &= DF(u(t))[u^{(1)}(t)], \\
u^{(4)}(t) &= DF(u(t))[u^{(2)}(t)] + D^2F(u(t))[u^{(1)}(t), u^{(1)}(t)] \\
u^{(5)}(t) &= DF(u(t))[u^{(3)}(t)] + 2D^2F(u(t))[u^{(2)}(t), u^{(1)}(t)] + D^3F(u(t))[u^{(1)}(t), u^{(1)}(t), u^{(1)}(t)] \\
&\vdots = \vdots
\end{aligned}$$

Therefore, we have

$$\begin{aligned}
\|u^{(3)}(0)\| &= \|DF(u(0))[u^{(1)}(0)]\| \\
&\leq f^{(1)}(0)\|u^{(1)}(0)\| \\
\|u^{(4)}(0)\| &= \|DF(u(0))[u^{(2)}(0)] + D^2F(u(0))[u^{(1)}(0), u^{(1)}(0)]\| \\
&\leq \|DF(u(0))[u^{(2)}(0)]\| + \|D^2F(u(0))[u^{(1)}(0), u^{(1)}(0)]\| \\
&\leq f^{(1)}(0)\|u^{(2)}(0)\| + f^{(2)}(0)\|u^{(1)}(0)\|^2 \\
\|u^{(5)}(0)\| &= \|DF(u(0))[u^{(3)}(0)] + 2D^2F(u(0))[u^{(2)}(0), u^{(1)}(0)] \\
&\quad + D^3F(u(0))[u^{(1)}(0), u^{(1)}(0), u^{(1)}(0)]\| \\
&\leq \|DF(u(0))[u^{(3)}(0)]\| + \|2D^2F(u(0))[u^{(2)}(0), u^{(1)}(0)]\| \\
&\quad + \|D^3F(u(0))[u^{(1)}(0), u^{(1)}(0), u^{(1)}(0)]\| \\
&\leq f^{(1)}(0)\|u^{(3)}(0)\| + 2f^{(2)}(0)\|u^{(2)}(0)\|\|u^{(1)}(0)\| + f^{(3)}(0)\|u^{(1)}(0)\|^3 \\
&\vdots = \vdots
\end{aligned}$$

Similarly, Theorem 4.6.5 shows that the solution ψ uniquely exists and is real analytic around 0. By expanding $\psi''(t) = f(\psi(t))$ at $t = 0$, we see that

$$\begin{aligned}
\psi^{(3)}(0) &= f^{(1)}(0)\psi^{(1)}(0), \\
\psi^{(4)}(0) &= f^{(1)}(0)\psi^{(2)}(0) + f^{(2)}(0)(\psi^{(1)}(0))^2, \\
\psi^{(5)}(0) &= f^{(1)}(0)\psi^{(3)}(0) + 2f^{(2)}\psi^{(2)}(0)\psi^{(1)}(0) + f^{(3)}(0)(\psi^{(1)}(0))^3, \\
&\vdots = \vdots
\end{aligned}$$

Since $\|u^{(1)}(0)\| \leq b = \psi^{(1)}(0)$, $\|u^{(2)}(0)\| = \|F(u(0))\| \leq f(0) = \psi^{(2)}(0)$.

For $k = 3, 4, 5, \cdots$, we have

$$\begin{aligned}
\|u^{(3)}(0)\| &\leq f^{(1)}(0)\|u^{(1)}(0)\| = f^{(1)}(0)\psi^{(1)}(0) = \psi^{(3)}(0) \\
\|u^{(4)}(0)\| &\leq \psi^{(4)}(0) \\
\|u^{(5)}(0)\| &\leq \psi^{(5)}(0) \\
\vdots &\leq \vdots
\end{aligned}$$

Thus, we have that $\|u^{(k)}(0)\| \leq \psi^{(k)}(0)$ for all $k \geq 1$.

□

Lemma 4.6.7. (Bounding scalar ODE) Let $f(x) = \frac{a}{1-cx}$ with positive a and c. Let $\psi(t)$ denote the solution of the ODE

$$\psi''(t) = f(\psi(t)), \psi'(0) = b, \psi(0) = 0$$

with $b \geq 0$. Then,

$$\psi^{(k)}(0) \leq \frac{k!\alpha^k}{c} \quad \forall k \geq 1$$

with $\alpha = \max(\sqrt{\frac{4}{3}ac}, 2bc)$.

Proof. Let $\widetilde{\psi}(t) = \frac{1}{c}\left(1 - \sqrt{1 - \alpha t}\right)$ with $\alpha = \max(\sqrt{\frac{4}{3}ac}, 2bc)$. Note that

$$\widetilde{\psi}''(t) = \frac{\alpha^2}{4c(1-\alpha t)^{3/2}} = \widetilde{f}(\widetilde{\psi}(t)) \quad \text{with} \quad \widetilde{f}(x) = \frac{\alpha^2}{4c(1-cx)^3}.$$

Since $\alpha^2 \geq \frac{4}{3}ac$, we have that

$$\widetilde{f}^{(k)}(0) = \frac{a}{3} \cdot \frac{(k+2)!}{2} c^k \geq k! \cdot a \cdot c^k = f^{(k)}(0).$$

Also, we have that $\widetilde{\psi}(0) = 0$ and $\widetilde{\psi}'(0) = \frac{\alpha}{2c} \geq b$. Hence, Lemma 4.6.6 shows that

$$\psi^{(k)}(0) \leq \widetilde{\psi}^{(k)}(0) = \frac{\alpha^k}{c} \prod_{i=1}^{k} \frac{|2i-3|}{2} \leq \frac{k!\alpha^k}{c}$$

for all $k \geq 1$. □

4.9 Cauchy Estimates of Some Functions

We first state a useful tool,

Lemma 4.9.1. *Let $f : U \to \mathbb{C}$ be holomorphic and suppose that $D_R = \{z \ : \ |z - z_0| \leq R\} \subset U$. Let $\gamma_R = \{z \ : \ |z - z_0| = R\}$ denote the boundary of D_R. For all $n \geq 0$*

$$|f^{(n)}(z_0)| \leq \frac{n!}{R^n} \max_{z \in \gamma_R} |f(z)|.$$

4.9.1 Logistic loss function

Lemma 4.9.2 (Property of Logistic loss function)**.** *Let $\phi(t) = \log(1 + e^{-t})$, then we know that $\phi'(t)$ has Cauchy estimate $M = 1$ with radius $r = 1$.*

Proof. Given the definition of $\phi(t)$, it is easy to see that

$$\phi'(t) = \frac{-1}{1 + e^t}.$$

Let $f(z) = \frac{1}{1+e^z}$. Let $z = a + b\mathbf{i}$. We have

$$|f(z)| = \left| \frac{1}{1 + e^a \cos b + \mathbf{i} e^a \sin b} \right| = \frac{1}{\sqrt{(1 + e^a \cos b)^2 + (e^a \sin b)^2}} = \frac{1}{\sqrt{1 + 2e^a \cos b + e^{2a}}}$$

Let $z_0 = a_0 + \mathbf{i} b_0$. We choose $R = 1$, then $(a - a_0)^2 + (b - b_0)^2 = 1$. Since we only care about real numbers, we have $b_0 = 0$. Then we know that $b \in [-1, 1]$, which means $\cos b \in [0.54, 1]$. Thus, we have,

$$\sqrt{1 + 2e^a \cos b + e^{2a}} \geq \sqrt{1 + e^a + e^{2a}} \geq 1.$$

Thus, $\left|\frac{1}{1+e^z}\right| \leq 1$. Therefore, using Lemma 4.9.1, for all real z_0,

$$|f^{(n)}(z_0)| \leq n!$$

□

4.9.2 Pseudo-Huber loss function

Huber function [Hub64] has been extensively studied in a large number of algorithmic questions, e.g. regression [CW15b, CW15a], low-rank approximation [SWZ19b], clustering [BFL16], sparse recovery [NSW19a]. Formally speaking, the Huber loss function can be defined as

$$f(x) = \begin{cases} \frac{x^2}{2\delta}, & \text{if } |x| \leq \delta; \\ |x| - \delta/2, & \text{otherwise .} \end{cases}$$

where $\delta > 0$ is a parameter. For many applications, the Pseudo-Huber loss function can be used as a smooth alternative for the Huber loss function.

Lemma 4.9.3 (Property of Pseudo-Huber function)**.** *Fix any $\delta > 0$. Let $\phi(x) = \sqrt{x^2 + \delta^2} - \delta$, then we know that $\phi'(x)$ has Cauchy estimate $M = 1$ with radius $r = \delta/2$.*

Proof. Given the definition of function $\phi(x)$, it is easy to see that

$$\phi'(x) = \frac{x}{\sqrt{x^2 + \delta^2}}$$

Let $f(z) = \frac{z}{\sqrt{z^2+\delta^2}}$. Let $z = a + b\mathbf{i}$. We have

$$|f(z)| = \left| \frac{(a+b\mathbf{i})}{\sqrt{(a+b\mathbf{i})^2 + \delta^2}} \right| = \left| \frac{(a+b\mathbf{i})}{\sqrt{a^2 - b^2 + \delta^2 + 2ab\mathbf{i}}} \right| = \frac{|(a+b\mathbf{i})|}{|\sqrt{a^2 - b^2 + \delta^2 + 2ab\mathbf{i}}|}$$

For the numerator, we have $|(a+b\mathbf{i})| = \sqrt{a^2 + b^2}$. For the denominator, we have

$$|\sqrt{a^2 - b^2 + \delta^2 + 2ab\mathbf{i}}| = \left((a^2 - b^2 + \delta^2)^2 + 4(ab)^2\right)^{1/4}$$

Let $z_0 = a_0 + \mathbf{i}b_0$. We choose $R = \frac{\delta}{2}$, then $(a - a_0)^2 + (b - b_0)^2 = (\delta/2)^2$. Since we are only real z_0, we have $b_0 = 0$. Then we know that $b \in [-\frac{\delta}{2}, \frac{\delta}{2}]$. Thus

$$|f(z)| = \frac{\sqrt{a^2 + b^2}}{((a^2 - b^2 + \delta^2)^2 + 4(ab)^4)^{1/4}} \leq \frac{\sqrt{a^2 + \frac{\delta^2}{4}}}{\left((a^2 - \frac{\delta^2}{4} + \delta^2)^2 + 0\right)^{1/4}} = \frac{\sqrt{a^2 + \frac{\delta^2}{4}}}{\sqrt{a^2 + \frac{3\delta^2}{4}}} \leq 1.$$

Therefore, using Lemma 4.9.1, for all real z_0,

$$|f^{(n)}(z_0)| \leq n! \cdot (2/\delta)^n.$$

□

Chapter 5

Convergence result of Deep Neural Network

Deep neural networks (DNNs) have demonstrated dominating performance in many fields; since AlexNet, networks used in practice are going wider and deeper. On the theoretical side, a long line of works has been focusing on training neural networks with one hidden layer. The theory of multi-layer networks remains largely unsettled.

In this work, we prove why stochastic gradient descent (SGD) can find *global minima* on the training objective of DNNs in *polynomial time*. We only make two assumptions: the inputs are non-degenerate and the network is over-parameterized. The latter means the network width is sufficiently large: *polynomial* in L, the number of layers and in n, the number of samples.

Our key technique is to derive that, in a sufficiently large neighborhood of the random initialization, the optimization landscape is almost-convex and semi-smooth even with ReLU activations. This implies an equivalence between over-parameterized neural networks and neural tangent kernel (NTK) in the finite (and polynomial) width setting.

As concrete examples, starting from randomly initialized weights, we prove that SGD can attain 100% training accuracy in classification tasks, or minimize regression loss in linear convergence speed, with running time polynomial in n, L. Our theory applies to the widely-used but non-smooth ReLU activation, and to any smooth and possibly non-

convex loss functions. In terms of network architectures, our theory at least applies to fully-connected neural networks, convolutional neural networks (CNN), and residual neural networks (ResNet).

5.1 Introduction

Neural networks have demonstrated a great success in numerous machine-learning tasks [KSH12, GMH13, LHP+15, AAA+16, HZRS16, SHM+16, SSS+17]. One of the empirical findings is that neural networks, trained by first-order methods from random initialization, have a remarkable ability to fit training data [ZBH+17].

From an *expressibility* perspective, this may not be surprising since modern neural networks are often over-parameterized: they have much more parameters than the number of training samples. There certainly *exist* parameter choices with zero training error as long as data is non-degenerate.

Yet, from an optimization perspective, the fact that randomly-initialized first-order methods can find global minima on the training data is *quite non-trivial*: neural networks are often equipped with the ReLU activation, making the training objective not only non-convex, but even non-smooth. Even the general convergence for finding approximate critical points of a non-convex, non-smooth function is not fully-understood [BLO05] and appears to be a challenging question on its own. This is in direct contrast to practice, in which ReLU networks trained by stochastic gradient descent (SGD) from random initialization *almost never* suffer from non-smoothness or non-convexity, and can avoid local minima for a variety of network architectures (see [GVS15]). A theoretical justification was missing to explain this phenomenon.

There are quite a few papers trying to understand the success of neural networks from optimization perspective. Many of them focus on the case when the inputs are random Gaussian, and work only for two-layer neural networks [BG17, Son17, Tia17, LY17, DLT+18,

GLM17, PRSZ18, ZSJ+17, ZSD17]. [LL18] show that for a two-layer network with ReLU activation, SGD finds nearly-global optimal (say, 99% classification accuracy) solutions on the training data, as long as the network is *over-parameterized*, meaning that the number of neurons is polynomially large comparing to the input size. Moreover, if the data is sufficiently structured (say, coming from mixtures of separable distributions), this accuracy extends also to *test data*. As a separate note, over-parameterization is suggested as the possible key to avoid bad local minima by [SS18] even for two-layer networks.

There are also results that go beyond two-layer networks with limitations. Some consider deep *linear* neural networks without any activation functions [HM17, ACGH18, BHL18, Kaw16]. [Dal17] studies multi-layer neural networks but essentially only with respect to the *convex* task of training the last layer.[1] [SC16] show that under over-parameterization and under random input perturbation, there is bad local minima for multi-layer neural networks. [JGH18] derive global convergence using neural tangent kernel for *infinite-width* neural networks.

In this paper, we study the following fundamental questions

Can DNN be trained close to zero training error efficiently under mild assumptions?

If so, can the running time depend only polynomially *in the network depth and input size?*

Motivation In 2012, AlexNet was born with 5 convolutional layers [KSH12]. The later VGG network uses 19 layers [SSZ14], and GoogleNet uses 22 layers [SLJ+15]. In practice, we

[1] [Dal17] works in a parameter regime where the weight changes of all layers except the last one make negligible contribution to the final output.

cannot go deeper by naively stacking layers together, due to the so-called vanishing/exploding gradient problem. To deal with this issue, networks with residual links (ResNet) were proposed with the capability of handling at least 152 layers [HZRS16]. Compared with practical networks that go much deeper, existing theory has been mostly around two-layer (thus one-hidden-layer) neural networks, even just for the training process alone. Thus,

Can we theoretically justify how the training process has worked for multi-layer neural networks?

In this paper, we extend the over-parameterization theory to *multi-layer* neural networks.

5.1.1 Our Result

We show that over-parameterized neural networks can be trained by vanilla first-order methods such as gradient descent (GD) or stochastic gradient descent (SGD) to global minima (e.g. *zero* training error), as long as the data is non-degenerate.

We say that the data is non-degenerate if every pairs of samples are distinct. This is a minimal requirement since a dataset with two identical data points of different labels cannot be trained to zero error. We denote by δ the minimum (relative) distance between two data points, and by n the number of training samples. Now, consider an L-layer fully-connected feedforward neural network, each hidden layer consisting of m neurons equipped with ReLU activation. We show that,

- As long as $m \geq \text{poly}(n, L, \delta^{-1})$, starting from random Gaussian initialization, GD/SGD finds an ϵ-error global minimum in ℓ_2 regression using at most $T = \text{poly}(n, L, \delta^{-1}) \log \frac{1}{\epsilon}$ iterations.

- If the task is multi-label classification, then GD/SGD finds an 100% accuracy classifier on the training set in $T = \text{poly}(n, L, \delta^{-1})$ iterations.

- Our result also applies to other Lipschitz-smooth loss functions, and some other network architectures including convolutional neural networks (CNNs) and residual networks (ResNet).

In contrast, prior work on this task either requires m and T to grow in $e^{O(L)}$ (and essentially only the last layer is trained) [Dal17]; or requires $m = \infty$ [JGH18].

Our Contributions We summarize our technical contributions below.

- For a sufficiently large neighborhood of the random initialization, we prove that the training landscape is almost convex and semi-smooth. This somewhat explains the empirical finding by [GVS15] that GD/SGD will not be trapped in local minima. (See Section 5.4.1.)

- For a sufficiently large neighborhood of the random initialization, we derive an equivalence between neural networks and the neural tangent kernel (NTK) introduced by [JGH18]. Unlike the prior work in which they show the equivalence only for infinite-width networks (i.e., $m = \infty$), here we only need $m = \text{poly}(L)$ for such an equivalence to hold. (See Section 5.4.2.)

- We show that equipped with ReLU activation, neural networks do not suffer from exponential gradient explosion or vanishing. This is the key reason we can avoid exponential dependency on L. If one is okay with $e^{O(L)}$ dependency, many proofs shall become trivial. (See Section 5.5.)

- We derive a stability theory of neural networks against small but adversarial perturbations that may be of independent interests. Previous results on this topic either have exponential blowup in L [Dal17] or requires the width to go to infinity [JGH18]. (See Section 5.5.)

- We derive our results by training only hidden layers. This can be more meaningful than training all the layers together, in which if one is not careful with parameter choices, the training process can degenerate as if only the last layer is trained [Dal17].

That is a convex task and may not reflect the true power of deep learning. (Of course, as a simple corollary, our results also apply to training all the layers together.)

Finally, we emphasize that this present paper as a deeply-simplified version of the recurrent neural network (RNN) paper [AZLS18] by the same set of authors. To some extent, DNN is a "special case" of RNN,[2] thus most of the technical tools were already developed in [AZLS18]. We write this DNN result as a separate paper because: (1) not all the readers can easily derive the DNN result from [AZLS18]; (2) the convergence of DNN can be important on its own; (3) the proof in this paper is much simpler (30 vs 80 pages) and could reach out to a wider audience; (4) the simplicity of this paper allows us to tighten parameters in some non-trivial ways; and (5) the simplicity of this paper allows us to also study convolutional networks, residual networks, as well as different loss functions (all of them were missing from [AZLS18]). We also note that the techniques of this paper can be combined with [AZLS18] to show the global convergence of training over-parameterized *deep* RNN. We ignore the details so as not to complicate this paper.

Towards Generalization In practice, deeper and wider neural networks generalize better [SGS15, ZK16], so what can we say in theory? Although this paper does not explicitly cover generalization to test data, since a neural network in our parameter regime simulates

[2] A recurrent neural network executed on input sequences with time horizon L is very similar to a feedforward neural network with L layers. The main difference is that in a feedforward network, weight matrices are different across layers, and thus independently randomly initialized; in contrast, in an RNN, the same weight matrix is applied across the entire time horizon, so we do not have fresh new randomness for proofs that involve in induction. In other words, the over-parameterized convergence theory of DNN is *much simpler* than that of RNN.

its neural tangent kernel (NTK), it is clear that neural networks provide generalization at least *as good as its NTK*.

In the PAC-learning language, one may study generalization with respect to *concept classes*. Follow-up work [ALL18c] shows that three-layer over-parameterized ReLU networks can efficiently (in polynomial time and sample complexity) learn the concept class of three-layer neural networks with smooth activations [ALL18c], and the follow-up work [AL19b] shows stronger results for three-layer ResNet.

It is worth pointing out that the three-layer result [ALL18c] goes beyond the almost-convex regime and thus is not captured by its NTK; more interestingly, the three-layer ResNet result [AL19b] is not achievable (in a provable sense) by any kernel method including any NTK.

A concurrent, independent and beautiful result We acknowledge a concurrent work [DLL+19] by Du, Lee, Li, Wang and Zhai. They proved a similar result.

5.1.2 Other Related Works

[LL18] originally prove their result for the cross-entropy loss, together with some test accuracy guarantee. (If data is "well-structured", they prove two-layer over-parameterized neural networks can learn it using SGD with polynomially many samples [LL18].) Later, the "training accuracy" part of [LL18] was extended to the ℓ_2 loss [DZPS19]. From another perspective, [DZPS19] focus on gradient descent.

Linear networks without activation functions are important subjects on its own. Besides the already cited references [HM17, ACGH18, BHL18, Kaw16], there are a number of works that study *linear dynamical systems*, which can be viewed as the linear version of recurrent neural networks or reinforcement learning. Recent works in this line of research include [HMR18, HSZ17, HLS+18, DMM+17, OO18, AAMM18, SMT+18, MT18, DTMR18, AHL+18].

There is sequence of work about one-hidden-layer (multiple neurons) CNN [BG17, ZSD17, DLT+18, GKM18, Oym18]. Whether the patches overlap or not plays a crucial role in analyzing algorithms for such CNN. One category of the results have required the patches to be disjoint [BG17, ZSD17, DLT+18]. The other category [GKM18, Oym18] have figured out a weaker assumption or even removed that patch-disjoint assumption. On input data distribution, most relied on inputs being Gaussian [BG17, ZSD17, DLT+18, Oym18], and some assumed inputs to be symmetrically distributed with identity covariance and boundedness [GKM18].

As for ResNet, [LY17] proved that SGD learns one-hidden-layer residual neural networks under Gaussian input assumption. The techniques in [ZSJ+17, ZSD17] can also be

generalized to one-hidden-layer ResNet under the Gaussian input assumption; they can show that GD starting from good initialization point (via tensor initialization) learns ResNet. [HM17] deep *linear* residual networks have no spurious local optima.

If no assumption is allowed, neural networks have been shown hard in several different perspectives. Thirty years ago, [BR93] first proved that learning the neural network is NP-complete. Stronger hardness results have been proved over the last decade [KS09, LSSS14, Dan16, DSS16, GKKT17, SVWX17, MR18].

5.2 Preliminaries

We use $\mathcal{N}(\mu, \sigma)$ to denote the Gaussian distribution of mean μ and variance σ; and $\mathcal{B}(m, \frac{1}{2})$ to denote the binomial distribution with m trials and $1/2$ success rate. We use $\|v\|_2$ or $\|v\|$ to denote Euclidean norms of vectors v, and $\|M\|_2, \|M\|_F$ to denote spectral and Frobenius norms of matrices M. For a tuple $\overrightarrow{W} = (W_1, \ldots, W_L)$ of matrices, we let $\|\overrightarrow{W}\|_2 = \max_{\ell \in [L]} \|W_\ell\|_2$ and $\|\overrightarrow{W}\|_F = (\sum_{\ell=1}^{L} \|W_\ell\|_F^2)^{1/2}$.

We use $\phi(x) = \max\{0, x\}$ to denote the ReLU function, and extend it to vectors $v \in \mathbb{R}^m$ by letting $\phi(v) = (\phi(v_1), \ldots, \phi(v_m))$. We use $\mathbb{1}_{event}$ to denote the indicator function for *event*.

The training data consist of vector pairs $\{(x_i, y_i^*)\}_{i \in [n]}$, where each $x_i \in \mathbb{R}^{\mathfrak{d}}$ is the feature vector and y_i^* is the label of the i-th training sample. We assume *without loss of generality* that data are normalized so that $\|x_i\| = 1$ and its last coordinate $(x_i)_{\mathfrak{d}} = \frac{1}{\sqrt{2}}$.[3] We also assume $\|y_i^*\| \leq O(1)$ for notation simplicity.[4]

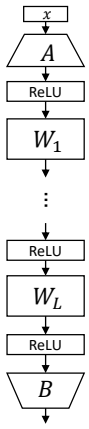
We make the following separable assumption on the training data (motivated by [LL18]):

Assumption 5.2.1. *For every pair $i, j \in [n]$, we have $\|x_i - x_j\| \geq \delta$.*

[3] Without loss of generality, one can re-scale and assume $\|x_i\| \leq 1/\sqrt{2}$ for every $i \in [n]$. Again, without loss of generality, one can pad each x_i by an additional coordinate to ensure $\|x_i\| = 1/\sqrt{2}$. Finally, without loss of generality, one can pad each x_i by an additional coordinate $\frac{1}{\sqrt{2}}$ to ensure $\|x_i\| = 1$. This last coordinate $\frac{1}{\sqrt{2}}$ is equivalent to introducing a (random) bias term, because $A(\frac{y}{\sqrt{2}}, \frac{1}{\sqrt{2}}) = \frac{A}{\sqrt{2}}(y, 0) + b$ where $b \sim \mathcal{N}(0, \frac{1}{m} I)$. In our proofs, the specific constant $\frac{1}{\sqrt{2}}$ does not matter.

[4] If $\|y_i^*\| \leq \Omega$ for some parameter Ω, our complexities shall also grow in poly(Ω).

To present the simplest possible proof, the main body of this paper only focuses on depth-L feedforward fully-connected neural networks with an ℓ_2-regression task. Therefore, each $y_i^* \in \mathbb{R}^d$ is a target vector for the regression task. We explain how to extend it to more general settings in Section 5.6 and the Appendix. For notational simplicity, we assume all the hidden layers have the same number of neurons, and our results trivially generalize to each layer having different number of neurons. Specifically, we focus on the following network



$$
\begin{aligned}
g_{i,0} &= Ax_i & h_{i,0} &= \phi(Ax_i) & &\text{for } i \in [n] \\
g_{i,\ell} &= W_\ell h_{i,\ell-1} & h_{i,\ell} &= \phi(W_\ell h_{i,\ell-1}) & &\text{for } i \in [n], \ell \in [L] \\
y_i &= Bh_{i,L} & & & &\text{for } i \in [n]
\end{aligned}
$$

where $A \in \mathbb{R}^{m \times \mathfrak{d}}$ is the weight matrix for the input layer, $W_\ell \in \mathbb{R}^{m \times m}$ is the weight matrix for the ℓ-th hidden layer, and $B \in \mathbb{R}^{d \times m}$ is the weight matrix for the output layer. For notational convenience in the proofs, we may also use $h_{i,-1}$ to denote x_i and W_0 to denote A.

Definition 5.2.1 (diagonal sign matrix)**.** For each $i \in [n]$ and $\ell \in \{0, 1, \ldots, L\}$, we denote by $D_{i,\ell}$ the diagonal sign matrix where $(D_{i,\ell})_{k,k} = \mathbb{1}_{(W_\ell h_{i,\ell-1})_k \geq 0}$ for each $k \in [m]$.

As a result, we have $h_{i,\ell} = D_{i,\ell} W_\ell h_{i,\ell-1} = D_{i,\ell} g_{i,\ell}$ and $(D_{i,\ell})_{k,k} = \mathbb{1}_{(g_{i,\ell})_k \geq 0}$. We make the following standard choices of random initialization:

Definition 5.2.2. We say that $\overrightarrow{W} = (W_1, \ldots, W_L)$, A and B are at random initialization if

- $[W_\ell]_{i,j} \sim \mathcal{N}(0, \frac{2}{m})$ for every $i, j \in [m]$ and $\ell \in [L]$;

- $A_{i,j} \sim \mathcal{N}(0, \frac{2}{m})$ for every $(i,j) \in [m] \times [\mathfrak{d}]$; and
- $B_{i,j} \sim \mathcal{N}(0, \frac{1}{d})$ for every $(i,j) \in [d] \times [m]$.

Assumption 5.2.2. *Throughout this paper we assume $m \geq \Omega\big(\operatorname{poly}(n, L, \delta^{-1}) \cdot d\big)$ for some sufficiently large polynomial. To present the simplest proof, we did not try to improve such polynomial factors. We will also assume $\delta \leq O(\frac{1}{L})$ for notation simplicity.*

5.2.1 Objective and Gradient

Our regression objective is

$$F(\overrightarrow{W}) \stackrel{\text{def}}{=} \sum_{i=1}^{n} F_i(\overrightarrow{W}) \quad \text{where} \quad F_i(\overrightarrow{W}) \stackrel{\text{def}}{=} \frac{1}{2}\|Bh_{i,L} - y_i^*\|^2 \quad \text{for each } i \in [n]$$

We also denote by $\mathsf{loss}_i \stackrel{\text{def}}{=} Bh_{i,L} - y_i^*$ the *loss vector* for sample i. For simplicity, we focus on training only hidden weights $\overrightarrow{W}$ in this paper and leave A and B at random initialization. Our result naturally extends to the case when A, B and $\overrightarrow{W}$ are jointly trained.[5]

Definition 5.2.3. For each $\ell \in \{1, 2, \cdots, L\}$, we define $\mathsf{Back}_{i,\ell} \stackrel{\text{def}}{=} BD_{i,L}W_L \cdots D_{i,\ell}W_\ell \in \mathbb{R}^{d\times m}$ and for $\ell = L+1$, we define $\mathsf{Back}_{i,\ell} = B \in \mathbb{R}^{d\times m}$.

Using this notation, one can calculate the gradient of $F(\overrightarrow{W})$ as follows.

Fact 5.2.3. *The gradient with respect to the k-th row of $W_\ell \in \mathbb{R}^{m\times m}$ is*

$$\nabla_{[W_\ell]_k} F(\overrightarrow{W}) = \textstyle\sum_{i=1}^n (\mathsf{Back}_{i,\ell+1}^\top \mathsf{loss}_i)_k \cdot h_{i,\ell-1} \cdot \mathbb{1}_{\langle [W_\ell]_k, h_{i,\ell-1}\rangle \geq 0}$$

The gradient with respect to W_ℓ is

$$\nabla_{W_\ell} F(\overrightarrow{W}) = \textstyle\sum_{i=1}^n D_{i,\ell}(\mathsf{Back}_{i,\ell+1}^\top \mathsf{loss}_i) h_{i,\ell-1}^\top$$

We denote by $\nabla F(\overrightarrow{W}) = \big(\nabla_{W_1} F(\overrightarrow{W}), \ldots, \nabla_{W_L} F(\overrightarrow{W})\big)$.

[5] We note that if one jointly trains all the layers, in certain parameter regimes, it may be equivalent to as if only the last layer is trained [Dal17]. We therefore choose to fix the last layer B to avoid such confusion.

5.3 Our Results and Techniques

To present our result in the simplest possible way, we choose to mainly focus on fully-connected L-layer neural networks with the ℓ_2 regression loss. We shall extend it to more general settings (such as convolutional and residual networks and other losses) in Section 5.6. Our main results can be stated as follows:

Theorem 5.3.1 (gradient descent)**.** *Suppose* $m \geq \widetilde{\Omega}\big(\operatorname{poly}(n, L, \delta^{-1}) \cdot d\big)$*. Starting from random initialization, with probability at least* $1 - e^{-\Omega(\log^2 m)}$*, gradient descent with learning rate* $\eta = \Theta\big(\frac{d\delta}{\operatorname{poly}(n,L)\cdot m}\big)$ *finds a point* $F(\overrightarrow{W}) \leq \epsilon$ *in* $T = \Theta\big(\frac{\operatorname{poly}(n,L)}{\delta^2} \cdot \log \epsilon^{-1}\big)$ *iterations.*

This is known as the linear convergence rate because ϵ drops exponentially fast in T. We have not tried to improve the polynomial factors in m and T, and are aware of several ways to improve these factors (but at the expense of complicating the proof). We note that $\mathfrak{d}$ is the data input dimension and our result is independent of $\mathfrak{d}$.

Theorem 5.3.2 (SGD)**.** *Suppose* $b \in [n]$ *and* $m \geq \widetilde{\Omega}\big(\frac{\operatorname{poly}(n,L,\delta^{-1})\cdot d}{b}\big)$*. Starting from random initialization, with probability at least* $1 - e^{-\Omega(\log^2 m)}$*, SGD with learning rate* $\eta = \Theta\big(\frac{b\delta d}{\operatorname{poly}(n,L) m \log^2 m}\big)$ *and mini-batch size* b *finds* $F(\overrightarrow{W}) \leq \epsilon$ *in* $T = \Theta\big(\frac{\operatorname{poly}(n,L)\cdot \log^2 m}{\delta^2 b} \cdot \log \epsilon^{-1}\big)$ *iterations.*

This is again a linear convergence rate because $T \propto \log \frac{1}{\epsilon}$. The reason for the additional $\log^2 m$ factor comparing to Theorem 5.13.1 is because we have a $1-e^{-\Omega(\log^2 m)}$ high confidence bound.

Remark 5.3.1. For experts in optimization theory, one may immediately question the accuracy of Theorem 5.14.1, because SGD is known to converge at a slower rate $T \propto \frac{1}{\operatorname{poly}(\epsilon)}$ even

for convex functions. There is no contradiction here. Imaging a strongly convex function $f(x) = \sum_{i=1}^{n} f_i(x)$ that has a common minimizer $x^* \in \text{argmin}_x\{f_i(x)\}$ for every $i \in [n]$, then SGD is known to converge in a linear convergence rate.

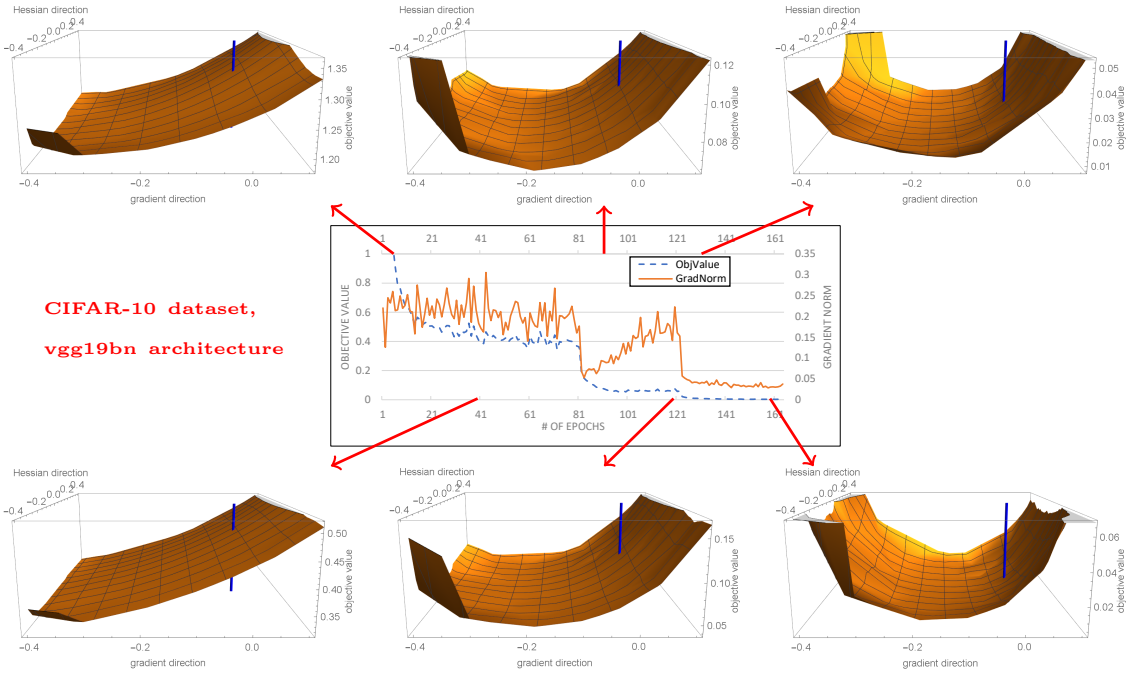


Figure 5.1: Landscapes of the CIFAR10 image-classification training objective $F(W)$ near the SGD training trajectory. The blue vertical stick marks the current point $W = W_t$ at the current iteration t. The x and y axes represent the gradient direction $\nabla F(W_t)$ and the most negatively curved direction of the Hessian after smoothing (approximately found by Oja's method [AL17, AL18]). The z axis represents the objective value. **Observation.** As far as minimizing objective is concerned, the (negative) gradient direction sufficiently decreases the training objective, and it is not needed to use second-order method to find negative curvature. This is consistent with our findings Theorem 5.11.1 and 5.12.1. Remark 1. Gradient norm does not tend to zero because cross-entropy loss is not strongly convex (see Section 5.6). Remark 2. The task is CIFAR10 (for CIFAR100 or CIFAR10 with noisy label, see Figure 5.2 through 5.7 in appendix). Remark 3. Architecture is VGG19 (for Resnet-32 or ResNet-110, see Figure 5.2 through 5.7 in the later sections). Remark 4. The six plots correspond to epochs 5, 40, 90, 120, 130 and 160. We start with learning rate 0.1, and decrease it to 0.01 at epoch 81, and to 0.001 at epoch 122. SGD with momentum 0.9 is used. The training code is unchanged from [Yan18] and we only write new code for plotting such landscapes.

5.4 Conceptual Messages and Technical Theorems

We highlight two conceptual messages that arise from the proofs of Theorem 5.13.1 and 5.14.1.

5.4.1 Objective is Almost Convex and Semi-Smooth

The first message is about the optimization landscape for points that are sufficiently close to the random initialization. It consists of two theorems, Theorem 5.11.1 says that the objective is "almost convex" and Theorem 5.12.1 says that the objective is "semi-smooth."

Theorem 5.4.1 (no critical point)**.** *With probability* $\geq 1 - e^{-\Omega(m/\operatorname{poly}(n,L,\delta^{-1}))}$ *over randomness* $\overrightarrow{W}^{(0)}, A, B$*, it satisfies for every* $\ell \in [L]$*, every* $i \in [n]$*, and every* $\overrightarrow{W}$ *with* $\|\overrightarrow{W} - \overrightarrow{W}^{(0)}\|_2 \leq \frac{1}{\operatorname{poly}(n,L,\delta^{-1})}$*,*

$$\|\nabla F(\overrightarrow{W})\|_F^2 \leq O\Big(F(\overrightarrow{W}) \times \frac{Lnm}{d}\Big) \quad \textit{and} \quad \|\nabla F(\overrightarrow{W})\|_F^2 \geq \Omega\Big(F(\overrightarrow{W}) \times \frac{\delta m}{dn^2}\Big) \ .$$

The first property above is easy to prove, while the second property above says that as long as the objective is large, the gradient norm is also large. (See also Figure 5.1.) This means, when we are sufficiently close to the random initialization, there is no saddle point or critical point of any order.

Theorem 5.11.1 gives us hope to find *global minima* of the objective $F(\overrightarrow{W})$, but is not enough. If we follow the negative gradient direction of $F(\overrightarrow{W})$, how can we guarantee that the objective truly decreases? Classical optimization theory usually relies on objective's (Lipscthiz) smoothness [Nes04] to derive an objective-decrease guarantee. Unfortunately, smoothness property at least requires the objective to be twice differentiable, but ReLU activation is not. To deal with this issue, we prove the following.

Theorem 5.4.2 (semi-smoothness)**.** *With probability at least* $1 - e^{-\Omega(m/\operatorname{poly}(L,\log m))}$ *over the randomness of* $\overrightarrow{W}^{(0)}, A, B$*, we have: for every* $\breve{\overrightarrow{W}} \in (\mathbb{R}^{m\times m})^L$ *with* $\|\breve{\overrightarrow{W}} - \overrightarrow{W}^{(0)}\|_2 \leq \frac{1}{\operatorname{poly}(L,\log m)}$*,*

and for every $\overrightarrow{W}' \in (\mathbb{R}^{m\times m})^L$ *with* $\|\overrightarrow{W}'\|_2 \le \frac{1}{\mathrm{poly}(L,\log m)}$*, the following inequality holds*

$$F(\overrightarrow{\breve{W}}+\overrightarrow{W}') \le F(\overrightarrow{\breve{W}}) + \langle \nabla F(\overrightarrow{\breve{W}}), \overrightarrow{W}'\rangle + \frac{\mathrm{poly}(L)\sqrt{nm\log m}}{\sqrt{d}} \cdot \|\overrightarrow{W}'\|_2 \big(F(\overrightarrow{\breve{W}})\big)^{1/2} + O\big(\frac{nL^2m}{d}\big)\|\overrightarrow{W}'\|_2^2$$

Different from classical smoothness, we still have a first-order term $\|\overrightarrow{W}'\|_2$ on the right hand side, while classical smoothness only has a second-order term $\|\overrightarrow{W}'\|_2^2$. As one can see in our final proofs, as m goes larger, the effect of the first-order term becomes smaller comparing to the second-order term. This brings Theorem 5.12.1 closer, but still not identical, to the classical Lipschitz smoothness.

Back to Theorem 5.13.1 and 5.14.1 The derivation of Theorem 5.13.1+5.14.1 from Theorem 5.11.1+5.12.1 is quite straightforward, and can be found in Section 5.13 and 5.14. At a high level, we show that GD/SGD can converge fast enough so that the weights stay close to random initialization by spectral norm bound $\frac{1}{\mathrm{poly}(n,L,\delta^{-1})}$. This ensures Theorem 5.11.1 and 5.12.1 both apply.[6]

In practice, one often goes beyond this theory-predicted spectral-norm boundary. However, quite interestingly, we still observe Theorem 5.11.1 and 5.12.1 hold in practice (see Figure 5.1). The gradient is sufficiently large and going in its negative direction can indeed decrease the objective.

[6]This spectral norm bound seems small, but is in fact quite large: it can totally change the outputs and fit the training data, because weights are randomly initialized (per entry) at around $\frac{1}{\sqrt{m}}$ for m being large.

5.4.2 Equivalence to Neural Tangent Kernel

Recall on input $x \in \mathbb{R}^{\mathfrak{d}}$, the network output $y(\overrightarrow{W}; x) \stackrel{\text{def}}{=} y = Bh_L \in \mathbb{R}^d$ is a function of the weights $\overrightarrow{W}$. Let us here focus on $d = 1$ for notational simplicity and leave $d > 1$ to the appendix. The *neural tangent kernel (NTK)* [JGH18] is usually referred to as the feature space defined by the network gradient at random initialization. In other words,

- Given two inputs $x, \widetilde{x} \in \mathbb{R}^{\mathfrak{d}}$, the NTK kernel function is given as

$$K^{\mathsf{ntk}}(x, \widetilde{x}) \stackrel{\text{def}}{=} \langle \nabla y(\overrightarrow{W}^{(0)}; x), \nabla y(\overrightarrow{W}^{(0)}; \widetilde{x}) \rangle$$

- Given weight matrix tuple $\overrightarrow{W}'$, the NTK model computes (we call the NTK objective)

$$y^{\mathsf{ntk}}(\overrightarrow{W}'; x) \stackrel{\text{def}}{=} \langle \nabla y(\overrightarrow{W}^{(0)}; x), \overrightarrow{W}' \rangle = \textstyle\sum_{\ell=1}^{L} \langle \nabla_{W_\ell} y(\overrightarrow{W}^{(0)}; x), W'_\ell \rangle \ .$$

In contrast, the dynamic NTK is given by arbitrary weight tuple $\overrightarrow{W} = \overrightarrow{W}^{(0)} + \overrightarrow{W}'$ that may not be at random initialization. [JGH18] proved in their original paper that, when m is infinite, dynamic NTK and NTK are identical because during the training process $\lim_{m\to\infty} \|\overrightarrow{W}'\|_2 = 0$ if $\overrightarrow{W} = \overrightarrow{W}^{(0)} + \overrightarrow{W}'$ is output of gradient descent.

In this paper, we complement [JGH18] by showing a *polynomial* bound on this equivalence, for *any* point that is within a certain ball of $\overrightarrow{W}^{(0)}$. It is a simple corollary of Theorem 5.11.1 and Theorem 5.12.1, but we state it independently here since it may be of additional interest.[7]

[7] Although Theorem 5.15.1 was not explicitly stated until version 5 of this paper, its proof was fully contained in the proofs of Theorem 5.13.1 and 5.14.1. Since some readers cannot find it, we state it here as a separate theorem.

Theorem 5.4.3. *Let $\overrightarrow{W}^{(0)}, A, B$ be at random initialization. For fixed unit vectors $x, \widetilde{x} \in \mathbb{R}^{\mathfrak{d}}$, every (small) parameter $\omega \leq \frac{1}{\mathrm{poly}(L, \log m)}$, with probability at least $1 - e^{-\Omega(m\omega^{2/3}L)}$ over $\overrightarrow{W}^{(0)}, A, B$, we have for all $\overrightarrow{W}'$ with $\|\overrightarrow{W}'\|_2 \leq \omega$,*

(a) $\|\nabla y(\overrightarrow{W}^{(0)} + \overrightarrow{W}'; x) - \nabla y^{\mathsf{ntk}}(\overrightarrow{W}'; x)\|_F \leq \widetilde{O}\big(\omega^{1/3} L^3\big) \cdot \|\nabla y^{\mathsf{ntk}}(\overrightarrow{W}'; x)\|_F$;

(b) $y(\overrightarrow{W}^{(0)} + \overrightarrow{W}'; x) = y(\overrightarrow{W}^{(0)}; x) + y^{\mathsf{ntk}}(\overrightarrow{W}'; x) \pm \widetilde{O}\big(L^3 \omega^{4/3} \sqrt{m}\big)$; *and*

(c) $\big\langle \nabla y(\overrightarrow{W}^{(0)} + \overrightarrow{W}'; x), \nabla y(\overrightarrow{W}^{(0)} + \overrightarrow{W}'; \widetilde{x}) \big\rangle = K^{\mathsf{ntk}}(x, \widetilde{x}) \pm \widetilde{O}\big(\omega^{1/3} L^3\big) \cdot \sqrt{K^{\mathsf{ntk}}(x, x) K^{\mathsf{ntk}}(\widetilde{x}, \widetilde{x})}$.

Theorem 5.15.1a and 5.15.1c says that dynamic NTK and NTK are almost equivalent up to a small multiplicative factor as long as $\omega < \frac{1}{\mathrm{poly}(L, \log m)}$; while Theorem 5.15.1b says that the NTK objective is almost exactly the first-order approximation of the neural network output as long as $\omega < \frac{1}{m^{3/8}\,\mathrm{poly}(L)}$.

In comparison, in Theorem 5.13.1 and 5.14.1, GD/SGD outputs $\overrightarrow{W}'$ satisfying $\omega \leq \frac{\mathrm{poly}(n, \delta^{-1})}{\sqrt{m}} \ll \frac{1}{m^{3/8}\,\mathrm{poly}(L)}$ under the assumption $m \geq \mathrm{poly}(n, L, \delta^{-1})$.[8] Thus, Theorem 5.15.1b implies $\overrightarrow{W}'$ is also a solution to the NTK regression objective.

Remark 5.4.1. If one wishes to have $y(\overrightarrow{W}^{(0)} + \overrightarrow{W}'; x) \approx y^{\mathsf{ntk}}(\overrightarrow{W}'; x)$ without the zero-order term $y(\overrightarrow{W}^{(0)}; x)$, this can be achieved by properly scaling down the random initialization by a factor of the target error $\epsilon < 1$. This was used in the follow-up [ALL18c] to achieve small generalization error on over-parameterized neural networks.

[8] See (5.19) and (5.21) in the proofs.

5.5 Proof Overview

Our proof to the Theorem 5.11.1 and 5.12.1 mostly consist of the following steps.

Step 1: properties at random initialization Let $\overrightarrow{W} = \overrightarrow{W}^{(0)}$ be at random initialization and $h_{i,\ell}$ and $D_{i,\ell}$ be defined with respect to $\overrightarrow{W}$. We first show that forward propagation neither explode or vanish. That is,

$$\|h_{i,\ell}\| \approx 1 \text{ for all } i \in [n] \text{ and } \ell \in [L].$$

This is basically because for a fixed y, we have $\|Wy\|^2$ is around 2, and if its signs are sufficiently random, then ReLU activation kills half of the norm, that is $\|\phi(Wy)\| \approx 1$. Then applying induction finishes the proof.

Analyzing forward propagation is not enough. We also need spectral norm bounds on the backward matrix and on the intermediate matrix

$$\|BD_{i,L}W_L \cdots D_{i,a}W_a\|_2 \leq O(\sqrt{m/d}) \quad \text{and} \quad \|D_{i,a}W_a \cdots D_{i,b}W_b\|_2 \leq O(\sqrt{L}) \tag{5.1}$$

for every $a, b \in [L]$. Note that if one naively bounds the spectral norm by induction, then $\|D_{i,a}W_a\|_2 \approx 2$ and it will *exponentially blow up!* Our careful analysis ensures that even when L layers are stacked together, there is no exponential blow up in L.

The final lemma in this step proves that, as long as $\|x_i - x_j\| \geq \delta$, then

$$\|h_{i,\ell} - h_{j,\ell}\| \geq \Omega(\delta) \text{ for each layer } \ell \in [L].$$

Again, if one is willing to sacrifice an exponential factor and prove a lower bound $\delta \cdot 2^{-\Omega(L)}$, this will be easy. What is hard is to derive such lower bound without sacrificing more than a constant factor, but under the condition of $\delta \leq \frac{1}{CL}$. Details are in Section 5.8.

Step 2: stability after adversarial perturbation We show that for every $\overrightarrow{W}$ that is "close" to initialization, meaning $\|\overrightarrow{W} - \overrightarrow{W}^{(0)}\|_2 \leq \omega$ for some $\omega \leq \frac{1}{\mathrm{poly}(L)}$, then

(a) the number of sign changes $\|D_{i,\ell} - \widetilde{D}_{i,\ell}\|_0$ is at most $O(m\omega^{2/3}L) \ll m$, and

(b) the perturbation amount $\|h_{i,\ell} - \widetilde{h}_{i,\ell}\| \leq O(\omega L^{5/2}) \ll 1$.

Since $\omega \leq \frac{1}{\mathrm{poly}(L)}$, both changes above become negligible. We call this "forward stability", and it is the most technical proof of this paper. Intuitively, both "(a) implies (b)" and "(b) implies (a)" are trivial to prove by matrix concentration.[9] Unfortunately, one cannot apply such derivation by induction, because constants will blow up exponentially in the number of layers. We need some careful double induction introduced by [AZLS18], and details in Section 5.9.1. Another main result in this step is to derive stability for the backward matrix and the intermediate matrix. We show that when $w \leq \mathrm{poly}(L)$, (5.1) remains to hold. Details are in Section 5.9.2 and 5.9.3.

Remark 5.5.1. In the final proof, $\overrightarrow{W}$ is a point obtained by GD/SGD starting from $\overrightarrow{W}^{(0)}$, and thus $\overrightarrow{W}$ may depend on the randomness of $\overrightarrow{W}^{(0)}$. Since we cannot control how such randomness correlates, we argue for the above stability properties against *all possible* $\overrightarrow{W}$. This is why we call it "stability against adversarial perturbation."

Step 3: gradient bound The hard part of Theorem 5.11.1 is to show gradient lower bound. For this purpose, recall from Fact 5.2.3 that each sample $i \in [n]$ contributes to the

[9]Namely, if the number of sign changes is bounded in all layers, then $h_{i,\ell}$ and $\widetilde{h}_{i,\ell}$ cannot be too far away by applying matrix concentration; and reversely, if $h_{i,\ell}$ is not far from $\widetilde{h}_{i,\ell}$ in all layers, then the number of sign changes per layer must be small.

full gradient matrix by $D_{i,\ell}(\mathsf{Back}_{i,\ell+1}^\top \mathsf{loss}_i)h_{i,\ell-1}^\top$, where the backward matrix is applied to a loss vector loss_i. To show this is large, intuitively, one wishes to show $(\mathsf{Back}_{i,\ell+1}^\top \mathsf{loss}_i)$ and $h_{i,\ell-1}$ are both vectors with large Euclidean norm.

Thanks to Step 1 and 2, this is not hard for a *single* sample $i \in [n]$. For instance, $\|\widetilde{h}_{i,\ell-1}\| \approx 1$ by Step 1 and we know $\|h_{i,\ell-1} - \widetilde{h}_{i,\ell-1}\| \leq o(1)$ from Step 2. One can also argue for $\mathsf{Back}_{i,\ell+1}^\top \mathsf{loss}_i$ but this is a bit harder. Indeed, when moving from random initialization $\overrightarrow{W}^{(0)}$ to $\overrightarrow{W}$, the loss vector loss_i can change completely. Fortunately, $\mathsf{loss}_i \in \mathbb{R}^d$ is a low-dimensional vector, so one can calculate $\|\mathsf{Back}_{i,\ell+1}^\top u\|$ for every fixed u and then apply ϵ-net.

Finally, how to combine the above argument with multiple samples $i \in [n]$? These matrices are clearly not independent and may (in principle) sum up to zero. To deal with this, we use $\|h_{i,\ell} - h_{j,\ell}\| \geq \Omega(\delta)$ from Step 1. In other words, even if the contribution matrix $D_{i,\ell}(\mathsf{Back}_{i,\ell+1}^\top \mathsf{loss}_i)h_{i,\ell-1}^\top$ with respect to one sample i is fixed, the contribution matrix with respect to other samples $j \in [n] \setminus \{i\}$ are still sufficiently random. Thus, the final gradient matrix will still be large. This idea comes from the prior work [LL18], [10] and helps us prove Theorem 5.11.1. Details in Section 5.10 and 5.11.

Step 4: semi-smoothness In order to prove Theorem 5.12.1, one needs to argue, if we are currently at $\breve{\overrightarrow{W}}$ and perturb it by $\overrightarrow{W}'$, then how much does the objective change in second and higher order terms. This is different from our stability theory in Step 2, because Step 2 is regarding having a perturbation on $\overrightarrow{W}^{(0)}$; in contrast, in Theorem 5.12.1 we need a (small) perturbation $\overrightarrow{W}'$ on top of $\breve{\overrightarrow{W}}$, which may already be a point perturbed from $\overrightarrow{W}^{(0)}$.

[10] This is the only technical idea that we borrowed from [LL18], which is the over-parameterization theory for 2-layer neural networks.

Nevertheless, we still manage to show that, if $\hbar_{i,\ell}$ is calculated on $\overrightarrow{\breve{W}}$ and $h_{i,\ell}$ is calculated on $\overrightarrow{\breve{W}} + \overrightarrow{W'}$, then $\|h_{i,\ell} - \hbar_{i,\ell}\| \leq O(L^{1.5})\|W'\|_2$. This, along with other properties to prove, ensures semi-smoothness. This explains Theorem 5.12.1 and details are in Section 5.12.

Remark 5.5.2. In other words, the amount of changes to each hidden layer (i.e., $h_{i,\ell} - \hbar_{i,\ell}$) is proportional to the amount of perturbation $\|W'\|_2$. This may sound familiar to some readers: a ReLU function is Lipschitz continuous $|\phi(a) - \phi(b)| \leq |a - b|$, and composing Lipschitz functions still yield Lipschitz functions. What is perhaps surprising here is that this "composition" does not create exponential blow-up in the Lipschitz continuity parameter, as long as the amount of over-parameterization is sufficient and $\overrightarrow{\breve{W}}$ is close to initialization.

5.6 Notable Extensions

Our Step 1 through Step 4 in Section 5.5 in fact give rise to a general plan for proving the training convergence of any neural network (at least with respect to the ReLU activation). Thus, it is expected that it can be generalized to many other settings. Not only we can have different number of neurons each layer, our theorems can be extended at least in the following three major directions.[11]

Different loss functions There is absolutely no need to restrict only to ℓ_2 regression loss. We prove in Section 5.16 that, for any Lipschitz-smooth loss function f:

Theorem 5.6.1 (arbitrary loss)**.** *From random initialization, with probability at least* $1 - e^{-\Omega(\log^2 m)}$*, gradient descent with appropriate learning rate satisfy the following.*

- *If f is nonconvex but σ-gradient dominant (a.k.a. Polyak-Łojasiewicz), GD finds ϵ-error minimizer in*[12]

$$T = \widetilde{O}\big(\tfrac{\mathrm{poly}(n,L)}{\sigma\delta^2} \cdot \log \tfrac{1}{\epsilon}\big) \text{ iterations}$$

  as long as $m \geq \widetilde{\Omega}\big(\mathrm{poly}(n, L, \delta^{-1}) \cdot d\sigma^{-2}\big)$.

- *If f is convex, then GD finds ϵ-error minimizer in*

$$T = \widetilde{O}\big(\tfrac{\mathrm{poly}(n,L)}{\delta^2} \cdot \tfrac{1}{\epsilon}\big) \text{ iterations}$$

[11] In principle, each such proof may require a careful rewriting of the main body of this paper. We choose to sketch only the proof difference (in the appendix) in order to keep this paper short. If there is sufficient interest from the readers, we can consider adding the full proofs in the future revision of this paper.

[12] Note that the loss function when combined with the neural network together $f(Bh_{i,L})$ is *not* gradient dominant. Therefore, one cannot apply classical theory on gradient dominant functions to derive our same result.

as long as $m \geq \widetilde{\Omega}\big(\operatorname{poly}(n, L, \delta^{-1}) \cdot d \log \epsilon^{-1}\big)$.

- *If* f *is non-convex, then SGD finds a point with* $\|\nabla f\| \leq \epsilon$ *in at most*[13]

$$T = \widetilde{O}\big(\tfrac{\operatorname{poly}(n,L)}{\delta^2} \cdot \tfrac{1}{\epsilon^2}\big) \text{ iterations}$$

as long as $m \geq \widetilde{\Omega}\big(\operatorname{poly}(n, L, \delta^{-1}) \cdot d\epsilon^{-1}\big)$.

- *If* f *is cross-entropy for multi-label classification, then GD attains* 100% *training accuracy in at most*[14].

$$T = \widetilde{O}\big(\tfrac{\operatorname{poly}(n,L)}{\delta^2}\big) \text{ iterations}$$

as long as $m \geq \widetilde{\Omega}\big(\operatorname{poly}(n, L, \delta^{-1}) \cdot d\big)$.

We remark here that the ℓ_2 loss is 1-gradient dominant so it falls into the above general Theorem 5.6.1. One can also derive similar bounds for (mini-batch) SGD so we do not repeat the statements here.

Convolutional neural networks (CNN) There are lots of different ways to design CNN and each of them may require somewhat different proofs. In Section 5.17, we study the case when $A, W_1, \ldots, W_{L-1}$ are convolutional while W_L and B are fully connected. We assume for notational simplicity that each hidden layer has $\mathfrak{d}$ points each with m channels. (In vision tasks, a point is a pixel). In the most general setting, these values $\mathfrak{d}$ and m can vary across layers. We prove the following theorem:

[13] Again, this cannot be derived from classical theory of finding approximate saddle points for non-convex functions, because weights $\overrightarrow{W}$ with small $\|\nabla f(Bh_{i,L})\|$ is a very different (usually much harder) task comparing to having small gradient with respect to $\overrightarrow{W}$ for the entire composite function $f(Bh_{i,L})$.

[14] This is because attaining constant objective error $\epsilon = 1/4$ for the cross-entropy loss suffices to imply perfect training accuracy.

Theorem 5.6.2 (CNN). *As long as* $m \geq \widetilde{\Omega}\big(\operatorname{poly}(n, L, \mathfrak{d}, \delta^{-1}) \cdot d\big)$, *with high probability, GD and SGD find an* ϵ*-error solution for* ℓ_2 *regression in* $T = \widetilde{O}\big(\frac{\operatorname{poly}(n,L,\mathfrak{d})}{\delta^2} \cdot \log \epsilon^{-1}\big)$ *iterations for CNN.*

Of course, one can replace ℓ_2 loss with other loss functions in Theorem 5.6.1 to get different types of convergence rates. We do not repeat them here.

Residual neural networks (ResNet) There are lots of different ways to design ResNet and each of them may require somewhat different proofs. In symbols, between two layers, one may study $h_\ell = \phi(h_{\ell-1} + Wh_{\ell-1})$, $h_\ell = \phi(h_{\ell-1} + W_2\phi(W_1 h_{\ell-1}))$, or even $h_\ell = \phi(h_{\ell-1} + W_3\phi(W_2\phi(W_1 h_{\ell-1})))$. Since the main purpose here is to illustrate the generality of our techniques but not to attack each specific setting, in Section 5.18, we choose to consider the simplest residual setting $h_\ell = \phi(h_{\ell-1} + Wh_{\ell-1})$ (that was also studied for instance by theoretical work [HM17]). With appropriately chosen random initialization, we prove the following theorem:

Theorem 5.6.3 (ResNet). *As long as* $m \geq \widetilde{\Omega}\big(\operatorname{poly}(n, L, \delta^{-1}) \cdot d\big)$, *with high probability, GD and SGD find an* ϵ*-error solution for* ℓ_2 *regression in* $T = \widetilde{O}\big(\frac{\operatorname{poly}(n,L)}{\delta^2} \cdot \log \epsilon^{-1}\big)$ *iterations for ResNet.*

Of course, one can replace ℓ_2 loss with other loss functions in Theorem 5.6.1 to get different types of convergence rates. We do not repeat them here.

5.7 Detailed Proofs

- In Section 5.8, we derive network properties at random initialization.
- In Section 5.9, we derive the stability theory against adversarial perturbation.
- In Section 5.10, we gradient upper and lower bounds at random initialization.
- In Section 5.11, we prove Theorem 5.11.1.
- In Section 5.12, we prove Theorem 5.12.1.
- In Section 5.13, we prove Theorem 5.13.1.
- In Section 5.14, we prove Theorem 5.14.1.
- In Section 5.15, we prove Theorem 5.15.1.

5.8 Properties at Random Initialization

Throughout this section we assume $\overrightarrow{W}, A$ and B are randomly generated according to Definition 5.2.2. The diagonal sign matrices $D_{i,\ell}$ are also determined according to this random initialization.

5.8.1 Forward Propagation

Lemma 5.8.1 (forward propagation)**.** *If $\epsilon \in (0,1]$, with probability at least $1 - O(nL) \cdot e^{-\Omega(m\epsilon^2/L)}$ over the randomness of $A \in \mathbb{R}^{m \times \mathfrak{d}}$ and $\overrightarrow{W} \in (\mathbb{R}^{m\times m})^L$, we have*

$$\forall i \in [n], \ell \in \{0,1,\ldots,L\} \quad : \quad \|h_{i,\ell}\| \in [1-\epsilon, 1+\epsilon] \ .$$

Remark 5.8.1. Lemma 5.8.1 is in fact trivial to prove if the allowed failure probability is instead $e^{-\Omega(m\epsilon^2/L^2)}$ (by applying concentration inequality layer by layer).

Before proving Lemma 5.8.1 we note a simple mathematical fact:

Fact 5.8.2. *Let $h, q \in \mathbb{R}^p$ be fixed vectors and $h \neq 0$, $W \in \mathbb{R}^{m\times p}$ be random matrix with i.i.d. entries $W_{i,j} \sim \mathcal{N}(0, \frac{2}{m})$, and vector $v \in \mathbb{R}^m$ defined as $v_i = \phi((Wh)_i) = \mathbb{1}_{(W(h+q))_i \geq 0}(Wh)_i$. Then,*

- *$|v_i|$ follows i.i.d. from the following distribution: with half probability $|v_i| = 0$, and with the other half probability $|v_i|$ follows from folded Gaussian distributions $|\mathcal{N}(0, \frac{2\|h\|^2}{m})|$.*
- *$\frac{m\|v\|^2}{2\|h\|^2}$ is in distribution identical to χ^2_ω (chi-square distribution of order ω) where ω follows from binomial distribution $\mathcal{B}(m, 1/2)$.*

Proof of Fact 5.8.2. We assume each vector W_i is generated by first generating a gaussian vector $g \sim \mathcal{N}(0, \frac{2I}{m})$ and then setting $W_i = \pm g$ where the sign is chosen with half-half probability. Now, $|\langle W_i, h\rangle| = |\langle g, h\rangle|$ only depends on g, and is in distribution identical to $|\mathcal{N}(0, \frac{2\|h\|^2}{m})|$. Next, after the sign is determined, the indicator $\mathbb{1}_{\langle W_i, h+q\rangle \geq 0}$ is 1 with half probability and 0 with another half. Therefore, $|v_i|$ satisfies the aforementioned distribution. As for $\|v\|^2$, letting $\omega \in \{0,1,\ldots,m\}$ be the variable indicator how many indicators are 1, then $\omega \sim \mathcal{B}(m, 1/2)$ and $\frac{m\|v\|^2}{2\|h\|^2} \sim \chi^2_\omega$. □

Proof of Lemma 5.8.1. We only prove Lemma 5.8.1 for a fixed $i \in [n]$ and $\ell \in \{0, 1, 2, \ldots, L\}$ because we can apply union bound at the end. Below, we drop the subscript i for notational convenience, and write $h_{i,\ell}$ and x_i as h_ℓ and x respectively.

Letting $\Delta_\ell \stackrel{\text{def}}{=} \frac{\|h_\ell\|^2}{\|h_{\ell-1}\|^2}$, we can write

$$\log \|h_{b-1}\|^2 = \log \|x\|^2 + \sum_{\ell=0}^{b-1} \log \Delta_\ell = \sum_{\ell=0}^{b-1} \log \Delta_\ell \ .$$

According to Fact 5.8.2, fixing any $h_{\ell-1} \neq 0$ and letting W_ℓ be the only source of randomness, we have $\frac{m}{2}\Delta_\ell \sim \chi^2_\omega$ where $\omega \sim \mathcal{B}(m, 1/2)$. For such reason, for each Δ_ℓ, we can write $\Delta_\ell = \Delta_{\ell,\omega}$ where $\frac{m}{2}\Delta_{\ell,\omega} \sim \chi^2_\omega$ and $\omega \sim \mathcal{B}(m, 1/2)$. In the analysis below, we condition on the event that $\omega \in [0.4m, 0.6m]$; this happens with probability $\geq 1 - e^{-\Omega(m)}$ for each layer $\ell \in [L]$. To simplify our notations, if this event does not hold, we set $\Delta_\ell = 1$.

Expectation One can verify that $\mathbb{E}[\log \Delta_{\ell,\omega} \mid \omega] = \log \frac{4}{m} + \psi(\frac{\omega}{2})$ where $\psi(h) = \frac{\Gamma'(h)}{\Gamma(h)}$ is the digamma function. Using the bound $\log h - \frac{1}{h} \leq \psi(h) \leq \log h - \frac{1}{2h}$ of digamma function, we have

$$\log \frac{2\omega}{m} - \frac{2}{\omega} \leq \mathbb{E}[\log \Delta_{\ell,\omega} \mid \omega] \leq \log \frac{2\omega}{m} - \frac{1}{\omega}.$$

Whenever $\omega \in [0.4m, 0.6m]$, we can write

$$\log \frac{2\omega}{m} = \log \left(1 + \frac{2\omega - m}{m}\right) \geq \frac{2\omega - m}{m} - \left(\frac{2\omega - m}{m}\right)^2$$

It is easy to verify $\mathbb{E}_\omega \left[\frac{2\omega - m}{m}\right] = 0$ and $\mathbb{E}_\omega \left[\left(\frac{2\omega - m}{m}\right)^2\right] = \frac{1}{m}$. Therefore,

$$\mathop{\mathbb{E}}_{\omega} \left[\log \frac{2\omega}{m}\right] \geq -\frac{1}{m} - \Pr\left[\omega \notin [0.4m, 0.6m]\right] \cdot \log \frac{2}{m} \geq -\frac{2}{m}$$

Combining everything together, along with the fact that $\mathbb{E}_\omega[\log \frac{2\omega}{m}] \le \log \frac{\mathbb{E}[2\omega]}{m} = 0$, we have (when m is sufficiently larger than a constant)

$$-\frac{4}{m} \le \mathbb{E}[\log \Delta_\ell] \le 0. \tag{5.2}$$

Subgaussian Tail By standard tail bound for chi-square distribution, we know that

$$\forall t \in [0,\infty): \quad \Pr\left[\left|\frac{m}{2}\Delta_{\ell,\omega} - \omega\right| \le t \,\middle|\, \omega\right] \ge 1 - 2e^{-\Omega(t^2/\omega)} - e^{-\Omega(t)} \ .$$

Since we only need to focus on $\omega \ge 0.4m$, this means

$$\forall t \in [0,m]: \quad \Pr\left[\left|\frac{m}{2}\Delta_{\ell,\omega} - \omega\right| \le t \,\middle|\, \omega \ge 0.4m\right] \ge 1 - O(e^{-\Omega(t^2/m)}) \ .$$

On the other hand, by Chernoff-Hoeffding bound, we also have

$$\Pr_\omega\left[\left|\omega - \frac{m}{2}\right| \le t\right] \ge 1 - O(e^{-\Omega(t^2/m)})$$

Together, using the definition $\Delta_\ell = \Delta_{\ell,\omega}$ (or $\Delta_\ell = 1$ if $\omega \notin [0.4m, 0.6m]$), we obtain

$$\forall t \in [0,m]: \quad \Pr\left[\left|\frac{m}{2}\Delta_{\ell} - \frac{m}{2}\right| \le t\right] \ge 1 - O(e^{-\Omega(t^2/m)}) \ .$$

This implies,

$$\forall t \in \left[0,\frac{m}{4}\right]: \quad \Pr\left[|\log \Delta_\ell| \le \frac{t}{m}\right] \ge 1 - O(e^{-\Omega(t^2/m)}) \ . \tag{5.3}$$

Now, let us make another simplification: define $\widehat{\Delta}_\ell = \Delta_\ell$ if $|\log \Delta_\ell| \le \frac{1}{4}$ and $\widehat{\Delta}_\ell = 1$ otherwise. In this way, (5.3) implies that $X = \log \widehat{\Delta}_\ell$ is an $O(m)$-subgaussian random variable.

Concentration Using martingale concentration on subgaussian variables (see for instance [Sha11]), we have for $\epsilon \in (0, 1]$,

$$\Pr\left[\left|\sum_{\ell=0}^{b-1} \log \widehat{\Delta}_\ell - \mathbb{E}[\log \widehat{\Delta}_\ell]\right| > \epsilon\right] \leq O\big(e^{-\Omega(\epsilon^2 m/L)}\big).$$

Since with probability $\geq 1 - Le^{-\Omega(m)}$ it satisfies $\widehat{\Delta}_\ell = \Delta_\ell$ for all $\ell \in [L]$, combining this with (5.2), we have

$$\Pr\left[\left|\sum_{\ell=0}^{b-1} \log \Delta_\ell\right| > \epsilon\right] \leq O\big(e^{-\Omega(\epsilon^2 m/L)}\big).$$

In other words, $\|h_{b-1}\|^2 \in \big[1 - \epsilon, 1 + \epsilon\big]$ with probability at least $1 - O\big(e^{-\Omega(\epsilon^2 m/L)}\big)$. □

5.8.2 Intermediate Layers

Lemma 5.8.3 (intermediate layers)**.** *Suppose $m \geq \Omega(nL\log(nL))$. With probability at least $\geq 1 - e^{-\Omega(m/L)}$ over the randomness of $\overrightarrow{W} \in (\mathbb{R}^{m\times m})^L$, for all $i \in [n], 1 \leq a \leq b \leq L$,*

(a) $\|W_b D_{i,b-1} W_{b-1} \cdots D_{i,a} W_a\|_2 \leq O(\sqrt{L})$.

(b) $\|W_b D_{i,b-1} W_{b-1} \cdots D_{i,a} W_a v\| \leq 2\|v\|$ *for all vectors v with* $\|v\|_0 \leq O\big(\frac{m}{L\log m}\big)$.

(c) $\|u^\top W_b D_{i,b-1} W_{b-1} \cdots D_{i,a} W_a\| \leq O(1)\|u\|$ *for all vectors u with* $\|u\|_0 \leq O\big(\frac{m}{L\log m}\big)$.

For any integer s with $1 \leq s \leq O\big(\frac{m}{L\log m}\big)$, with probability at least $1 - e^{-\Omega(s\log m)}$ over the randomness of $\overrightarrow{W} \in (\mathbb{R}^{m\times m})^L$:

(d) $|u^\top W_b D_{i,b-1} W_{b-1} \cdots D_{i,a} W_a v| \leq \|u\|\|v\| \cdot O\big(\frac{\sqrt{s\log m}}{\sqrt{m}}\big)$ *for all vectors u, v with* $\|u\|_0, \|v\|_0 \leq s$.

Proof. Again we prove the lemma for fixed i, a and b because we can take a union bound at the end. We drop the subscript i for notational convenience.

(a) Let z_{a-1} be any fixed unit vector, and define $z_\ell = D_\ell W_\ell \cdots D_a W_a z_{a-1}$. According to Fact 5.8.2 again, fixing any $z_{\ell-1}$ and letting W_ℓ be the only source of randomness, defining $\Delta_\ell \stackrel{\text{def}}{=} \frac{\|z_\ell\|^2}{\|z_{\ell-1}\|^2}$, we have that $\frac{m}{2}\Delta_\ell$ is distributed according to a χ^2_ω where $\omega \sim \mathcal{B}(m, \frac{1}{2})$. Therefore, we have

$$\log \|z_{b-1}\|^2 = \log \|z_{a-1}\|^2 + \sum_{\ell=a}^{b-1} \log \Delta_\ell = \sum_{\ell=a}^{b-1} \log \Delta_\ell \ .$$

Using exactly the same proof as Lemma 5.8.1, we have

$$\|z_{b-1}\|^2 = \|W_b D_{b-1} W_{b-1} \cdots D_a W_a z_{a-1}\|^2 \in \big[1 - 1/3, 1 + 1/3\big]$$

with probability at least $1 - e^{-\Omega(m/L)}$. As a result, if we fix a subset $M \subseteq [m]$ of cardinality $|M| \leq O(m/L)$, taking ϵ-net, we know that with probability at least $e^{-\Omega(m/L)}$, it satisfies

$$\|W_b D_{b-1} W_{b-1} \cdots D_a W_a u\| \leq 2\|u\| \tag{5.4}$$

for all vectors u whose coordinates are zeros outside M. Now, for an arbitrary unit vector $v \in \mathbb{R}^m$, we can decompose it as $v = u_1 + \cdots + u_N$ where $N = O(L)$, each u_j is non-zero only at $O(m/L)$ coordinates, and the vectors $u_1, \ldots, u_N$ are non-zeros on different coordinates. We can apply (5.4) for each each such u_j and triangle inequality. This gives

$$\|W_b D_{b-1} W_{b-1} \cdots D_a W_a v\| \leq 2 \sum_{j=1}^{N} \|u_j\| \leq 2\sqrt{N} \Big(\sum_{j=1}^{N} \|u_j\|^2 \Big)^{1/2} \leq O(\sqrt{L}) \cdot \|v\|.$$

(b) The proof of Lemma 5.8.3b is the same as Lemma 5.8.3a, except to take ϵ-net over all $O\big(\frac{m}{L \log m}\big)$-sparse vectors u and then applying union bound.

(c) Similar to the proof of Lemma 5.8.3a, for any fixed vector v, we have that with probability at least $1 - e^{-\Omega(m/L)}$ (over the randomness of $W_{b-1}, \ldots, W_1, A$),

$$\|D_{b-1} W_{b-1} \cdots D_a W_a v\| \leq 2\|v\|.$$

Conditioning on this event happens, using the randomness of W_b, we have for each fixed vector $u \in \mathbb{R}^m$, we have

$$\Pr_{W_b} \left[\Big| u^\top W_b \big(D_{b-1} W_{b-1} \cdots D_a W_a v \big) \Big| \geq \frac{4}{\sqrt{L}} \|u\| \|v\| \right] \leq e^{-\Omega(m/L)}.$$

Now consider the case that v is a sparse vector that is only non-zero over some fixed index set $M \subseteq [m]$ (with $|M| \leq O(m/L)$), and that u is of sparsity $s = O\big(\frac{m}{L \log m}\big)$. Taking ϵ-net over all such possible vectors u and v, we have with probability at least $1 - e^{-\Omega(m/L)}$, for all vectors $u \in \mathbb{R}^m$ with $\|u\|_0 \leq s$ and all vectors $v \in \mathbb{R}^m$ that have non-zeros only in M,

$$\Big|u^\top W_b\big(D_{b-1}W_{b-1}\cdots D_a W_a v\big)\Big| \leq \frac{8}{\sqrt{L}}\|u\|\|v\| \ . \tag{5.5}$$

Back to the case when v is an arbitrary vector, we can partition $[m]$ into N index sets $[m] = M_1 \cup M_2 \cup \cdots \cup M_N$ and write $v = v_1 + v_2 + \cdots + v_N$, where $N = O(L)$ and each v_j is non-zero only in M_j. By applying (5.5) for N times and using triangle inequality, we have

$$\begin{aligned}\Big|u^\top W_b\big(D_{b-1}W_{b-1}\cdots D_a W_a v\big)\Big| &\leq \sum_{j=1}^{N}\Big|u^\top W_b\big(D_{b-1}W_{b-1}\cdots D_a W_a v_j\big)\Big| \\ &\leq \frac{8}{\sqrt{L}}\|u\| \times \sum_{j=1}^{N}\|v_j\| \leq O(1) \times \|u\|\|v\| \ .\end{aligned}$$

(d) We apply the same proof as Lemma 5.8.3c with minor changes to the parameters. We can show with probability at least $1-e^{-\Omega(m/L)}$ (over the randomness of $W_{b-1}, \ldots, W_1, A$), for a fixed vector $v \in \mathbb{R}^m$:

$$\|D_{b-1}W_{b-1}\cdots D_a W_a v\| \leq 2\|v\| \ .$$

Further using the randomness of W_b, we have that conditioning on the above event, fixing any $u \in \mathbb{R}^m$, with probability at least $1 - e^{-\Omega(s\log m)}$ over the randomness of W_b:

$$\big|uW_b\big(D_{b-1}W_{b-1}\cdots D_a W_a v\big)\big| \leq \big(\frac{s\log m}{m}\big)^{1/2} \times O\big(\|v\|\|u\|\big) \ .$$

Finally, taking ϵ-net over all possible vectors u, v that are s sparse, we have the desired result.

□

5.8.3 Backward Propagation

Lemma 5.8.4 (backward propagation)**.** *Suppose $m \geq \Omega(nL\log(nL))$. If $s \geq \Omega\big(\frac{d}{\log m}\big)$ and $s \leq O\big(\frac{m}{L\log m}\big)$, then with probability at least $1-e^{-\Omega(s\log m)}$, for all $i \in [n]$, $a = 1, 2, \ldots, L+1$,*

(a) $|v^\top B D_{i,L} W_L \cdots D_{i,a} W_a u| \leq O\big(\frac{\sqrt{s\log m}}{\sqrt{d}}\big)\|v\|\|u\|$ *for all $v \in \mathbb{R}^d$ and all $u \in \mathbb{R}^m$ with $\|u\|_0 \leq s$.*

With probability at least $\geq 1 - e^{-\Omega(m/L)}$, for all $i \in [n], 1 \leq a \leq L$,

(b) $\|v^\top B D_{i,L} W_L \cdots D_{i,a} W_a\| \leq O(\sqrt{m/d})\|v\|$ *for all vectors $u \in \mathbb{R}^d$ if $d \leq O\big(\frac{m}{L\log m}\big)$.*

Proof. (a) The proof follows the same idea of Lemma 5.8.3 (but choosing $b = L$). Given any fixed vector u, we have with probability at least $1-e^{-\Omega(m/L)}$ (over the randomness of $W_L, \ldots, W_1, A$),

$$\|D_L W_L \cdots D_a W_a u\| \leq 2\|u\| \ .$$

Conditioning on this event happens, using the randomness of B (recall each entry of B follows from $\mathcal{N}(0, \frac{1}{d})$), we have for each fixed vector $u \in \mathbb{R}^m$,

$$\Pr_B\left[\left|v^\top B\big(D_L W_L \cdots D_a W_a u\big)\right| \geq \frac{\sqrt{s\log m}}{\sqrt{d}} \cdot O(\|u\|\|v\|)\right] \leq e^{-\Omega(s\log m)} \ .$$

Finally, one can take ϵ-net over all s-sparse vectors $u \in \mathbb{R}^m$ and all vectors $v \in \mathbb{R}^d$ and apply union bound.

(b) The proof is identical to Lemma 5.8.3c, except the fact that each entry of B follows from $\mathcal{N}(0, \frac{1}{d})$ instead of $\mathcal{N}(0, \frac{2}{m})$.

□

5.8.4 δ-Separateness

Lemma 5.8.5 (δ-separateness)**.** *Let $m \geq \Omega\big(\frac{L\log(nL)}{\delta^6}\big)$. There exists some constant $C > 1$ so that, if $\delta \leq \frac{1}{CL}$, $\|x_1\| = \cdots = \|x_n\| = 1$ and $\|x_i - x_j\| \geq \delta$ for every pair $i, j \in [n]$, then with probability at least $1 - e^{-\Omega(\delta^6 m/L)}$, we have :*

$$\forall i \neq j \in [n], \quad \forall \ell \in \{0, 1, \ldots, L\}\colon \|(I - \frac{h_{i,\ell}h_{i,\ell}^\top}{\|h_{i,\ell}\|^2})h_{j,\ell}\| \geq \frac{\delta}{2}.$$

Proof of Lemma 5.8.5. We first apply Lemma 5.8.1 to show that $\|h_{i,\ell}\| \in [1 - \delta^3/10, 1 + \delta^3/10]$. Next we prove Lemma 5.8.5 by induction.

In the base case of $\ell = -1$, since $\|x_i - x_j\| \geq \delta$ by our Assumption 5.2.1 and without loss of generality $\|x_i\| = 1$ and $(x_i)_\mathfrak{d} = \frac{1}{\sqrt{2}}$, we already have

$$\|(I - \frac{h_{i,\ell}h_{i,\ell}^\top}{\|h_{i,\ell}\|^2})h_{j,\ell}\|^2 = \|(I - \frac{x_i x_i^\top}{\|x_i\|^2})x_j\|^2 = \|x_j - x_i \cdot \langle x_i, x_j\rangle\|^2 = 1 - \big(\langle x_i, x_j\rangle\big)^2 \geq \frac{3}{4}\delta^2 \ .$$

Suppose $h_{i,\ell-1}$ and $h_{j,\ell-1}$ are fixed and satisfies $\|(I - \frac{h_{i,\ell-1}h_{i,\ell-1}^\top}{\|h_{i,\ell-1}\|^2})h_{j,\ell-1}\|^2 \geq \delta_{\ell-1}^2$ for some $\delta_{\ell-1} \geq \delta/2$. We write $W_\ell h_{i,\ell-1} = \vec{g}_1$ where $\vec{g}_1 \sim N(0, \frac{2\|h_{i,\ell-1}\|^2}{m} I)$.

Denoting by $\widehat{h} = h_{i,\ell-1}/\|h_{i,\ell-1}\|$, we can write $W_\ell h_{j,\ell-1} = W_\ell \widehat{h}\widehat{h}^\top h_{j,\ell-1} + W_\ell\big(I - \widehat{h}\widehat{h}^\top\big)h_{j,\ell-1}$ and the randomness of the two terms are independent. In particular, we can write

$$W_\ell h_{j,\ell-1} = \frac{\langle h_{i,\ell-1}, h_{j,\ell-1}\rangle}{\|h_{i,\ell-1}\|^2} \cdot \vec{g}_1 + \|\big(I - \widehat{h}\widehat{h}^\top\big)h_{j,\ell-1}\| \cdot \vec{g}_2 \tag{5.6}$$

where $\vec{g}_2 \sim \mathcal{N}(0, \frac{2}{m}I)$ is independent of g_1. Applying Claim 5.8.6 for each coordinate $k \in [m]$ (and re-scaling by $\frac{m}{\|h_{i,\ell-1}\|^2}$, we have

$$\mathbb{E}[(\phi(W_\ell h_{i,\ell-1}) - \phi(W_\ell h_{j,\ell-1}))_k^2] \geq \left(\frac{\delta_{\ell-1}}{\|h_{i,\ell-1}\|}\right)^2 \left(1 - \frac{\delta_{\ell-1}}{\|h_{i,\ell-1}\|}\right) \cdot \frac{\|h_{i,\ell-1}\|^2}{m} \geq \frac{\delta_{\ell-1}^2\,(1 - O(\delta_{\ell-1}))}{m}$$

Applying Chernoff bound (on independent subgaussian random variables), we have with probability at least $1 - e^{-\Omega(\delta_{\ell-1}^4 m)}$,[15]

$$\|h_{i,\ell} - h_{j,\ell}\|^2 = \|\phi(W_\ell h_{i,\ell-1}) - \phi(W_\ell h_{j,\ell-1})\|^2 \geq \delta_{\ell-1}^2 \left(1 - O(\delta_{\ell-1})\right) \ .$$

Since $\|h_{i,\ell}\|$ and $\|h_{j,\ell}\|$ are close to 1, we have

$$\begin{aligned}\left\| \left(I - \frac{h_{i,\ell} h_{i,\ell}^\top}{\|h_{i,\ell}\|^2} \right) h_{j,\ell} \right\|^2 &= \|h_{j,\ell}\|^2 - \frac{\langle h_{i,\ell}, h_{j,\ell} \rangle^2}{\|h_{i,\ell}\|^2} \\ &= \|h_{j,\ell}\|^2 + \frac{\|h_{i,\ell} - h_{j,\ell}\|^2 - \|h_{i,\ell}\|^2 - \|h_{j,\ell}\|^2}{2\|h_{i,\ell}\|^2} \geq \delta_{\ell-1}^2 (1 - O(\delta_{\ell-1})) \ .\end{aligned}$$

□

5.8.4.1 Auxiliary Claim

The following mathematical fact is needed in the proof of Lemma 5.8.5. Its proof is by carefully integrating the PDF of Gaussian distribution.

Claim 5.8.6. *Given $g_1, g_2 \sim \mathcal{N}(0, 2)$, constant $\alpha \in \mathbb{R}$ and $\delta \in [0, \frac{1}{6}]$, we have*

$$\mathop{\mathbb{E}}_{g_1, g_2} \left[(\phi(g_1) - \phi(\alpha g_1 + \delta g_2))^2 \right] \geq \delta^2 (1 - \delta) \ .$$

Proof of Claim 5.8.6. We first tackle two easy cases.

Suppose $a < \frac{3}{4}$. If so, then with probability at least 0.3 we have $g_1 > 1$. If this happens, then with probability at least $1/2$ we have $g_2 < 0$. If both happens, we have

$$\phi(g_1) - \phi(\alpha g_1 + \delta g_2) = g_1 - \phi(\alpha g_1 + \delta g_2) \geq g_1 - \alpha g_1 \geq \frac{1}{4} \ .$$

[15] More specifically, we can let $X_k = m \left(\phi(W_\ell h_{i,\ell-1}) - \phi(W_\ell h_{j,\ell-1})\right)_k^2$ which is $O(1)$-subgaussian and let $X = X_1 + \cdots + X_m$. We have $\Pr[X \geq \mathbb{E}[X](1 - \delta_{\ell-1})] \geq 1 - e^{-\Omega(\delta_{\ell-1}^2 \mathbb{E}[X])}$.

Therefore, we have if $a < \frac{3}{4}$ then the expectation is at least 0.03. For similar reason, if $a > \frac{5}{4}$ we also have the expectation is at least 0.03. In the remainder of the proof, we assume $\alpha \in \left[\frac{3}{4}, \frac{5}{4}\right]$.

If $g_1 \geq 0$, we have

$$\begin{aligned} f(g_1) &\stackrel{\text{def}}{=} \mathop{\mathbb{E}}_{g_2}\left[(\phi(g_1) - \phi(\alpha g_1 + \delta g_2))^2 \,|\, g_1 \geq 0\right] \\ &= \int_0^\infty \frac{(x-g_1)^2 \exp\left(-\frac{(x-\alpha g_1)^2}{4\delta^2}\right)}{\sqrt{4\pi\delta^2}} \,\mathrm{d}x \\ &= \frac{(\alpha-2)\delta g_1 e^{-\frac{\alpha^2 g_1^2}{4\delta^2}}}{\sqrt{\pi}} + \frac{1}{2}\left((\alpha-1)^2 g_1^2 + 2\delta^2\right)\left(\mathrm{erf}\left(\frac{\alpha g_1}{2\delta}\right) + 1\right). \end{aligned}$$

If $g_1 < 0$, we have

$$\begin{aligned} f(g_1) &\stackrel{\text{def}}{=} \mathop{\mathbb{E}}_{g_2}\left[(\phi(g_1) - \phi(\alpha g_1 + \delta g_2))^2 \,|\, g_1 < 0\right] \\ &= \int_0^\infty \frac{x^2 \exp\left(-\frac{(x-\alpha g_1)^2}{4\delta^2}\right)}{\sqrt{4\pi\delta^2}} \,\mathrm{d}x \\ &= \frac{1}{2}\left(\alpha^2 g_1^2 + 2\delta^2\right)\left(\mathrm{erf}\left(\frac{\alpha g_1}{2\delta}\right) + 1\right) + \frac{\alpha\delta g_1 e^{-\frac{\alpha^2 g_1^2}{4\delta^2}}}{\sqrt{\pi}}. \end{aligned}$$

Overall, we have

$$
\begin{aligned}
&\mathop{\mathbb{E}}_{g_1,g_2}\left[(\phi(g_1)-\phi(\alpha g_1+\delta g_2))^2\right] \\
&= \int_0^\infty \frac{f(g)\exp\left(-\frac{g^2}{4}\right)}{\sqrt{4\pi}}\,\mathrm{d}g + \int_{-\infty}^0 \frac{f(g)\exp\left(-\frac{g^2}{4}\right)}{\sqrt{4\pi}}\,\mathrm{d}g \\
&= \left(\frac{(\alpha-1)^2\alpha\delta}{\pi\left(\alpha^2+\delta^2\right)} + \frac{(\alpha-2)\delta^3}{\pi\left(\alpha^2+\delta^2\right)} + \frac{1}{2}\left((\alpha-1)^2+\delta^2\right) + \frac{1}{\pi}\left((\alpha-1)^2+\delta^2\right)\arctan\left(\frac{\alpha}{\delta}\right)\right) \\
&\quad + \frac{1}{2\pi}\left(\pi\left(\alpha^2+\delta^2\right) - 2\left(\alpha^2+\delta^2\right)\arctan\left(\frac{\alpha}{\delta}\right) - 2\alpha\delta\right) \\
&= \frac{\delta\left(-2\alpha^2+\alpha-2\delta^2\right)}{\pi\left(\alpha^2+\delta^2\right)} + \frac{(1-2\alpha)\arctan\left(\frac{\alpha}{\delta}\right)}{\pi} + (\alpha-1)\alpha+\delta^2+\frac{1}{2} \\
&= \left(\alpha^2-2\alpha+1\right)+\delta^2+\frac{2}{\pi}\sum_{k=1}^{\infty}(-1)^k\frac{(\alpha+k)\delta^{2k+1}}{(2k+1)\alpha^{2k+1}}.
\end{aligned}
$$

It is easy to see that, as long as $\delta \le \alpha$, we always have $\frac{(\alpha+k)\delta^{2k+1}}{(2k+1)\alpha^{2k+1}} \ge \frac{(\alpha+k+1)\delta^{2k+3}}{(2k+3)\alpha^{2k+3}}$. Therefore

$$
\mathop{\mathbb{E}}_{g_1,g_2}\left[(\phi(g_1)-\phi(\alpha g_1+\delta g_2))^2\right] \ge \left(\alpha^2-2\alpha+1\right)+\delta^2-\frac{2}{\pi}\frac{(\alpha+1)\delta^3}{3\alpha^3} \ge \delta^2(1-\delta)\ . \quad \square
$$

5.9 Stability against Adversarial Weight Perturbations

Let A, B and $\overrightarrow{W}^{(0)} = (\widetilde{W}_1, \ldots, \widetilde{W}_L)$ be matrices at random initialization (see Definition 5.2.2), and throughout this section, we consider (adversarially) perturbing $\overrightarrow{W}$ by $\overrightarrow{W}' = (W'_1, \ldots, W'_L)$ satisfying $\|\overrightarrow{W}'\|_2 \leq \omega$ (meaning, $\|W'_\ell\|_2 \leq \omega$ for every $\ell \in [L]$). We stick to the following notations in this section

Definition 5.9.1.

$$\begin{aligned}
&\widetilde{g}_{i,0} = Ax_i && g_{i,0} = Ax_i && \text{for } i \in [n] \\
&\widetilde{h}_{i,0} = \phi(Ax_i) && h_{i,0} = \phi(Ax_i) && \text{for } i \in [n] \\
&\widetilde{g}_{i,\ell} = \widetilde{W}_\ell h_{i,\ell-1} && g_{i,\ell} = (\widetilde{W}_\ell + W'_\ell)h_{i,\ell-1} && \text{for } i \in [n] \text{ and } \ell \in [L] \\
&\widetilde{h}_{i,\ell} = \phi(\widetilde{W}_\ell h_{i,\ell-1}) && h_{i,\ell} = \phi((\widetilde{W}_\ell + W'_\ell)h_{i,\ell-1}) && \text{for } i \in [n] \text{ and } \ell \in [L]
\end{aligned}$$

Define diagonal matrices $\widetilde{D}_{i,\ell} \in \mathbb{R}^{m\times m}$ and $D_{i,\ell} \in \mathbb{R}^{m\times m}$ by letting $(\widetilde{D}_{i,\ell})_{k,k} = \mathbb{1}_{(\widetilde{g}_{i,\ell})_k \geq 0}$ and $(D_{i,\ell})_{k,k} = \mathbb{1}_{(g_{i,\ell})_k \geq 0}, \forall k \in [m]$. Accordingly, we let $g'_{i,\ell} = g_{i,\ell} - \widetilde{g}_{i,\ell}$, $h'_{i,\ell} = h_{i,\ell} - \widetilde{h}_{i,\ell}$, and diagonal matrix $D'_{i,\ell} = D_{i,\ell} - \widetilde{D}_{i,\ell}$.

5.9.1 Forward Perturbation

Lemma 5.9.1 (forward perturbation)**.** *Suppose $\omega \le \frac{1}{CL^{9/2}\log^3 m}$ for some sufficiently large constant $C > 1$. With probability at least $1 - e^{-\Omega(m\omega^{2/3}L)}$, for every $\overrightarrow{W}'$ satisfying $\|\overrightarrow{W}'\|_2 \le \omega$,*

(a) $g'_{i,\ell}$ can be written as $g'_{i,\ell} = g'_{i,\ell,1} + g'_{i,\ell,2}$ where $\|g'_{i,\ell,1}\| \le O(\omega L^{3/2})$ and $\|g'_{i,\ell,2}\|_\infty \le O\left(\frac{\omega L^{5/2}\sqrt{\log m}}{\sqrt{m}}\right)$

(b) $\|D'_{i,\ell}\|_0 \le O(m\omega^{2/3}L)$ and $\|D'_{i,\ell}g_{i,\ell}\| \le O(\omega L^{3/2})$.

(c) $\|g'_{i,\ell}\|, \|h'_{i,\ell}\| \le O(\omega L^{5/2}\sqrt{\log m})$.

Proof of Lemma 5.9.1. In our proof below, we drop the subscript with respect to i for notational simplicity, and one can always take a union bound over all possible indices i at the end.

Using Lemma 5.8.1, we can first assume that $\|\widetilde{h}_\ell\|, \|\widetilde{g}_\ell\| \in [\frac{2}{3}, \frac{4}{3}]$ for all ℓ. This happens with probability at least $1 - e^{-\Omega(m/L)}$. We also assume $\left\|\prod_{b=\ell}^{a+1} \widetilde{W}_b \widetilde{D}_{b-1}\right\|_2 \le c_1\sqrt{L}$ where $c_1 > 0$ is the hidden constant in Lemma 5.8.3a.

We shall inductively prove Lemma 5.9.1. In the base case $\ell = 0$, we have $g'_\ell = 0$ so all the statements holds. In the remainder of the proof, we assume that Lemma 5.9.1 holds for $\ell - 1$ and we shall prove the three statements for layer ℓ. To help the readers understand how the constants propagate without blowing up, we shall prove $\|g'_{i,\ell,1}\| \le 4c_1 L^{1.5}\omega$ in Lemma 5.9.1a without the big-O notation, while for all other terms we use big-O to hide polynomial dependency on c_1.[16]

[16] Alternatively, one can fully specify all the constants without using the big-O notation. This was done in our prior work [AZLS18] but is notation-heavy. We refrain from doing so in this simplified paper.

We first carefully rewrite:

$$\begin{aligned}
g'_\ell &= (\widetilde{W}_\ell + W'_\ell)(\widetilde{D}_{\ell-1} + D'_{\ell-1})(\widetilde{g}_{\ell-1} + g'_{\ell-1}) - \widetilde{W}_\ell \widetilde{D}_{\ell-1}\widetilde{g}_{\ell-1} \\
&= W'_\ell(\widetilde{D}_{\ell-1} + D'_{\ell-1})(\widetilde{g}_{\ell-1} + g'_{\ell-1}) + \widetilde{W}_\ell D'_{\ell-1}(\widetilde{g}_{\ell-1} + g'_{\ell-1}) + \widetilde{W}_\ell \widetilde{D}_{\ell-1} g'_{\ell-1} \\
&= \cdots \\
&= \sum_{a=1}^{\ell} \Big(\prod_{b=\ell}^{a+1} \widetilde{W}_b \widetilde{D}_{b-1} \Big) \Big(\underbrace{W'_a(\widetilde{D}_{a-1} + D'_{a-1})(\widetilde{g}_{a-1} + g'_{a-1})}_{(\diamondsuit)} + \underbrace{\widetilde{W}_a D'_{a-1}(\widetilde{g}_{a-1} + g'_{a-1})}_{(\heartsuit)} \Big)
\end{aligned}$$

For each term in $(\diamondsuit)$, we have

$$\begin{aligned}
&\Big\| \Big(\prod_{b=\ell}^{a+1} \widetilde{W}_b \widetilde{D}_{b-1} \Big) \Big(W'_a(\widetilde{D}_{a-1} + D'_{a-1})(\widetilde{g}_{a-1} + g'_{a-1}) \Big) \Big\| \\
\le &\Big\| \prod_{b=\ell}^{a+1} \widetilde{W}_b \widetilde{D}_{b-1} \Big\|_2 \cdot \Big\| W'_a \Big\|_2 \cdot \Big\| \widetilde{D}_{a-1} + D'_{a-1} \Big\|_2 \cdot \Big\| \widetilde{g}_{a-1} + g'_{a-1} \Big\| \\
\overset{①}{\le} &\, c_1 \cdot \omega \cdot 1 \cdot \Big\| \widetilde{g}_{a-1} + g'_{a-1} \Big\| \overset{②}{\le} 2c_1\sqrt{L}\omega + O\big(\omega^2 L^3 \sqrt{\log m}\big) \ .
\end{aligned}$$

Above, inequality ① uses Lemma 5.8.3a and $\|\widetilde{D}_{a-1} + D'_{a-1}\|_2 = \|D_{a-1}\|_2 \le 1$; and inequality ② has used $\|\widetilde{g}_\ell\| \le 2$ and our inductive assumption Lemma 5.9.1c. By triangle inequality, we have

$$g'_\ell = \overrightarrow{\mathsf{err}}_1 + \sum_{a=1}^{\ell} \Big(\prod_{b=\ell}^{a+1} \widetilde{W}_b \widetilde{D}_{b-1} \Big) \Big(\underbrace{\widetilde{W}_a D'_{a-1}(\widetilde{g}_{a-1} + g'_{a-1})}_{(\heartsuit)} \Big)$$

where $\|\overrightarrow{\mathsf{err}}_1\| \le 2c_1 L^{1.5}\omega + O\big(\omega^2 L^4 \sqrt{\log m}\big)$. We next look at each term in $(\heartsuit)$. For each $a = 2, 3, \ldots, \ell$, we let

$$x \overset{\text{def}}{=} D'_{a-1}(\widetilde{g}_{a-1} + g'_{a-1}) = D'_{a-1}(\widetilde{W}_{a-1}\widetilde{h}_{a-1} + g'_{a-1}) \ .$$

If we re-scale x by $\frac{1}{\|\widetilde{h}_{a-1}\|}$ (which is a constant in $[0.75, 1.5]$), we can apply Claim 5.9.2 (with parameter choices in Corollary 5.9.3) on x and this tells us, with probability at least

$1 - e^{-\Omega(m\omega^{2/3}L)}$:

$$\|x\|_0 \le O(m\omega^{2/3}L) \quad \text{and} \quad \|x\| \le O(\omega L^{3/2}). \tag{5.7}$$

Next, each term in (♡) contributes to g'_ℓ by

$$y = \Big(\prod_{b=\ell}^{a+1} \widetilde{W}_b \widetilde{D}_{b-1}\Big)\widetilde{W}_a\Big(D'_{a-1}(\widetilde{g}_{a-1} + g'_{a-1})\Big)$$

using (5.7) and Claim 5.9.4 (with $s = O(m\omega^{2/3}L)$), we have with probability at least $1 - e^{-\Omega(s\log m)}$, one can write $y = y_1 + y_2$ for

$$\|y_1\| \le O\big(\omega L^{3/2} \cdot L^{1/2}\omega^{1/3}\log m\big) \quad \text{and} \quad \|y_2\|_\infty \le O\Big(\omega L^{3/2} \cdot \frac{\sqrt{\log m}}{\sqrt{m}}\Big) \ .$$

And therefore by triangle inequality we can write

$$g'_\ell = \overrightarrow{\mathsf{err}}_1 + \overrightarrow{\mathsf{err}}_2 + \overrightarrow{\mathsf{err}}_3$$

where $\|\overrightarrow{\mathsf{err}}_2\| \le O\big(L \cdot \omega L^{3/2} \cdot L^{1/2}\omega^{1/3}\log m\big) = O\big(\omega^{4/3}L^3 \log m\big)$ and $\|\overrightarrow{\mathsf{err}}_3\|_\infty \le O\Big(L \cdot \omega L^{3/2} \cdot \frac{\sqrt{\log m}}{\sqrt{m}}\Big)$. Together with the upper bound on $\overrightarrow{\mathsf{err}}_1$, we have

$$\|\overrightarrow{\mathsf{err}}_1 + \overrightarrow{\mathsf{err}}_2\| \le 2c_1 L^{1.5}\omega + O\big(\omega^2 L^4\sqrt{\log m} + \omega^{4/3}L^3\log m\big) \ .$$

We emphasize that the above big-O notion can hide polynomial dependency on c_1. Nevertheless, when ω is sufficiently small, the above term is at most $4c_1L^{1.5}\omega$. This finishes the proof of Lemma 5.9.1a for layer ℓ without blowing up the constant. Finally,

- Lemma 5.9.1b is due to (5.7),
- g'_ℓ part of Lemma 5.9.1c is a simple corollary of Lemma 5.9.1a, and
- h'_ℓ part of Lemma 5.9.1c is due to $h'_\ell = D_\ell g'_\ell + D'_\ell g_\ell$ together with the bound on $\|g'_\ell\|$ and the bound on $D'_\ell g_\ell$ from Lemma 5.9.1b. □

5.9.1.1 Auxiliary Claim

Claim 5.9.2. *Suppose $\delta_2 \in [0, O(1)]$ and $\delta_\infty \in [0, \frac{1}{4\sqrt{m}}]$. Suppose $\widetilde{W} \in \mathbb{R}^{m\times m}$ is a random matrix with entries drawn i.i.d. from $\mathcal{N}\big(0, \frac{2}{m}\big)$. With probability at least $1 - e^{-\Omega(m^{3/2}\delta_\infty)}$, the following holds. Fix any unit vector $\widetilde{h} \in \mathbb{R}^m$, and for all $g' \in \mathbb{R}^m$ that can be written as*

$$g' = g'_1 + g'_2 \text{ where } \|g'_1\| \le \delta_2 \text{ and } \|g'_2\|_\infty \le \delta_\infty.$$

Let $D' \in \mathbb{R}^{m\times m}$ be the diagonal matrix where $(D')_{k,k} = \mathbb{1}_{(\widetilde{W}\widetilde{h}+g')_k \ge 0} - \mathbb{1}_{(\widetilde{W}\widetilde{h})_k \ge 0}, \forall k \in [m]$. Then, letting $x = D'(\widetilde{W}\widetilde{h} + g') \in \mathbb{R}^m$, we have

$$\|x\|_0 \le \|D'\|_0 \le O(m(\delta_2)^{2/3} + \delta_\infty m^{3/2}) \quad \text{and} \quad \|x\| \le O(\delta_2 + (\delta_\infty)^{3/2} m^{3/4}) \ .$$

Corollary 5.9.3. *In particular, if $\omega L^{3/2} \le O(1)$, then with probability at least $1 - e^{-\Omega(m\omega^{2/3}L)}$, for every $g' = g'_1 + g'_2$ with $\|g'_1\| \le O(\omega L^{3/2})$ and $\|g'_2\|_\infty \le O\big(\frac{\omega^{2/3}L}{m^{1/2}}\big)$, it satisfies*

$$\|D'\|_0 \le O(m\omega^{2/3}L) \quad \text{and} \quad \|x\| \le O(\omega L^{3/2}) \ .$$

Proof of Claim 5.9.2. We first observe $\widetilde{g} = \widetilde{W}\widetilde{h}$ follows from $\mathcal{N}\big(0, \frac{2I}{m}\big)$ regardless of the choice of $\widetilde{h}$. Therefore, in the remainder of the proof, we just focus on the randomness of $\widetilde{g}$.

We also observe that $(D')_{j,j}$ is non-zero for some diagonal $j \in [m]$ only if

$$|(g'_1 + g'_2)_j| > |(\widetilde{g})_j| \ . \tag{5.8}$$

Let $\xi \le \frac{1}{2\sqrt{m}}$ be a parameter to be chosen later. We shall make sure that $\|g'_2\|_\infty \le \xi/2$.

- We denote by $S_1 \subseteq [m]$ the index sets where j satisfies $|(\widetilde{g})_j| \le \xi$. Since we know $(\widetilde{g})_j \sim \mathcal{N}(0, 2/m)$, we have $\Pr[|(\widetilde{g})_j| \le \xi] \le O\left(\xi\sqrt{m}\right)$ for each $j \in [m]$. Using Chernoff bound for all $j \in [m]$, we have with probability at least $1 - e^{-\Omega(m^{3/2}\xi)}$,

$$|S_1| = |\{i \in [m] \colon |(\widetilde{g})_j| \le \xi\}| \le O(\xi m^{3/2}) \ .$$

Now, for each $j \in S_1$ such that $x_j \neq 0$, we must have $|x_j| = |(\widetilde{g}+g_1'+g_2')_j| \leq |(g_1')_j|+2\xi$ so we can calculate the ℓ_2 norm of x on S_1:

$$\sum_{i\in S_1} x_j^2 \leq O(\|g_1'\|^2 + \xi^2|S_1|) \leq O(\|g_1'\|^2 + \xi^3 m^{3/2}) \ .$$

- We denote by $S_2 \subseteq [m] \setminus S_1$ the index set of all $j \in [m] \setminus S_1$ where $x_j \neq 0$. Using (5.8), we have for each $j \in S_2$:

$$|(g_1')_j| \geq |(\widetilde{g})_j| - |(g_2')_j| \geq \xi - \|g_2'\|_\infty \geq \xi/2 \ .$$

This means

$$|S_2| \leq \frac{4\|g_1'\|^2}{\xi^2} \ .$$

Now, for each $j \in S_2$ where $x_j \neq 0$, we know that the signs of $(\widetilde{g} + g_1' + g_2')_j$ and $(\widetilde{g})_j$ are opposite. Therefore, we must have

$$|x_j| = |(\widetilde{g} + g_1' + g_2')_j| \leq |(g_1' + g_2')_j| \leq |(g_1')_j| + \xi/2 \leq 2|(g_1')_j|$$

and therefore

$$\sum_{j\in S_2} x_j^2 \leq 4\sum_{j\in S_2} (g_1')_j^2 \leq 4\|g_1'\|^2 \ .$$

From above, we have $\|x\|_0 \leq |S_1| + |S_2| \leq O\big(\xi m^{3/2} + \frac{(\delta_2)^2}{\xi^2}\big)$ and $\|x\|^2 \leq O\big((\delta_2)^2 + \xi^3 m^{3/2}\big)$. Choosing $\xi = \max\{2\delta_\infty, \Theta(\frac{(\delta_2)^{2/3}}{m^{1/2}})\}$ for the former, and choosing $\xi = 2\delta_\infty$ for the latter, we have the desired result. □

Claim 5.9.4. *For any $2 \leq a \leq b \leq L$ and any positive integer $s \leq O\big(\frac{m}{L\log m}\big)$, with probability at least $1 - e^{-\Omega(s\log m)}$, for all $x \in \mathbb{R}^m$ with $\|x\| \leq 1$ and $\|x\|_0 \leq s$, letting $y = \widetilde{W}_b\widetilde{D}_{b-1}\widetilde{W}_{b-1}\cdots\widetilde{D}_a\widetilde{W}_a x$, we can write $y = y_1 + y_2$ with*

$$\|y_1\| \leq O\big(\sqrt{s/m}\log m\big) \quad \textit{and} \quad \|y_2\|_\infty \leq \frac{2\sqrt{\log m}}{\sqrt{m}} \ .$$

Proof of Claim 5.9.4. First of all, fix any x, we can let $u = \widetilde{D}_{b-1}\widetilde{W}_{b-1}\cdots\widetilde{D}_a\widetilde{W}_a x$ and the same proof of Lemma 5.8.3 implies that with probability at least $1 - e^{-\Omega(m/L)}$ we have $\|u\| \le O(\|x\|)$. We next condition on this event happens.

Let $\beta = \sqrt{\log m}/\sqrt{m}$. If u is fixed and using only the randomness of W_b, we have $y_i \sim \mathcal{N}\big(0, \frac{2\|u\|^2}{m}\big)$ so for every $p \ge 1$, by Gaussian tail bound

$$\Pr[|y_i| \ge \beta p] \le e^{-\Omega(\beta^2 p^2 m/\|x\|^2)} \le e^{-\Omega(\beta^2 p^2 m)} \ .$$

As long as $\beta^2 p^2 m \ge \beta^2 m \ge \Omega(\log m)$, we know that if $|y_i| \ge \beta p$ occurs for q/p^2 indices i out of $[m]$, this cannot happen with probability more than

$$\binom{m}{q/p^2} \times \left(e^{-\Omega(\beta^2 p^2 m)}\right)^{q/p^2} \le e^{\frac{q}{p^2}\left(O(\log m) - \Omega(\beta^2 p^2 m)\right)} \le e^{-\Omega(\beta^2 q m)} \ .$$

In other words,

$$\Pr\left[\left|\{i \in [m] \colon |y_i| \ge \beta p\}\right| > q/p^2\right] \le e^{-\Omega(\beta^2 q m)} \ .$$

Finally, by applying union bound over $p = 1, 2, 4, 8, 16, \ldots$ we have with probability $\ge 1 - e^{-\Omega(\beta^2 q m)} \cdot \log q$,

$$\sum_{i\colon |y_i| \ge \beta} y_i^2 \le \sum_{k=0}^{\lceil \log q \rceil} (2^{k+1}\beta)^2 \left|\left\{i \in [m] \colon |y_i| \ge 2^k \beta\right\}\right| \le \sum_{k=0}^{\lceil \log q \rceil} (2^{k+1}\beta)^2 \cdot \frac{q}{2^{2k}} \le O(q\beta^2 \log q) \quad (5.9)$$

In other words, vector y can be written as $y = y_1 + y_2$ where $\|y_2\|_\infty \le \beta$ and $\|y_1\|^2 \le O(q\beta^2 \log q)$.

Finally, we want to take ϵ-net over all s-sparse inputs x. This requires $\beta^2 q m \ge \Omega(s \log m)$, so we can choose $q = \Theta\big(\frac{s \log m}{m\beta^2}\big) = \Theta(s)$. □

5.9.2 Intermediate Layers

Lemma 5.9.5 (intermediate perturbation)**.** *For any integer s with $1 \le s \le O\big(\frac{m}{L^3 \log m}\big)$, with probability at least $1 - e^{-\Omega(s \log m)}$ over the randomness of $\overrightarrow{W}^{(0)}, A$,*

- *for every $i \in [n], 1 \le a \le b \le L$,*
- *for every diagonal matrices $D''_{i,0}, \ldots, D''_{i,L} \in [-3,3]^{m \times m}$ with at most s non-zero entries.*
- *for every perturbation matrices $W'_1, \ldots, W'_L \in \mathbb{R}^{m \times m}$ with $\|\overrightarrow{W}'\|_2 \le \omega \in [0,1]$.*

we have

(a) $\|\widetilde{W}_b(\widetilde{D}_{i,b-1} + D''_{i,b-1}) \cdots (\widetilde{D}_{i,a} + D''_{i,a})\widetilde{W}_a\|_2 \le O(\sqrt{L})$.

(b) $\|(\widetilde{W}_b + W'_b)(\widetilde{D}_{i,b-1} + D''_{i,b-1}) \cdots (\widetilde{D}_{i,a} + D''_{i,a})(\widetilde{W}_a + W'_a)\|_2 \le O(\sqrt{L})$ *if* $\omega \le O(\frac{1}{L^{1.5}})$.

Proof. For notational simplicity we ignore subscripts in i in the proofs.

(a) Note that each D''_ℓ can be written as $D''_\ell = D_\ell^{0/1} D''_\ell D_\ell^{0/1}$, where each $D_\ell^{0/1}$ is a diagonal matrix satisfying

$$(D_\ell^{0/1})_{k,k} = \begin{cases} 1, & (D''_\ell)_{k,k} \neq 0; \\ 0, & (D''_\ell)_{k,k} = 0. \end{cases} \quad \text{and} \quad \|D_\ell^{0/1}\|_0 \le s \ .$$

In order to bound the spectral norm of $\widetilde{W}_b(\widetilde{D}_{b-1} + D''_{b-1})\widetilde{W}_{b-1} \cdots (\widetilde{D}_a + D''_a)\widetilde{W}_a$, by triangle inequality, we can expend it into 2^{b-a} matrices and bound their spectral norms individually. Each such matrix can be written as (ignoring the subscripts)

$$(\widetilde{W}\widetilde{D} \cdots \widetilde{W} D^{0/1}) D'' (D^{0/1} \widetilde{W}\widetilde{D} \cdots \widetilde{W} D^{0/1}) D'' \cdots D'' (D^{0/1} \widetilde{W}\widetilde{D} \cdots \widetilde{W}) \tag{5.10}$$

Therefore, it suffices for us to bound the spectral norm of the following four types of matrices:

- $\widetilde{W}\widetilde{D}\cdots\widetilde{W}D^{0/1}$, such matrix has spectral norm at most 2 owing to Lemma 5.8.3b;
- $D^{0/1}\widetilde{W}\widetilde{D}\cdots\widetilde{W}$, such matrix has spectral norm at most $O(1)$ owing to Lemma 5.8.3c;
- $D^{0/1}\widetilde{W}\widetilde{D}\cdots\widetilde{W}D^{0/1}$, such matrix has spectral norm at most $\frac{1}{100L^{1.5}}$ owing to Lemma 5.8.3d and our choice $s \le O(\frac{m}{L^3 \log m})$;
- D'', such matrix has spectral norm at most 3.

Together, we have

$$\begin{aligned}&\left\|\widetilde{W}_b(\widetilde{D}_{b-1}+D''_{b-1})\widetilde{W}_{b-1}\cdots(\widetilde{D}_a+D''_a)\widetilde{W}_a\right\| \\ \le O(\sqrt{L}) + &\sum_{j=1}^{b-a}\binom{b-a}{j}\cdot O(1)\cdot\left(\frac{1}{100L^{1.5}}\right)^{j-1}\cdot 3^j\cdot O(1) \le O(\sqrt{L})\ .\end{aligned}$$

(b) In order to bound the spectral norm of $(\widetilde{W}_b+W'_b)(\widetilde{D}_{b-1}+D''_{b-1})\cdots(\widetilde{D}_a+D''_a)(\widetilde{W}_a+W'_a)$, by triangle inequality, we can expend it into 2^{b-a+1} matrices in terms of W' and bound their spectral norms individually. Each such matrix can be written as (ignoring the subscripts, and denoting $\breve{D}=\widetilde{D}+D'$)

$$(\widetilde{W}\breve{D}\cdots\widetilde{W}\breve{D})W'(\breve{D}\widetilde{W}\cdots\widetilde{W}\breve{D})\cdots W'(\breve{D}\widetilde{W}\cdots\breve{D}\widetilde{W})$$

Moreover, from Lemma 5.9.5a, we know the following three types of matrices

- $\widetilde{W}\breve{D}\cdots\widetilde{W}\breve{D}$,
- $\breve{D}\widetilde{W}\cdots\widetilde{W}\breve{D}$, and
- $\breve{D}\widetilde{W}\cdots\breve{D}\widetilde{W}$

all have spectral norm at most $O(\sqrt{L})$. Together, using $\|W'_\ell\|_2 \leq O(\frac{1}{L^{1.5}})$, we have

$$\begin{aligned}
&\left\|(\widetilde{W}_b + W'_b)(\widetilde{D}_{b-1} + D''_{b-1})(\widetilde{W}_{b-1} + W'_{b-1}) \cdots (\widetilde{D}_a + D''_a)(\widetilde{W}_a + W'_a)\right\| \\
&\leq \sum_{j=0}^{b-a+1} \binom{b-a+1}{j} \cdot \Big(O(\sqrt{L})\Big)^{j+1} \cdot \Big(O(\frac{1}{L^{1.5}})\Big)^{j} \leq O(\sqrt{L}) \ . \qquad \square
\end{aligned}$$

5.9.3 Backward

Lemma 5.9.6 (backward perturbation)**.** *For any integer* $s \in \left[\Omega\left(\frac{d}{\log m}\right), O\left(\frac{m}{L^3 \log m}\right)\right]$*, for* $d \leq O\left(\frac{m}{L \log m}\right)$*, with probability at least* $1 - e^{-\Omega(s \log m)}$ *over the randomness of* $\overrightarrow{W}^{(0)}, A, B$*,*

- *for all* $i \in [n]$*,* $a = 1, 2, \ldots, L+1$*,*
- *for every diagonal matrices* $D''_{i,0}, \ldots, D''_{i,L} \in [-3, 3]^{m \times m}$ *with at most* s *non-zero entries,*
- *for every perturbation matrices* $W'_{i,1}, \ldots, W'_{i,L} \in \mathbb{R}^{m \times m}$ *with* $\|\overrightarrow{W}'\|_2 \leq \omega = O(\frac{1}{L^{1.5}})$*,*

it satisfies $\|B(\widetilde{D}_{i,L}+D''_{i,L})(\widetilde{W}_L+W'_L)\cdots(\widetilde{W}_{a+1}+W'_{a+1})(\widetilde{D}_{i,a}+D''_{i,a})-B\widetilde{D}_{i,L}\widetilde{W}_L\cdots\widetilde{W}_{a+1}\widetilde{D}_{i,a}\|_2 \leq O\left(\frac{\sqrt{L^3 s \log m+\omega^2 L^3 m}}{\sqrt{d}}\right)$*. Note that if* $s = O(m\omega^{2/3}L)$*, this upper bound becomes* $O\left(\frac{\omega^{1/3}L^2\sqrt{m \log m}}{\sqrt{d}}\right)$*.*

Proof. For notational simplicity we ignore subscripts in i in the proofs.

Ignoring the subscripts for cleanness, we have

$$
\begin{aligned}
&\left\|B(\widetilde{D}_{i,L} + D''_{i,L})(\widetilde{W}_L + W'_L)\cdots(\widetilde{W}_{a+1} + W'_{a+1})(\widetilde{D}_{i,a} + D''_{i,a}) - B\widetilde{D}_{i,L}\widetilde{W}_L\cdots\widetilde{W}_{a+1}\widetilde{D}_{i,a}\right\|_2 \\
&\leq \sum_{\ell=a}^{L} \underbrace{\left\|B\widetilde{D}_{i,L}\widetilde{W}_L\cdots\widetilde{W}_{\ell+1}D_\ell^{0/1}\right\|_2}_{\text{Lemma 5.8.4a}} \|D''_\ell\|_2 \underbrace{\left\|D_\ell^{0/1}(\widetilde{W}_\ell + W'_\ell)\cdots(\widetilde{D}_{i,a} + D''_{i,a})\right\|_2}_{\text{Lemma 5.9.5b}} \\
&\quad + \sum_{\ell=a+1}^{L} \underbrace{\left\|B\widetilde{D}_{i,L}\widetilde{W}_L\cdots\widetilde{W}_{\ell+1}\widetilde{D}_\ell\right\|_2}_{\text{Lemma 5.8.4b}} \|W'_\ell\|_2 \underbrace{\left\|(\widetilde{D}_{\ell-1} + D''_{\ell-1})(\widetilde{W}_{\ell-1} + W'_{\ell-1})\cdots(\widetilde{D}_{i,a} + D''_{i,a})\right\|_2}_{\text{Lemma 5.9.5b}} \\
&\leq L \cdot O\left(\frac{\sqrt{s \log m}}{\sqrt{d}}\right) \cdot O(\sqrt{L}) + L \cdot O(\sqrt{m/d}) \cdot \omega \cdot O(\sqrt{L})
\end{aligned}
$$

□

5.10 Gradient Bound at Random Initialization

Throughout this section we assume $\overrightarrow{W}, A$ and B are randomly generated according to Definition 5.2.2. The diagonal sign matrices $D_{i,\ell}$ are also determined according to this random initialization.

Recall we have defined $\mathsf{Back}_{i,\ell} \stackrel{\text{def}}{=} BD_{i,L}W_L \cdots D_{i,\ell}W_\ell \in \mathbb{R}^{d\times m}$. In this section, we introduce the following notion

Definition 5.10.1. For any vector tuple $\vec{\mathsf{v}} = (\mathsf{v}_1, \ldots, \mathsf{v}_n) \in (\mathbb{R}^d)^n$ (viewed as a fake loss vector), for each $\ell \in [L]$, we define

$$\widehat{\nabla}^{\vec{\mathsf{v}}}_{[W_\ell]_k} F(\overrightarrow{W}) \stackrel{\text{def}}{=} \sum_{i=1}^n (\mathsf{Back}_{i,\ell+1}^\top \mathsf{v}_i)_k \cdot h_{i,\ell-1} \cdot \mathbb{1}_{\langle [W_\ell]_k, h_{i,\ell-1}\rangle \geq 0}, \forall k \in [m]$$

$$\widehat{\nabla}^{\vec{\mathsf{v}}}_{W_\ell} F(\overrightarrow{W}) \stackrel{\text{def}}{=} \sum_{i=1}^n \widehat{\nabla}^{\vec{\mathsf{v}}}_{W_\ell} F_i(\overrightarrow{W}) \quad \text{where} \quad \widehat{\nabla}^{\vec{\mathsf{v}}}_{W_\ell} F_i(\overrightarrow{W}) \stackrel{\text{def}}{=} D_{i,\ell}(\mathsf{Back}_{i,\ell+1}^\top \mathsf{v}_i) h_{i,\ell-1}^\top$$

Remark 5.10.1. It is an easy exercise to check that, if letting $\vec{\mathsf{v}} = (\mathsf{v}_1, \ldots, \mathsf{v}_n)$ where $\mathsf{v}_i = Bh_{i,L} - y_i^*$, then $\widehat{\nabla}^{\vec{\mathsf{v}}}_{[W_\ell]_k} F(\overrightarrow{W}) = \nabla_{[W_\ell]_k} F(\overrightarrow{W})$ and $\widehat{\nabla}^{\vec{\mathsf{v}}}_{W_\ell} F_i(\overrightarrow{W}) = \nabla_{W_\ell} F_i(\overrightarrow{W})$.

Our main lemma of this section is the following.

Lemma 5.10.1 (gradient bound at random initialization)**.** *Fix any $\vec{\mathsf{v}} \in (\mathbb{R}^d)^n$, with probability at least $1 - e^{-\Omega(\delta m/n)}$ over the randomness of $A, \overrightarrow{W}, B$, it satisfies for every $\ell \in [L]$:*

$$\|\widehat{\nabla}^{\vec{\mathsf{v}}}_{W_\ell} F_i(\overrightarrow{W})\|_F^2 \leq O\Big(\frac{\|\mathsf{v}_i\|^2}{d} \times m\Big) \qquad \|\widehat{\nabla}^{\vec{\mathsf{v}}}_{W_\ell} F(\overrightarrow{W})\|_F^2 \leq O\Big(\frac{\|\vec{\mathsf{v}}\|^2}{d} \times mn\Big)$$

$$\|\widehat{\nabla}^{\vec{\mathsf{v}}}_{W_L} F(\overrightarrow{W})\|_F^2 \geq \Omega\Big(\frac{\max_{i\in[n]} \|\mathsf{v}_i\|^2}{dn/\delta} \times m\Big)$$

5.10.1 Proof of Lemma 5.10.1: Upper Bound

For each $i \in [n], \ell \in [L]$, we can calculate that

$$\begin{aligned}
\left\| \widehat{\nabla}^{\vec{\mathsf{v}}}_{W_\ell} F_i(\overrightarrow{W}) \right\|_F &= \left\| D_{i,\ell}(\mathsf{Back}_{i,\ell+1}^\top \cdot \mathsf{v}_i) \cdot h_{i,\ell-1}^\top \right\|_F \\
&= \left\| D_{i,\ell}(\mathsf{Back}_{i,\ell+1}^\top \cdot \mathsf{v}_i) \right\|_2 \cdot \|h_{i,\ell-1}\|_2 \\
&\leq \|\mathsf{Back}_{i,\ell+1}\|_2 \cdot \|\mathsf{v}_i\|_2 \cdot \|h_{i,\ell-1}\|_2 \\
&\leq \|BW_L D_{L-1} \cdots D_{i,\ell+1} W_{\ell+1}\|_2 \cdot \|\mathsf{v}_i\|_2 \cdot \|h_{i,\ell-1}\|_2 \\
&\overset{①}{\leq} O(\sqrt{m/d}) \cdot O(1) \cdot \|\mathsf{v}_i\|_2 \ .
\end{aligned}$$

where inequality ① uses Lemma 5.8.4b and Lemma 5.8.1 with high probability. Applying triangle inequality with respect to all $\ell \in [L]$, taking square on both sides, and summing up over all $i \in [n]$ finish the proof.

5.10.2 Proof of Lemma 5.10.1: Lower Bound

Let $i^* = \operatorname{argmax}_{i\in[n]}\{\|\mathsf{v}_i\|\}$. Recall

$$\widehat{\nabla}^{\vec{\mathsf{v}}}_{[W_L]_k} F(\overrightarrow{W}) = \sum_{i=1}^{n} \langle B_k, \mathsf{v}_i\rangle \cdot h_{i,L-1} \cdot \mathbb{1}_{(W_L h_{i,L-1})_k \geq 0}$$

Let $\widehat{h} \stackrel{\text{def}}{=} \frac{h_{i^*,L-1}}{\|h_{i^*,L-1}\|}$. For analysis purpose, after $\widehat{h}$ is fixed (so after fixing the randomness of $A, W_1, \ldots, W_{L-1}$), we redefine $W_L\widehat{h} = \sqrt{1-\theta^2}\widehat{g}_1 + \theta\widehat{g}_2$ where $\widehat{g}_1$ and $\widehat{g}_2$ are generated independently from $\mathcal{N}(0, \frac{2I}{m})$. We can do so because the two sides are equal in distribution. In other words, we can set

$$W'_L \stackrel{\text{def}}{=} W_L\big(I - \widehat{h}\widehat{h}^\top\big) - \sqrt{1-\theta^2}\widehat{g}_1\widehat{h}^\top \text{ and } W''_L \stackrel{\text{def}}{=} \theta\widehat{g}_2\widehat{h}^\top,$$

then we have $W_L = W'_L + W''_L$. In particular, the randomness of W'_L and W''_L are *independent*.

In the remainder of the proof, let us choose $\theta \stackrel{\text{def}}{=} \frac{\delta}{5n} \leq \frac{1}{5}$.

We first make two technical claims, and the proof of the first one can be found in Section 5.10.2.1.

Claim 5.10.2. *We have* $\Pr_{W'_L, W_{L-1}, \ldots, W_1, A}\left[|N_2| \geq \frac{\delta}{40n}m\right] \geq 1 - e^{\Omega(\delta m/n)}$

$$N_2 \stackrel{\text{def}}{=} \left\{k \in [m]\colon \left(|(W'_L h_{i^*,L-1})_k| \leq \frac{\delta}{10n\sqrt{m}}\right) \bigwedge \left(\forall i \in [n]\setminus\{i^*\}, \quad \big|\big(W'_L h_{i,L-1}\big)_k\big| \geq \frac{\delta}{4n\sqrt{m}}\right)\right\}$$

Claim 5.10.3. *Given set* $N_2 \subset [m]$ *and* $\vec{\mathsf{v}}$*, we have*

$$\Pr_{B_k}\left[\left|\left\{k \in N_2\colon \big|\langle B_k, \mathsf{v}_{i^*}\rangle\big| \geq \frac{\|\mathsf{v}_{i^*}\|}{\sqrt{d}}\right\}\right| \geq \frac{|N_2|}{2}\right] \geq 1 - e^{-\Omega(|N_2|)}$$

Proof of Claim 5.10.3. Observe that each $\langle B_k, \mathsf{v}_{i^*}\rangle$ follows from $\mathcal{N}(0, \|\mathsf{v}_{i^*}\|^2/d)$, so with probability at least 0.68 it satisfies $|\langle B_k, \mathsf{v}_{i^*}\rangle| \geq \frac{\|\mathsf{v}_{i^*}\|}{\sqrt{d}}$. Using Chernoff bound we have the desired claim. □

Combining Claim 5.10.4 and Claim 5.10.3, we can obtain a set $N \subseteq [m]$ satisfying

$$N \stackrel{\text{def}}{=} \left\{ k \in [m] \colon \left(|(W_L' h_{i^*,L-1})_k| \le \frac{\delta}{10n\sqrt{m}} \right) \bigwedge \left(\forall i \in [n] \setminus \{i^*\}, \quad |\left(W_L' h_{i,L-1}\right)_k| \ge \frac{\delta}{4n\sqrt{m}} \right) \bigwedge |\langle B_k, \mathsf{v}_{i^*} \rangle| \ge \frac{\|\mathsf{v}_{i^*}\|}{\sqrt{d}} \right\}$$

of cardinality $|N| \ge \frac{\delta}{100n} m$. Let us fix the randomness of W_L' so that N is fixed. Let k be any index in N. We can write

$$\widehat{\nabla}^{\vec{\mathsf{v}}}_{[W_L]_k} F(\overrightarrow{W}) = \sum_{i=1}^{n} \langle B_k, \mathsf{v}_i \rangle \cdot h_{i,L-1} \cdot \mathbb{1}_{(W_L' h_{i,L-1})_k + (W_L'' h_{i,L-1})_k \ge 0}.$$

The only remaining source of randomness comes from $W_L'' = \theta \widehat{g}_2 \widehat{h}^\top$.

Recalling that $\theta = \frac{1}{5n}$ and $\widehat{g}_2 \sim \mathcal{N}(0, \frac{2}{m} I)$, so since $\theta(\widehat{g}_2)_k \sim \mathcal{N}(0, \frac{2\theta^2}{m})$, using numerical values of Gaussian CDF, one can verify that

$$\Pr_{\widehat{g}_2} \left[|\theta(\widehat{g}_2)_k| \in \left(\frac{\delta}{9n\sqrt{m}}, \frac{\delta}{5n\sqrt{m}} \right) \right] \ge 0.2 \ .$$

Let us denote this event of $\widehat{g}_2$ as $\mathfrak{E}_k$. Conditioning on $\mathfrak{E}_k$ happens, recalling $\|h_{i,L-1}\| \in [0.9, 1.1]$ from Lemma 5.8.1,

- For every $i \in [n] \setminus \{i^*\}$, we have

  $$|(W_L'' h_{i,L-1})_k| = |(\theta \widehat{g}_2 \widehat{h}^\top h_{i,L-1})_k| \le |(\theta \widehat{g}_2)_k| \cdot \|h_{i,L-1}\| < \frac{\delta}{5n\sqrt{m}} \cdot 1.1 < |(W_L' h_{i,L-1})_k|$$

  and this means $\mathbb{1}_{(W_L h_{i,L-1})_k \ge 0} = \mathbb{1}_{(W_L' h_{i,L-1})_k \ge 0}$.

- For $i = i^*$, we have

  $$|(W_L'' h_{i^*,L-1})_k| = |(\theta \widehat{g}_2 \widehat{h}^\top h_{i^*,L-1})_k| = |(\theta \widehat{g}_2)_k| \cdot \|h_{i^*,L-1}\| > \frac{\delta}{9n\sqrt{m}} \cdot 0.9 > |(W_L' h_{i^*,L-1})_k|$$

  and this means $\mathbb{1}_{(W_L h_{i^*,L-1})_k \ge 0} \ne \mathbb{1}_{(W_L' h_{i^*,L-1})_k \ge 0}$ with probability exactly $\frac{1}{2}$ — this is because, conditioning on event $\mathfrak{E}_k$, the sign of $(\theta \widehat{g}_2)_k$ is ± 1 each with half probability.

Recall that for every $k \in N$,

$$\widehat{\nabla}^{\vec{\mathsf{v}}}_{[W_L]_k} F(\overrightarrow{W}) = \underbrace{\langle B_k, \mathsf{v}_{i^*} \rangle \cdot h_{i^*,L-1} \cdot \mathbb{1}_{(W_L h_{i^*,L-1})_k \geq 0}}_{\spadesuit} + \sum_{i \in [n] \setminus \{i^*\}} \underbrace{\langle B_k, \mathsf{v}_i \rangle \cdot h_{i,L-1} \cdot \mathbb{1}_{(W_L h_{i,L-1})_k \geq 0}}_{\clubsuit}$$

Now, fix the randomness of $A, B, W_1, \ldots, W_{L-1}, W'_L$ and let $\widehat{g}_2$ be the only randomness. Conditioning on $\mathfrak{E}_k$, we have that each term in $\clubsuit$ is fixed (i.e., independent of $\widehat{g}_2$) because $\mathbb{1}_{(W_L h_{i,L-1})_k \geq 0} = \mathbb{1}_{(W'_L h_{i,L-1})_k \geq 0}$. In contrast, conditioning on $\mathfrak{E}_k$, the indicator $\mathbb{1}_{(W_L h_{i^*,L-1})_k \geq 0}$ of the $\spadesuit$ term may be 1 or 0 each with half probability. This means,

$$\Pr_{(\widehat{g}_2)_k} \left[\|\widehat{\nabla}^{\vec{\mathsf{v}}}_{[W_L]_k} F(\overrightarrow{W})\|^2 \geq |\langle B_k, \mathsf{v}_{i^*} \rangle|^2 \cdot \|h_{i^*,L-1}\|^2 \,\middle|\, k \in N \wedge \mathfrak{E}_k \right] \geq \frac{1}{2} \ .$$

Taking into account the fact that $|\langle B_k, \mathsf{v}_{i^*} \rangle| \geq \frac{\|\mathsf{v}_{i^*}\|}{\sqrt{d}}$ (by definition of N), the fact that $\|h_{i,L-1}\| \geq 0.9$, and the fact that $\Pr_{(\widehat{g}_2)_k}[\mathfrak{E}] \geq 0.2$, we have

$$\Pr_{(\widehat{g}_2)_k} \left[\|\widehat{\nabla}^{\vec{\mathsf{v}}}_{[W_L]_k} F(\overrightarrow{W})\|^2 \geq 0.8 \frac{\|\mathsf{v}_{i^*}\|^2}{d} \,\middle|\, k \in N \right] \geq \frac{1}{10} \ .$$

Using the independence of $(\widehat{g}_2)_k$ with respect to different $k \in N$, we can apply Chernoff bound and derive:

$$\Pr_{\widehat{g}_2} \left[\sum_{k \in N} \|\widehat{\nabla}^{\vec{\mathsf{v}}}_{[W_L]_k} F(\overrightarrow{W})\|^2 \geq 0.8 \frac{\|\mathsf{v}_{i^*}\|^2}{d} \cdot \frac{|N|}{15} \,\middle|\, N \right] \geq 1 - e^{-\Omega(|N|)} \ .$$

Finally, using and $|N| \geq \frac{\delta}{100n} m$, we have

$$\Pr \left[\|\widehat{\nabla}^{\vec{\mathsf{v}}}_{W_L} F(\overrightarrow{W})\|_F^2 \geq \frac{\|\mathsf{v}_{i^*}\|^2}{d} \frac{\delta}{2000n} m \right] \geq 1 - e^{-\Omega(\delta m/n)} \ .$$

We finish the upper bound proof of Lemma 5.10.1. ■

5.10.2.1 Proof of Claim 5.10.4

Claim 5.10.4. *We have* $\Pr_{W_L', W_{L-1}, \ldots, W_1, A}\left[|N_2| \geq \frac{\delta}{40n} m\right] \geq 1 - e^{\Omega(\delta m/n)}$

$$N_2 \stackrel{\text{def}}{=} \left\{ k \in [m] \colon \left(|(W_L' h_{i^*, L-1})_k| \leq \frac{\delta}{10n\sqrt{m}} \right) \bigwedge \left(\forall i \in [n] \setminus \{i^*\}, \quad |\left(W_L' h_{i, L-1}\right)_k| \geq \frac{\delta}{4n\sqrt{m}} \right) \right\}$$

Proof of Claim 5.10.4. Throughout the proof we assume $W_{L-1}, \ldots, A$ are good enough so that Lemma 5.8.1 holds (for $\epsilon = 0.01$) and we fix their randomness. Define

$$N_1 \stackrel{\text{def}}{=} \left\{ k \in [m] \colon |(W_L' h_{i^*, L-1})_k| \leq \frac{\delta}{10n\sqrt{m}} \right\}$$

Since $\|h_{i^*, L-1}\|^2 \leq 1.1$ by Lemma 5.8.1, and since by definition of W_L' we have $(W_L' h_{i^*, L-1})_k \sim \mathcal{N}(0, \frac{2(1-\theta^2)\|h_{i^*, L-1}\|^2}{m})$. By standard properties of Gaussian CDF (see Fact 5.10.5), we know $|(W_L' h_{i^*, L-1})_k| \leq \frac{\delta}{10n\sqrt{m}}$ with probability at least $\frac{\delta}{25n}$ for each $k \in [m]$. By Chernoff bound,

$$\Pr_{W_L'}\left[|N_1| \geq \frac{\delta}{30n} m \right] \geq 1 - e^{-\Omega(\delta m/n)}$$

Next, suppose we fix the randomness of $W_L' \widehat{h}$. Define

$$N_2 \stackrel{\text{def}}{=} \left\{ k \in N_1 \colon \forall i \in [n] \setminus \{i^*\}, \quad |\left(W_L' h_{i, L-1}\right)_k| \geq \frac{\delta}{4n\sqrt{m}} \right\}$$

For each $k \in N_1$ and $i \in [n] \setminus \{i^*\}$, we can write

$$W_L' h_{i, L-1} = W_L' \widehat{h} (\widehat{h}^\top h_{i, L-1}) + W_L' (I - \widehat{h}\widehat{h}^\top) h_{i, L-1} \ .$$

Above, the first term on the right hand side is fixed (because we have fixed the randomness of $W_L' \widehat{h}$); however, $W_L'(I - \widehat{h}\widehat{h}^\top) h_{i, L-1}$ is still fresh new random Gaussian. In symbols,

$$W_L' h_{i, L-1} \sim \mathcal{N}\left(W_L' \widehat{h}\widehat{h}^\top h_{i, L-1}, \frac{2\|(I - \widehat{h}\widehat{h}^\top) h_{i, L-1}\|^2}{m} I \right) \ .$$

According to Lemma 5.8.5, the variance here is at least $\frac{2}{m}\|(I - \widehat{h}\widehat{h}^\top)h_{i,L-1}\|^2 \geq \frac{\delta^2}{2m}$. Using standard properties of Gaussian CDF (see Fact 5.10.5), we know $|(W_L' h_{i,L-1})_k| \geq \frac{\delta}{4n\sqrt{m}}$ with probability at least $1 - \frac{1}{8n}$ for each $k \in [m]$. By union bound, for this $k \in [m]$, with probability at least $\frac{7}{8}$ we know $|(W_L' h_{i,L-1})_k| \geq \frac{\delta}{4n\sqrt{m}}$ for all $i \in [n] \setminus \{i^*\}$. By Chernoff bound (over all $k \in N_1$), we conclude that

$$\Pr_{W_L'}\left[|N_2| \geq \frac{3}{4}|N_1| \,\middle|\, N_1\right] \geq 1 - e^{-\Omega(|N_1|)} = 1 - e^{-\Omega(\delta m/n)} \ .$$

Combining the two bounds we finish the proof. □

Fact 5.10.5. *Suppose $x \sim \mathcal{N}(0, \sigma^2)$ is a Gaussian random variable. For any $t \in (0, \sigma)$ we have*

$$\Pr[x \geq t] \in \left[\tfrac{1}{2}(1 - \tfrac{4}{5}\tfrac{t}{\sigma}), \tfrac{1}{2}(1 - \tfrac{2}{3}\tfrac{t}{\sigma})\right].$$

Similarly, if $x \sim \mathcal{N}(\mu, \sigma^2)$, for any $t \in (0, \sigma)$, we have

$$\Pr[|x| \geq t] \in \left[1 - \tfrac{4}{5}\tfrac{t}{\sigma}, 1 - \tfrac{2}{3}\tfrac{t}{\sigma}\right].$$

5.11 Theorem 5.11.1: Gradient Bound at After Perturbation

In this section we prove our main theorem on the gradient upper and lower bounds.

Theorem 5.11.1 (gradient bound, restated)**.** *Let* $\omega \stackrel{\text{def}}{=} O\big(\frac{\delta^{3/2}}{n^{9/2}L^6\log^3 m}\big)$*. With probability at least* $1-e^{-\Omega(m\omega^{2/3}L)}$ *over the randomness of* $\overrightarrow{W}^{(0)}, A, B$*, it satisfies for every* $\ell\in[L]$*, every* $i\in[n]$*, and every* $\overrightarrow{W}$ *with* $\|\overrightarrow{W}-\overrightarrow{W}^{(0)}\|_2\le\omega$*,*

$$\|\nabla_{W_\ell}F_i(\overrightarrow{W})\|_F^2 \le O\Big(\frac{F_i(\overrightarrow{W})}{d}\times m\Big) \qquad \|\nabla_{W_\ell}F(\overrightarrow{W})\|_F^2 \le O\Big(\frac{F(\overrightarrow{W})}{d}\times mn\Big)$$
$$\|\nabla_{W_L}F(\overrightarrow{W})\|_F^2 \ge \Omega\Big(\frac{\max_{i\in[n]}F_i(\overrightarrow{W})}{dn/\delta}\times m\Big)\ .$$

Remark 5.11.1. Our Theorem 5.11.1 only gives gradient lower bound on $\|\nabla_{W_L}F(\overrightarrow{W})\|_F$. In principle, one can derive similar lower bounds on $\|\nabla_{W_\ell}F(\overrightarrow{W})\|_F$ for all $\ell=1,2,\dots,L-1$. However, the proof will be significantly more involved. We choose not to derive those bounds at the expense of losing a polynomial factor in L in the final running time. For readers interested in the techniques for obtaining those bounds, we refer to them to the "randomness decomposition" part of [AZLS18].

Proof of Theorem 5.11.1. Again we denote by $\widetilde{D}_{i,\ell}$ and $D_{i,\ell}$ respectively the sign matrix at the initialization $\overrightarrow{W}^{(0)}$ and at the current point $\overrightarrow{W}$; and by $\widetilde{h}_{i,\ell}$ and $h_{i,\ell}$ respectively the forward vector at $\overrightarrow{W}^{(0)}$ and at $\overrightarrow{W}$. Let us choose $s=O(m\omega^{2/3}L)$ which bounds the sparsity of $\|D_{i,\ell}-\widetilde{D}_{i,\ell}\|_0$ by Lemma 5.9.1b. Recall

$$\begin{aligned}&\widehat{\nabla}^{\mathsf{v}}_{W_\ell}F(\overrightarrow{W}^{(0)})-\widehat{\nabla}^{\mathsf{v}}_{W_\ell}F(\overrightarrow{W})\\ =&\sum_{i=1}^n\Big(\big(\mathsf{v}_i^\top B\widetilde{D}_{i,L}\widetilde{W}_L\cdots\widetilde{W}_{\ell+1}\widetilde{D}_{i,\ell}\big)^\top(\widetilde{h}_{i,\ell-1})^\top-\big(\mathsf{v}_i^\top BD_{i,L}W_L\cdots W_{\ell+1}D_{i,\ell}\big)^\top(h_{i,\ell-1})^\top\Big)\end{aligned} \tag{5.11}$$

By Lemma 5.9.6, we know that

$$\|\mathsf{v}_i^\top B\widetilde{D}_{i,L}\widetilde{W}_L\cdots\widetilde{D}_{i,a}\widetilde{W}_a\widetilde{D}_{i,a-1}-\mathsf{v}_i^\top BD_{i,L}W_L\cdots D_{i,a}W_aD_{i,a-1}\|\le O(\omega^{1/3}L^2\sqrt{m\log m}/\sqrt{d})\cdot\|\mathsf{v}_i\|$$

By Lemma 5.8.4b we know

$$\|\mathsf{v}_i^\top B\widetilde{D}_{i,L}\widetilde{W}_L\cdots\widetilde{D}_{i,a}\widetilde{W}_a\widetilde{D}_{i,a-1}\|\le O(\sqrt{m/d})\cdot\|\mathsf{v}_i\|$$

By Lemma 5.8.1 and Lemma 5.9.1c, we have

$$\|h_{i,\ell-1}\|\le 1.1\quad\text{and}\quad\|h_{i,\ell-1}-\widetilde{h}_{i,\ell-1}\|\le O(\omega L^{5/2}\sqrt{\log m})$$

Together, they imply

$$\begin{aligned}\Big\|\widehat{\nabla}^{\vec{\mathsf{v}}}_{W_\ell}F(\overrightarrow{W}^{(0)})-\widehat{\nabla}^{\vec{\mathsf{v}}}_{W_\ell}F(\overrightarrow{W})\Big\|_F^2&\le n\|\vec{\mathsf{v}}\|^2\cdot O\left(\omega^{1/3}L^2\sqrt{m\log m}/\sqrt{d}+\sqrt{m/d}\times\omega L^{5/2}\sqrt{\log m}\right)^2\\&\le n\|\vec{\mathsf{v}}\|^2\cdot O\left(\frac{m\log m}{d}\cdot\omega^{2/3}L^4\right)\quad.\end{aligned}\tag{5.12}$$

With our parameter assumption on ω, this together with Lemma 5.10.1 implies the same upper and lower bounds at point $\overrightarrow{W}=\overrightarrow{W}^{(0)}+\overrightarrow{W}'$:

$$\|\widehat{\nabla}^{\vec{\mathsf{v}}}_{W_\ell}F_i(\overrightarrow{W}^{(0)}+\overrightarrow{W}')\|_F^2\le O\Big(\frac{\|\mathsf{v}_i\|^2}{d}\times m\Big)\quad\|\widehat{\nabla}^{\vec{\mathsf{v}}}_{W_\ell}F(\overrightarrow{W}^{(0)}+\overrightarrow{W}')\|_F^2\le O\Big(\frac{\|\vec{\mathsf{v}}\|^2}{d}\times mn\Big)$$
$$\|\widehat{\nabla}^{\vec{\mathsf{v}}}_{W_L}F(\overrightarrow{W}^{(0)}+\overrightarrow{W}')\|_F^2\ge\Omega\Big(\frac{\max_{i\in[n]}\|\mathsf{v}_i\|^2}{dn/\delta}\times m\Big)\quad.$$

Finally, taking ϵ-net over all possible vectors $\vec{\mathsf{v}}=(\mathsf{v}_1,\dots,\mathsf{v}_n)\in(\mathbb{R}^d)^n$, we know that the above bounds hold not only for fixed $\vec{\mathsf{v}}$ but for all $\vec{\mathsf{v}}$. In particular, we can now plug in the choice of $\mathsf{v}_i=\mathsf{loss}_i=Bh_{i,L}-y_i^*$ and it implies our desired bounds on the true gradients. □

5.12 Theorem 5.12.1: Objective Semi-Smoothness

The purpose of this section is to prove

Theorem 5.12.1 (objective semi-smoothness, restated). *Let* $\omega \in \big[\Omega(\frac{d^{3/2}}{m^{3/2}L^{3/2}\log^{3/2} m}), O(\frac{1}{L^{4.5}\log^3 m})\big]$ *and* $\overrightarrow{W}^{(0)}, A, B$ *be at random initialization. With probability at least* $1 - e^{-\Omega(m\omega^{2/3}L)}$ *over the randomness of* $\overrightarrow{W}^{(0)}, A, B$*, we have for every* $\breve{\overrightarrow{W}} \in (\mathbb{R}^{m\times m})^L$ *with* $\|\breve{\overrightarrow{W}} - \overrightarrow{W}^{(0)}\|_2 \le \omega$*, and for every* $\overrightarrow{W}' \in (\mathbb{R}^{m\times m})^L$ *with* $\|\overrightarrow{W}'\|_2 \le \omega$*, we have*

$$F(\breve{\overrightarrow{W}} + \overrightarrow{W}') \le F(\breve{\overrightarrow{W}}) + \langle \nabla F(\breve{\overrightarrow{W}}), \overrightarrow{W}'\rangle + \sqrt{nF(\breve{\overrightarrow{W}})} \cdot \frac{\omega^{1/3}L^2\sqrt{m\log m}}{\sqrt{d}} \cdot O(\|\overrightarrow{W}'\|_2) + O\big(\frac{nL^2m}{d}\big)\|\overrightarrow{W}'\|_2^2$$

We introduce the following notations before we go to proofs.

Definition 5.12.1. For $i \in [n]$ and $\ell \in [L]$:

$$\begin{array}{lll}
\widetilde{g}_{i,0} = Ax_i & \breve{g}_{i,0} = Ax_i & g_{i,0} = Ax_i \\
\widetilde{h}_{i,0} = \phi(Ax_i) & \hbar_{i,0} = \phi(Ax_i) & h_{i,0} = \phi(Ax_i) \\
\widetilde{g}_{i,\ell} = \widetilde{W}_\ell \widetilde{h}_{i,\ell-1} & \breve{g}_{i,\ell} = \breve{W}_\ell \hbar_{i,\ell-1} & g_{i,\ell} = (\breve{W}_\ell + W'_\ell)h_{i,\ell-1} \\
\widetilde{h}_{i,\ell} = \phi(\widetilde{W}_\ell \widetilde{h}_{i,\ell-1}) & \hbar_{i,\ell} = \phi(\breve{W}_\ell \hbar_{i,\ell-1}) & h_{i,\ell} = \phi((\breve{W}_\ell + W'_\ell)h_{i,\ell-1}) \\
 & \breve{\mathsf{loss}}_i = B\hbar_{i,L} - y_i^* &
\end{array}$$

Define diagonal matrices $\widetilde{D}_{i,\ell} \in \mathbb{R}^{m\times m}$ and $\breve{D}_{i,\ell} \in \mathbb{R}^{m\times m}$ respectively by letting

$$(\widetilde{D}_{i,\ell})_{k,k} = \mathbb{1}_{(\widetilde{g}_{i,\ell})_k \ge 0} \text{ and } (\breve{D}_{i,\ell})_{k,k} = \mathbb{1}_{(\breve{g}_{i,\ell})_k \ge 0}, \forall k \in [m].$$

The following claim gives rise to a new recursive formula to calculate $h_{i,\ell} - \hbar_{i,\ell}$.

Claim 5.12.2. *There exist diagonal matrices $D''_{i,\ell} \in \mathbb{R}^{m\times m}$ with entries in $[-1,1]$ such that,*

$$\forall i \in [n], \forall \ell \in [L]: \quad h_{i,\ell} - \hbar_{i,\ell} = \sum_{a=1}^{\ell} (\breve{D}_{i,\ell} + D''_{i,\ell}) \breve{W}_\ell \cdots \breve{W}_{a+1} (\breve{D}_{i,a} + D''_{i,a}) W'_a h_{i,a-1} \tag{5.13}$$

Furthermore, we have $\|h_{i,\ell} - \hbar_{i,\ell}\| \le O(L^{1.5})\|W'\|_2$, $\|Bh_{i,\ell} - B\hbar_{i,\ell}\| \le O(L\sqrt{m/d})\|W'\|_2$ and $\|D''_{i,\ell}\|_0 \le O(m\omega^{2/3}L)$.

Proof of Theorem 5.12.1. First of all, since

$$\frac{1}{2}\|Bh_{i,L} - y_i^*\|^2 = \frac{1}{2}\|\breve{\mathsf{loss}}_i + B(h_{i,L} - \hbar_{i,L})\|^2 = \frac{1}{2}\|\breve{\mathsf{loss}}_i\|^2 + \breve{\mathsf{loss}}_i^\top B(h_{i,L} - \hbar_{i,L}) + \frac{1}{2}\|B(h_{i,L} - \hbar_{i,L})\|^2 \tag{5.14}$$

we can write

$$\begin{aligned}
&F(\breve{\overrightarrow{W}} + \overrightarrow{W}') - F(\overrightarrow{W}) - \langle \nabla F(\overrightarrow{W}), \overrightarrow{W}' \rangle \\
&\overset{①}{=} -\langle \nabla F(\breve{\overrightarrow{W}}), \overrightarrow{W}' \rangle + \frac{1}{2}\sum_{i=1}^n \|Bh_{i,L} - y^*_{i,L}\|^2 - \|B\hbar_{i,L} - y^*_{i,L}\|^2 \\
&\overset{②}{=} -\langle \nabla F(\breve{\overrightarrow{W}}), \overrightarrow{W}' \rangle + \sum_{i=1}^n \breve{\mathsf{loss}}_i^\top B(h_{i,L} - \hbar_{i,L}) + \frac{1}{2}\|B(h_{i,L} - \hbar_{i,L})\|^2 \\
&\overset{③}{=} \sum_{i=1}^n \breve{\mathsf{loss}}_i^\top B \left((h_{i,L} - \hbar_{i,L}) - \sum_{\ell=1}^L \breve{D}_{i,L}\breve{W}_L \cdots \breve{W}_{\ell+1}\breve{D}_{i,\ell} W'_\ell \hbar_{i,\ell-1} \right) + \frac{1}{2}\|B(h_{i,L} - \hbar_{i,L})\|^2 \\
&\overset{④}{=} \sum_{i=1}^n \breve{\mathsf{loss}}_i^\top B \left(\sum_{\ell=1}^L (\breve{D}_{i,L} + D''_{i,L})\breve{W}_L \cdots \breve{W}_{\ell+1}(\breve{D}_{i,\ell} + D''_{i,\ell}) W'_\ell h_{i,\ell-1} - \breve{D}_{i,L}\breve{W}_L \cdots \breve{W}_{\ell+1}\breve{D}_{i,\ell} W'_\ell \hbar_{i,\ell-1} \right) \\
&\quad + \frac{1}{2}\sum_{i=1}^n \|B(h_{i,L} - \hbar_{i,L})\|^2
\end{aligned} \tag{5.15}$$

Above, ① is by the definition of $F(\cdot)$; ② is by (5.14); ③ is by the definition of $\nabla F(\cdot)$ (see Fact 5.2.3 for an explicit form of the gradient).

We next bound the RHS of (5.15). We first note that by Lemma 5.9.1b, we have $\|\breve{D}_{i,\ell} + D''_{i,\ell} - \widetilde{D}_{i,\ell}\|_0 \le s$ and $\|\breve{D}_{i,\ell} - \widetilde{D}_{i,\ell}\|_0 \le s$ for $s = O(m\omega^{2/3}L)$.

We ignore subscripts in i for notational convenience. We first use Claim 5.12.2 to get

$$\|B(h_L - \hbar_L)\| \le O(L\sqrt{m/d}) \cdot \|\overrightarrow{W}'\|_2 \ . \tag{5.16}$$

Next we calculate that

$$\begin{aligned}
&\left|\breve{\mathsf{loss}}_i^\top B(\breve{D}_L + D_L'')\breve{W}_L \cdots (\breve{D}_\ell + D_\ell'')W_\ell' h_{\ell-1} - \breve{\mathsf{loss}}_i^\top B\breve{D}_L\breve{W}_L \cdots \breve{D}_\ell W_\ell' h_{\ell-1}\right| \\
&\le \|\breve{\mathsf{loss}}_i\| \cdot \underbrace{\left\|B(\breve{D}_L + D_L'')\breve{W}_L \cdots \breve{W}_{\ell-1}(\breve{D}_\ell + D_\ell'') - B\breve{D}_L\breve{W}_L \cdots \breve{W}_{\ell-1}\breve{D}_\ell\right\|_2}_{\text{Lemma 5.9.6 with } s = O(m\omega^{2/3}L)} \cdot \|W_\ell' h_{\ell-1}\| \\
&\le \|\breve{\mathsf{loss}}_i\| \cdot O\left(\frac{\sqrt{L^3\omega^{2/3}Lm\log m}}{\sqrt{d}}\right) \cdot O(\|W_\ell'\|_2) \ .
\end{aligned} \tag{5.17}$$

Finally, we also have

$$\begin{aligned}
&\left|\breve{\mathsf{loss}}_i^\top B\breve{D}_L\breve{W}_L \cdots \breve{D}_\ell W_\ell'(h_{\ell-1} - \hbar_{\ell-1})\right| \\
&\overset{①}{\le} \|\breve{\mathsf{loss}}_i\| \cdot O\left(\sqrt{m/d} + \frac{\omega^{1/3}L^2\sqrt{m\log m}}{\sqrt{d}}\right) \cdot \|W_\ell'\|_2 \cdot \|h_\ell - \hbar_\ell\|_2 \\
&\overset{②}{\le} O(L^{0.5}\sqrt{m/d}) \cdot \|\breve{\mathsf{loss}}_i\|_2 \cdot L^{1.5}\|W_\ell'\|^2
\end{aligned} \tag{5.18}$$

where ① uses Lemma 5.8.4b (and Lemma 5.9.6 for bounding the perturbation) and ② uses Claim 5.12.2 to bound $\|h_\ell - \hbar_\ell\|_2$ and our choice of ω.

Putting (5.16), (5.17) and (5.18) back to (5.15), and using triangle inequality, we have the desired result. □

5.12.1 Proof of Claim 5.12.2

We first present a simple proposition about the ReLU function.

Proposition 5.12.3. *Given vectors $a, b \in \mathbb{R}^m$ and $D \in \mathbb{R}^{m \times m}$ the diagonal matrix where $D_{k,k} = \mathbb{1}_{a_k \geq 0}$. Then, then there exists a diagonal matrix $D'' \in \mathbb{R}^{m \times m}$ with*

- $|D_{k,k} + D''_{k,k}| \leq 1$ *and* $|D''_{k,k}| \leq 1$ *for every* $k \in [m]$,
- $D''_{k,k} \neq 0$ *only when* $\mathbb{1}_{a_k \geq 0} \neq \mathbb{1}_{b_k \geq 0}$, *and*
- $\phi(a) - \phi(b) = (D + D'')(a - b)$

Proof. We verify coordinate by coordinate for each $k \in [m]$.

- If $a_k \geq 0$ and $b_k \geq 0$, then $(\phi(a) - \phi(b))_k = a_k - b_k = \big(D(a-b)\big)_k$.
- If $a_k < 0$ and $b_k < 0$, then $(\phi(a) - \phi(b))_k = 0 - 0 = \big(D(a-b)\big)_k$.
- If $a_k \geq 0$ and $b_k < 0$, then $(\phi(a) - \phi(b))_k = a_k = (a_k - b_k) + \frac{b_k}{a_k - b_k}(a_k - b_k) = \big(D(a-b) + D''(a-b)\big)_k$, if we define $(D'')_{k,k} = \frac{b_k}{a_k - b_k} \in [-1, 0]$.
- If $a_k < 0$ and $b_k \geq 0$, then $(\phi(a) - \phi(b))_k = -b_k = 0 \cdot (a_k - b_k) - \frac{b_k}{b_k - a_k}(a_k - b_k) = \big(D(a-b) + D''(a-b)\big)_k$, if we define $(D'')_{k,k} = \frac{b_k}{b_k - a_k} \in [0, 1]$. □

Proof of Claim 5.12.2. We ignore the subscript in i for cleanness, and calculate that

$$\begin{aligned} h_\ell - \hbar_\ell &\overset{①}{=} \phi((\breve{W}_\ell + W'_\ell)h_{\ell-1}) - \phi(\breve{W}_\ell \hbar_{\ell-1}) \\ &\overset{②}{=} (\breve{D}_\ell + D''_\ell)\left((\breve{W}_\ell + W'_\ell)h_{\ell-1} - \breve{W}_\ell \hbar_{\ell-1}\right) \\ &= (\breve{D}_\ell + D''_\ell)\breve{W}_\ell(h_{\ell-1} - \hbar_{\ell-1}) + (\breve{D}_\ell + D''_\ell)W'_\ell h_{\ell-1} \\ &\overset{③}{=} \sum_{a=1}^{\ell} (\breve{D}_\ell + D''_\ell)\breve{W}_\ell \cdots \breve{W}_{a+1}(\breve{D}_a + D''_a)W'_a h_{a-1} \end{aligned}$$

Above, ① is by the recursive definition of h_ℓ and $\hbar_\ell$; ② is by Proposition 5.12.3 and D''_ℓ is defined according to Proposition 5.12.3; and inequality ③ is by recursively computing $h_{\ell-1} - \hbar_{\ell-1}$. As for the remaining properties:

- We have $\|D''_\ell\|_0 \le O(m\omega^{2/3}L)$.

  This is because, $(D''_\ell)_{k,k}$ is non-zero only at the coordinates $k \in [m]$ where the signs of $\breve{g}_\ell$ and g_ℓ are opposite (by Proposition 5.12.3). Such a coordinate k must satisfy either $(\widetilde{D}_\ell)_{k,k} \neq (\breve{D}_\ell)_{k,k}$ or $(\widetilde{D}_\ell)_{k,k} \neq (D_\ell)_{k,k}$, and therefore by Lemma 5.9.1b there are at most $O(m\omega^{2/3}L)$ such coordinates k.

- We have $\|h_\ell - \hbar_\ell\| \le O(L^{1.5})\|\overrightarrow{W}'\|_2$.

  This is because we have $\left\|(\breve{D}_\ell + D''_\ell)\breve{W}_\ell \cdots \breve{W}_{a+1}(\breve{D}_a + D''_a)\right\|_2 \le O(\sqrt{L})$ from Lemma 5.9.5b, we have $\|h_{a-1}\| \le O(1)$ (by $\|\widetilde{h}_{a-1}\| \le O(1)$ from Lemma 5.8.1 and $\|\widetilde{h}_{a-1} - h_{a-1}\| \le o(1)$ from Lemma 5.9.1c); and and $\|W'_a h_{a-1}\| \le \|W'_a\|_2 \|h_{a-1}\| \le O(\|\overrightarrow{W}'\|_2)$.

- We have $\|Bh_\ell - B\hbar_\ell\| \le O(L\sqrt{m/d})\|\overrightarrow{W}'\|_2$.

  This is because we have $\left\|B(\breve{D}_\ell + D''_\ell)\breve{W}_\ell \cdots \breve{W}_{a+1}(\breve{D}_a + D''_a)\right\|_2 \le O(\sqrt{m/d})$ from Lemma 5.8.4b (along with perturbation bound Lemma 5.9.6), we have $\|h_{a-1}\| \le O(1)$

(by $\|\widetilde{h}_{a-1}\| \leq O(1)$ from Lemma 5.8.1 and $\|\widetilde{h}_{a-1} - h_{a-1}\| \leq o(1)$ from Lemma 5.9.1c); and and $\|W'_a h_{a-1}\| \leq \|W'_a\|_2 \|h_{a-1}\| \leq O(\|\overrightarrow{W}'\|_2)$.

□

5.13 Theorem 5.13.1: Convergence Rate of GD

Theorem 5.13.1 (gradient descent, restated)**.** *For any $\epsilon \in (0,1]$, $\delta \in \big(0, O(\frac{1}{L})\big]$. Let $m \geq \widetilde{\Omega}\big(\operatorname{poly}(n, L, \delta^{-1})d\big)$, $\eta = \Theta\big(\frac{d\delta}{\operatorname{poly}(n,L)m}\big)$, and $\overrightarrow{W}^{(0)}, A, B$ are at random initialization. Then, with probability at least $1-e^{-\Omega(\log^2 m)}$, suppose we start at $\overrightarrow{W}^{(0)}$ and for each $t = 0, 1, \ldots, T-1$,*

$$\overrightarrow{W}^{(t+1)} = \overrightarrow{W}^{(t)} - \eta \nabla F(\overrightarrow{W}^{(t)}) \ .$$

Then, it satisfies

$$F(\overrightarrow{W}^{(T)}) \leq \epsilon \quad \textit{for} \quad T = \Theta\left(\frac{\operatorname{poly}(n,L)}{\delta^2} \log \frac{1}{\epsilon}\right) \ .$$

In other words, the training loss drops to ϵ in a linear convergence speed.

Proof of Theorem 5.13.1. Using Lemma 5.8.1 we have $\|h_{i,L}\|_2 \leq 1.1$ and then using the randomness of B, it is easy to show that $\|B\widetilde{h}_{i,L} - y_i^*\|^2 \leq O(\log^2 m)$ with at least $1-e^{-\Omega(\log^2 m)}$ (where $\widetilde{h}_{i,L}$ is defined with respect to the random initialization $\overrightarrow{W}^{(0)}$), and therefore

$$F(\overrightarrow{W}^{(0)}) \leq O(n \log^2 m) \ .$$

Let us assume for every $t = 0, 1, \ldots, T-1$, the following holds

$$\|\overrightarrow{W}^{(t)} - \overrightarrow{W}^{(0)}\|_F \leq \omega \stackrel{\text{def}}{=} O\left(\frac{n^3\sqrt{d}}{\delta\sqrt{m}} \log m\right) \ . \tag{5.19}$$

We shall prove the convergence of GD assuming (5.19) holds, so that previous statements such as Theorem 5.12.1 and Theorem 5.11.1 can be applied. At the end of the proof, we shall verify that (5.19) is satisfied.

To make the proof simple, we choose

$$m \geq \Omega\big(\frac{n^{24}L^{12}d\log^5 m}{\delta^8}\big),$$
$$\eta = \Theta\big(\frac{d\delta}{n^4L^2m}\big),$$
$$T = \Theta\left(\frac{n^6L^2}{\delta^2}\log\frac{1}{\epsilon}\right)$$

We emphasize that

- Most of the polynomial dependency in n, L, δ^{-1} come from the non-smoothness of the ReLU activation; if one instead studies smooth activations, their power can be significantly reduced. For instance, for smooth activation functions, one does not need the semi-smoothness Theorem 5.12.1.
- We have not tried to tighten the polynomial dependency on n, L, δ^{-1}. We are aware of many ways to improve the constant in the exponents at the expense of complicating the proofs. Since the main focus of this paper is to derive the first *polynomial* running time, we do not include such improvements.

Letting $\nabla_t = \nabla F(\overrightarrow{W}^{(t)})$, we calculate that

$$\begin{aligned}
&F(\overrightarrow{W}^{(t+1)}) \\
&\overset{①}{\leq} F(\overrightarrow{W}^{(t)}) - \eta\|\nabla F(\overrightarrow{W}^{(t)})\|_F^2 + \eta\sqrt{nF(\overrightarrow{W}^{(t)})}\cdot O\left(\frac{\omega^{1/3}L^2\sqrt{m\log m}}{\sqrt{d}}\right)\cdot\|\nabla_t\|_2 + O\big(\eta^2\frac{nL^2m}{d}\big)\|\nabla_t\|_2^2 \\
&\overset{②}{\leq} F(\overrightarrow{W}^{(t)}) - \eta\|\nabla F(\overrightarrow{W}^{(t)})\|_F^2 + O\left(\frac{\eta nL^2m\omega^{1/3}\sqrt{\log m}}{d} + \frac{\eta^2n^2L^2m^2}{d^2}\right)\cdot F(\overrightarrow{W}^{(t)}) \\
&\overset{③}{\leq} \left(1 - \Omega\Big(\frac{\eta\delta m}{dn^2}\Big)\right)F(\overrightarrow{W}^{(t)}) \ . \qquad (5.20)
\end{aligned}$$

Above, ① uses Theorem 5.12.1; ② uses Theorem 5.11.1 (which gives $\|\nabla_t\|_2^2 \le \max_{\ell\in[L]} \|\nabla_{W_\ell} F(\overrightarrow{W}^{(t)})\|_F^2 \le O\big(\frac{F(\overrightarrow{W}^{(t)})}{d} \times mn\big)$); ③ use gradient lower bound from Theorem 5.11.1 and our choice of η. In other words, after $T = \Theta(\frac{dn^2}{\eta\delta m}) \log \frac{n \log m}{\epsilon}$ iterations we have $F(\overrightarrow{W}^{(T)}) \le \epsilon$.

We need to verify for each t, $\|\overrightarrow{W}^{(t)} - \overrightarrow{W}^{(0)}\|_F$ is small so that (5.19) holds. By Theorem 5.11.1,

$$\begin{aligned}\|W_\ell^{(t)} - W_\ell^{(0)}\|_F &\le \sum_{i=0}^{t-1} \|\eta \nabla_{W_\ell} F(\overrightarrow{W}^{(i)})\|_F \le O(\eta\sqrt{nm/d}) \cdot \sum_{i=0}^{t-1} \sqrt{F(\overrightarrow{W}^{(i)})} \\ &\le O(\eta\sqrt{nm/d}) \cdot \Theta(\frac{dn^2}{\eta\delta m}) \cdot O(\sqrt{n\log^2 m}) \le O\left(\frac{n^3\sqrt{d}}{\delta\sqrt{m}} \log m\right) .\end{aligned}$$

where the last step follows by our choice of T. □

5.14 Theorem 5.14.1: Convergence Rate of SGD

Theorem 5.14.1 (stochastic gradient descent, stated)**.** *For any* $\epsilon \in (0,1]$, $\delta \in \big(0, O(\frac{1}{L})\big]$, $b \in [n]$. *Let* $m \geq \widetilde{\Omega}\big(\frac{\mathrm{poly}(n,L,\delta^{-1})\cdot d}{b}\big)$, $\eta \stackrel{\text{def}}{=} \Theta(\frac{b\delta d}{\mathrm{poly}(n,L)m\log^2 m})$, *and* $\overrightarrow{W}^{(0)}, A, B$ *are at random initialization. Suppose we start at* $W^{(0)}$ *and for each* $t = 0, 1, \ldots, T-1$,

$$W^{(t+1)} = W^{(t)} - \eta \cdot \frac{n}{|S_t|} \sum_{i \in S_t} \nabla F(W^{(t)})$$

(for a random subset $S_t \subseteq [n]$ of fixed cardinality b.)

Then, it satisfies with probability at least $1 - e^{-\Omega(\log^2 m)}$ *over the randomness of* $S_1, \ldots, S_T$*:*

$$F(W^{(T)}) \leq \epsilon \quad \textit{for all} \quad T = \Theta\Big(\frac{\mathrm{poly}(n,L)\log^2 m}{b\delta^2} \log \frac{n \log m}{\epsilon}\Big) \ .$$

The proof of Theorem 5.14.1 is the same as Theorem 5.13.1 plus the careful use of martingale concentration.

Proof of Theorem 5.14.1. Using similar argument as the proof of Theorem 5.13.1, we have with at least $1 - e^{-\Omega(\log^2 m)}$ probability

$$F(\overrightarrow{W}^{(0)}) \leq O(n \log^2 m) \ .$$

Let us assume for every $t = 0, 1, \ldots, T-1$, the following holds

$$\|\overrightarrow{W}^{(t)} - \overrightarrow{W}^{(0)}\|_F \leq \omega \stackrel{\text{def}}{=} O\left(\frac{n^{3.5}\sqrt{d}}{\delta\sqrt{bm}} \log m\right) \ . \tag{5.21}$$

We shall prove the convergence of SGD assuming (5.21) holds, so that previous statements such as Theorem 5.12.1 and Theorem 5.11.1 can be applied. At the end of the proof, we shall verify that (5.21) is satisfied throughout the SGD with high probability.

To make the proof simple, we choose

$$m \geq \Omega\big(\frac{n^{24}L^{12}bd\log^5 m}{\delta^8}\big),$$
$$\eta = \Theta\big(\frac{b\delta d}{n^5L^2m\log^2 m}\big),$$

$$T = \Theta\Big(\frac{dn^2}{\eta\delta m}\log\frac{n\log m}{\epsilon}\Big)$$
$$= \Theta\Big(\frac{n^7L^2\log^2 m}{b\delta^2}\log\frac{n\log m}{\epsilon}\Big)$$

We emphasize that

- Most of the polynomial dependency in n, L, δ^{-1} come from the non-smoothness of the ReLU activation; if one instead studies smooth activations, their power can be significantly reduced. For instance, for smooth activation functions, one does not need the semi-smoothness Theorem 5.12.1.
- We have not tried to tighten the polynomial dependency on n, L, δ^{-1}. We are aware of many ways to improve the constant in the exponents at the expense of complicating the proofs. Since the main focus of this paper is to derive the first *polynomial* running time, we do not include such improvements.

For each $t = 0, 1, \ldots, T-1$, using the same notation as Theorem 5.13.1, except that

we choose $\nabla_t = \frac{n}{|S_t|}\sum_{i\in S_t}\nabla F_i(\overrightarrow{W}^{(t)})$. We have $\mathbb{E}_{S_t}[\nabla_t] = \nabla F(\overrightarrow{W}^{(t)})$ and therefore

$$\begin{aligned}
&\mathop{\mathbb{E}}_{S_t}[F(\overrightarrow{W}^{(t+1)})] \\
&\overset{①}{\le} F(\overrightarrow{W}^{(t)}) - \eta\|\nabla F(\overrightarrow{W}^{(t)})\|_F^2 + \eta\sqrt{nF(\overrightarrow{W}^{(t)})}\cdot O\left(\frac{\omega^{1/3}L^2\sqrt{m\log m}}{\sqrt{d}}\right)\cdot \mathop{\mathbb{E}}_{S_t}[\|\nabla_t\|_2] \\
&\quad + O\big(\eta^2\frac{nL^2m}{d}\big)\mathop{\mathbb{E}}_{S_t}[\|\nabla_t\|_2^2] \\
&\overset{②}{\le} F(\overrightarrow{W}^{(t)}) - \eta\|\nabla_t\|_F^2 + O\left(\frac{\eta nL^2m\omega^{1/3}\sqrt{\log m}}{d} + \frac{\eta^2n^2L^2m^2}{d^2}\right)\cdot F(\overrightarrow{W}^{(t)}) \\
&\overset{③}{\le} \left(1 - \Omega\Big(\frac{\eta\delta m}{dn^2}\Big)\right)F(\overrightarrow{W}^{(t)}) \ . \qquad (5.22)
\end{aligned}$$

Above, ① uses Theorem 5.12.1 and $\mathbb{E}_{S_t}[\nabla_t] = \nabla F(\overrightarrow{W}^{(t)})$; ② uses Theorem 5.11.1 which give

$$\begin{aligned}
&\mathop{\mathbb{E}}_{S_t}\left[\|\nabla_t\|_2^2\right] \le \frac{n^2}{b}\mathop{\mathbb{E}}_{S_t}\left[\sum_{i\in S_t}\max_{\ell\in[L]}\left\|\nabla_{W_\ell}F_i(\overrightarrow{W}^{(t)})\right\|_F^2\right] \le O\Big(\frac{nmF(\overrightarrow{W}^{(t)})}{d}\Big) \\
&\mathop{\mathbb{E}}_{S_t}\left[\|\nabla_t\|_2\right] \le \left(\mathop{\mathbb{E}}_{S_t}\left[\|\nabla_t\|_2^2\right]\right)^{1/2} \le O\Big(\big(\frac{nmF(\overrightarrow{W}^{(t)})}{d}\big)^{1/2}\Big) \ ;
\end{aligned}$$

③ use gradient lower bound from Theorem 5.11.1 and our choice of η.

At the same time, we also have the following absolute value bound:

$$\begin{aligned}
F(\overrightarrow{W}^{(t+1)}) &\overset{①}{\le} F(\overrightarrow{W}^{(t)}) + \eta\|\nabla F(\overrightarrow{W}^{(t)})\|_F \cdot \|\nabla_t\|_F \\
&\quad + \eta\sqrt{nF(\overrightarrow{W}^{(t)})} \cdot O\left(\frac{\omega^{1/3}L^2\sqrt{m\log m}}{\sqrt{d}}\right) \cdot \|\nabla_t\|_2 + O\Big(\eta^2\frac{nL^2m}{d}\Big) \cdot \|\nabla_t\|_2^2 \\
&\overset{②}{\le} F(\overrightarrow{W}^{(t)}) + \eta \cdot O\left(\sqrt{\frac{LF(\overrightarrow{W}^{(t)})mn}{d}}\right) \cdot O\left(\sqrt{\frac{n^2mLF(\overrightarrow{W}^{(t)})}{bd}}\right) \\
&\quad + \eta\sqrt{nF(\overrightarrow{W}^{(t)})} \cdot O\left(\frac{\omega^{1/3}L^2\sqrt{m\log m}}{\sqrt{d}}\right) \cdot \frac{\sqrt{n^2mF(\overrightarrow{W}^{(t)})}}{\sqrt{bd}} \\
&\quad + O\Big(\eta^2\frac{nL^2m}{d}\Big) \cdot \frac{n^2}{b}O\Big(\frac{mF(\overrightarrow{W}^{(t)})}{d}\Big) \\
&\overset{③}{\le} \Big(1 + O\Big(\frac{\eta Lmn^{1.5}}{\sqrt{bd}} + \frac{\eta n^{1.5}\omega^{1/3}L^2m\sqrt{\log m}}{\sqrt{bd}} + \frac{\eta^2n^3L^2m^2}{d^2b}\Big)\Big)F(\overrightarrow{W}^{(t)}) \ . \qquad (5.23)
\end{aligned}$$

Above, ① uses Theorem 5.12.1 and Cauchy-Schwarz $\langle A, B\rangle \le \|A\|_F\|B\|_F$, and ② uses Theorem 5.11.1 which give

$$\|\nabla_t\|_2^2 \le \frac{n^2}{b}\left[\sum_{i\in S_t}\max_{\ell\in[L]}\Big\|\nabla_{W_\ell}F_i(\overrightarrow{W}^{(t)})\Big\|_F^2\right] \le \frac{n^2}{b}O\Big(\frac{mF(\overrightarrow{W}^{(t)})}{d}\Big)$$

$$\|\nabla_t\|_F^2 \le \frac{n^2}{b}\left[\sum_{i\in S_t}\sum_{\ell=1}^{L}\Big\|\nabla_{W_\ell}F_i(\overrightarrow{W}^{(t)})\Big\|_F^2\right] \le \frac{Ln^2}{b}O\Big(\frac{mF(\overrightarrow{W}^{(t)})}{d}\Big)$$

and the derivation from (5.22).

Next, taking logarithm on both sides of (5.22) and (5.23), and using Jensen's inequality $\mathbb{E}[\log X] \le \log\mathbb{E}[X]$, we have

$$\mathbb{E}[\log F(\overrightarrow{W}^{(t+1)})] \le \log F(\overrightarrow{W}^{(t)}) - \Omega\Big(\frac{\eta\delta m}{dn^2}\Big) \quad \text{and} \quad \log F(\overrightarrow{W}^{(t+1)}) \le \log F(\overrightarrow{W}^{(t)}) + O\Big(\frac{\eta Lmn^{1.5}}{\sqrt{bd}}\Big)$$

By (one-sided) martingale concentration, we have with probability at least $1 - e^{-\Omega(\log^2 m)}$, for every $t = 1, 2, \ldots, T$:

$$\log F(\overrightarrow{W}^{(t)}) - \mathbb{E}[\log F(\overrightarrow{W}^{(t)})] \le \sqrt{t} \cdot O\Big(\frac{\eta Lmn^{1.5}}{\sqrt{bd}}\Big) \cdot \log m \ .$$

This implies for every $t = 1, 2, \ldots, T$, we have

$$\begin{aligned}
\log F(\overrightarrow{W}^{(t)}) &\le \sqrt{t} \cdot O\Big(\frac{\eta L m n^{1.5}}{\sqrt{b} d}\Big) \cdot \log m + \log F(\overrightarrow{W}^{(0)}) - \Omega\Big(\frac{\eta \delta m}{d n^2}\Big) t \\
&\overset{①}{=} \log F(\overrightarrow{W}^{(0)}) - \left(\sqrt{\frac{\eta\delta m}{dn^2}} \cdot \Omega(\sqrt{t}) - \sqrt{\frac{dn^2}{\eta\delta m}} \cdot O\Big(\frac{\eta L m n^{1.5}}{\sqrt{b} d} \log m\Big)\right)^2 \\
&\quad + O\Big(\frac{\eta L^2 m n^5}{b\delta d} \log^2 m\Big) \\
&\overset{②}{\le} \log F(\overrightarrow{W}^{(0)}) + 1 - \left(\sqrt{\frac{\eta\delta m}{dn^2}} \cdot \Omega(\sqrt{t}) - \sqrt{\frac{dn^2}{\eta\delta m}} \cdot O\Big(\frac{\eta L m n^{1.5}}{\sqrt{b} d} \log m\Big)\right)^2 \\
&\overset{③}{\le} \log F(\overrightarrow{W}^{(0)}) + 1 - \mathbb{1}\left[t \ge \Theta\Big(\frac{L^2 n^7}{b\delta^2} \log^2 m\Big)\right] \cdot \Omega\left(\frac{\eta\delta m}{dn^2} t\right) \\
&\overset{④}{\le} \log F(\overrightarrow{W}^{(0)}) + 1 - \mathbb{1}\left[t \ge \Theta\Big(\frac{L^2 n^7}{b\delta^2} \log^2 m\Big)\right] \cdot \Omega\left(\frac{b\delta^2}{L^2 n^7 \log^2 m} t\right) \quad .
\end{aligned}$$

Above, in ① we have used $2a\sqrt{t} - b^2 t = -(b\sqrt{t} - a/b)^2 + a^2/b^2$; in ② we have used our choice of η; in ③ we have used $-(a\sqrt{t} - b)^2 \le -\mathbb{1}[t \ge 2b^2/a^2] \cdot \frac{a^2 t}{4}$; and in ④ we have used our choice of η again. We can read two things from the above formula:

- If $T \ge \Omega\big(\frac{L^2 n^7}{b\delta^2} \log^2 m \log \frac{n \log m}{\epsilon}\big)$ then we have

  $$\log F(\overrightarrow{W}^{(T)}) \le \log O(n \log^2 m) - \Omega\Big(\log \frac{n \log^2 m}{\epsilon}\Big) \le \log \epsilon \quad .$$

  so $F(\overrightarrow{W}^{(T)}) \le \epsilon$.

- Letting $T_0 = \Omega\big(\frac{L^2 n^7}{b\delta^2} \log^2 m\big)$, we have

  $$\sum_{i=0}^{t-1} \sqrt{F(\overrightarrow{W}^{(i)})} \le \sqrt{n \log^2 m} \cdot 2T_0 + \frac{\sqrt{n \log^2 m}}{2} \cdot 2T_0 + \frac{\sqrt{n \log^2 m}}{4} \cdot 2T_0 + \cdots \le O\big(\sqrt{n \log^2 m} T_0\big)$$

and therefore one can verify that $\|\overrightarrow{W}^{(t)} - \overrightarrow{W}^{(0)}\|_F$ is small and (5.21) holds: by Theorem 5.11.1,

$$\|W_\ell^{(t)} - W_\ell^{(0)}\|_F \le \sum_{i=0}^{t-1} \left\| \eta \frac{n}{|S_t|} \sum_{i \in S_t} \nabla_{W_\ell} F_i(\overrightarrow{W}^{(t)}) \right\|_F \le O\left(\eta \sqrt{\frac{n^2 m}{bd}}\right) \cdot \sum_{i=0}^{t-1} \sqrt{F(\overrightarrow{W}^{(i)})}$$
$$\le O\left(\eta \sqrt{\frac{n^2 m}{bd}}\right) \cdot O(T_0 \sqrt{n} \log m) \le O\left(\frac{n^{3.5}\sqrt{d}}{\delta \sqrt{bm}} \log m\right) \quad . \qquad \square$$

5.15 Theorem 5.15.1: Equivalence to Neural Tangent Kernel

Recall on input $x \in \mathbb{R}^{\mathfrak{d}}$, the network output $y(\overrightarrow{W}; x) \stackrel{\text{def}}{=} y = Bh_L \in \mathbb{R}^d$ is a function of the weights $\overrightarrow{W}$. The *neural tangent kernel (NTK)* [JGH18] is usually referred to as the feature space defined by the network gradient at random initialization. In other words, for the j-th output dimension,

- the NTK kernel function $K_j^{\mathsf{ntk}}(x, \widetilde{x}) \stackrel{\text{def}}{=} \langle \nabla y_j(\overrightarrow{W}^{(0)}; x), \nabla y_j(\overrightarrow{W}^{(0)}; \widetilde{x}) \rangle$
- the NTK objective $y_j^{\mathsf{ntk}}(\overrightarrow{W}'; x) \stackrel{\text{def}}{=} \langle \nabla y_j(\overrightarrow{W}^{(0)}; x), \overrightarrow{W}' \rangle$.

We have the following theorem whose proof is subsumed by the proofs of Theorem 5.11.1 and 5.12.1. We prove it here for completeness' sake.

Theorem 5.15.1. *Let $\overrightarrow{W}^{(0)}, A, B$ be at random initialization. For every fixed unit vector $x \in \mathbb{R}^{\mathfrak{d}}$, every (small) parameter $\omega \in \big[\Omega(\frac{d^{3/2}}{m^{3/2}L^{3/2}\log^{3/2} m}), O(\frac{1}{L^{4.5}\log^3 m})\big]$, with probability at least $1 - e^{-\Omega(m\omega^{2/3}L)}$ over $\overrightarrow{W}^{(0)}, A, B$, we have for all $\overrightarrow{W}' \in (\mathbb{R}^{m\times m})^L$ with $\|\overrightarrow{W}'\|_2 \le \omega$, for all $j \in [d]$,*

(a) $\|\nabla y_j(\overrightarrow{W}^{(0)} + \overrightarrow{W}'; x) - \nabla y_j^{\mathsf{ntk}}(\overrightarrow{W}'; x)\|_F \le O\big(\sqrt{\log m} \cdot \omega^{1/3} L^3\big) \cdot \|\nabla y_j^{\mathsf{ntk}}(\overrightarrow{W}'; x)\|_F$ *; and*

(b) $y_j(\overrightarrow{W}^{(0)} + \overrightarrow{W}'; x) = y_j(\overrightarrow{W}^{(0)}; x) + y_j^{\mathsf{ntk}}(\overrightarrow{W}'; x) + O\big(\frac{L^3\omega^{4/3}\sqrt{m\log m}}{\sqrt{d}}\big)$.

(c) If $x, \widetilde{x} \in \mathbb{R}^{\mathfrak{d}}$ are two fixed unit vectors, and $\omega \le O(\frac{1}{L^9 \log^{3/2} m})$, then

$$\big|\big\langle \nabla y_j(\overrightarrow{W}^{(0)} + \overrightarrow{W}'; x), \nabla y_j(\overrightarrow{W}^{(0)} + \overrightarrow{W}'; \widetilde{x})\big\rangle - K_j^{\mathsf{ntk}}(x, \widetilde{x})\big| \le O\big(\sqrt{\log m} \cdot \omega^{1/3} L^3\big) \cdot \sqrt{K_j^{\mathsf{ntk}}(x,x) K_j^{\mathsf{ntk}}(\widetilde{x}, \widetilde{x})} \ .$$

Proof of Theorem 5.15.1. As before we denote by $\widetilde{D}_1, \dots \widetilde{D}_L$ and $\widetilde{h}_1, \dots, \widetilde{h}_L$ the diagonal sign matrices and forward vectors determined at random initialization $\overrightarrow{W}^{(0)}$ and by $D_1, \dots, D_L$ and $h_1, \dots, h_L$ those determined at $\overrightarrow{W} \stackrel{\text{def}}{=} \overrightarrow{W}^{(0)} + \overrightarrow{W}'$. Recall $\|D'_\ell\|_0 = \|D_\ell - \widetilde{D}_\ell\|_0 \le s \stackrel{\text{def}}{=} O(m\omega^{2/3}L)$ from Lemma 5.9.1b.

(a) Let $e_j \in \mathbb{R}^d$ be the j-th basis vector and ℓ be in $[L]$. We have

$$\begin{aligned}&\nabla_{W_\ell} y_j^{\mathsf{ntk}}(\overrightarrow{W}'; x) - \nabla_{W_\ell} y_j(\overrightarrow{W}^{(0)} + \overrightarrow{W}'; x) \\ &= \left(e_j^\top B \widetilde{D}_L \widetilde{W}_L \cdots \widetilde{W}_{\ell+1} \widetilde{D}_\ell\right)^\top (\widetilde{h}_{\ell-1})^\top - \left(e_j^\top B D_L W_L \cdots W_{\ell+1} D_\ell\right)^\top (h_{\ell-1})^\top\end{aligned}$$

This difference matrix is precisely (5.11) (by setting $n = 1$ and $\mathsf{v} = e_j$). Using the bound (5.12) we have its Frobenius norm is at most $O\left(\sqrt{m \log m/d} \cdot \omega^{1/3} L^2\right)$. On the other hand, one can calculate for every $k \in [m]$,

$$\nabla_{[W_L]_k} y_j^{\mathsf{ntk}}(\overrightarrow{W}'; x) = (B^\top e_j)_k \cdot \widetilde{h}_{L-1} \cdot \mathbb{1}_{\langle [W_L]_k, \widetilde{h}_{L-1} \rangle \ge 0} \ .$$

We already know $\|\widetilde{h}_{L-1}\| \ge \Omega(1)$ from Lemma 5.8.1. Now, regardless of the randomness of $\widetilde{h}_{L-1}$, we have $\mathbb{1}_{\langle [W_L]_k, \widetilde{h}_{L-1} \rangle \ge 0} = 1$ with exactly half probability; also, regardless of the randomness of $\overrightarrow{W}^{(0)}$ and A, we have $(B^\top e_j)_k \sim \mathcal{N}(0, \frac{1}{d})$. Therefore, we conclude that with probability at least $1 - e^{-\Omega(m)}$ it satisfies $\|\nabla_{W_L} y_j^{\mathsf{ntk}}(\overrightarrow{W}'; x)\|_F^2 \ge \Omega(m/d)$. Putting the two abounds together we finish the proof.

(b) This statement can be derived from (5.15), (5.17) and (5.18). For completeness' sake,

below we provide a direct proof without invoking them. We first calculate that

$$\Big|y_j(\overrightarrow{W}^{(0)}+\overrightarrow{W}';x)-e_j^\top B\widetilde{D}_L W_L\cdots\widetilde{D}_1W_1x\Big| = \Big|\sum_{\ell=1}^{L} e_j^\top B\widetilde{D}_L W_L\cdots\widetilde{D}_{\ell+1}W_{\ell+1}D'_\ell g_{\ell-1}\Big|$$

$$\le \sum_{\ell=1}^{L}\Big(\underbrace{\Big\|B\widetilde{D}_L\widetilde{W}_L\cdots\widetilde{D}_{\ell+1}\widetilde{W}_{\ell+1}D'_\ell\Big\|_2}_{\text{Lemma 5.8.4a}} + \underbrace{\Big\|B\widetilde{D}_L\widetilde{W}_L\cdots\widetilde{D}_{\ell+1}\widetilde{W}_{\ell+1}-B\widetilde{D}_L W_L\cdots\widetilde{D}_{\ell+1}W_{\ell+1}\Big\|_2}_{\text{Lemma 5.9.6}}\Big)\cdot\underbrace{\|D'_\ell g_{\ell-1}\|}_{\text{Lemma 5.9.1b}}$$

$$\le L\cdot\Big(O\big(\frac{\sqrt{s\log m}}{\sqrt{d}}\big)+O\big(\omega L^{1.5}\frac{\sqrt{m}}{\sqrt{d}}\big)\Big)\cdot O(\omega L^{3/2}) \le O\big(\frac{L^3\omega^{4/3}\sqrt{m\log m}}{\sqrt{d}}\big) \tag{5.24}$$

We next calculate that

$$\Big|e_j^\top B\widetilde{D}_L W_L\cdots\widetilde{D}_1W_1x-y_j(\overrightarrow{W}^{(0)})-y^{\mathsf{ntk}}(\overrightarrow{W}';x)\Big|$$

$$=\Big|\sum_{\ell=1}^{L} e_j^\top B\widetilde{D}_L W_L\cdots W_{\ell+1}\widetilde{D}_\ell W'_\ell\widetilde{h}_{\ell-1}-e_j^\top B\widetilde{D}_L\widetilde{W}_L\cdots\widetilde{W}_{\ell+1}\widetilde{D}_\ell W'_\ell\widetilde{h}_{\ell-1}\Big|$$

$$\le\sum_{\ell=1}^{L}\underbrace{\Big\|B\Big(\widetilde{D}_L W_L\cdots W_{\ell+1}\widetilde{D}_\ell-\widetilde{D}_L\widetilde{W}_L\cdots\widetilde{W}_{\ell+1}\widetilde{D}_\ell\Big)\Big\|_2}_{\text{Lemma 5.9.6}}\cdot\|W'_\ell\|_2\cdot\underbrace{\|\widetilde{h}_{\ell-1}\|}_{\text{Lemma 5.8.1}}$$

$$\le L\cdot O\big(\omega L^{1.5}\frac{\sqrt{m}}{\sqrt{d}}\big)\cdot\omega\cdot O(1)\le O\big(\omega^2L^{2.5}\frac{\sqrt{m}}{\sqrt{d}}\big) \tag{5.25}$$

Putting (5.24) and (5.25) together finishes the proof.

(c) This is a direct corollary of (a). □

5.16 Extension to Other Loss Functions

For simplicity, in them main body of this paper we have used the ℓ_2 regression loss. Our results generalize easily to other Lipschitz smooth (but possibly nonconvex) loss functions.

Suppose we are given loss function $f(z;y)$ that takes as input a neural-network output $z \in \mathbb{R}^d$ and a label y. Then, our training objective for the i-th training sample becomes $F_i(W) = f(Bh_{i,L}; y_i^*)$. We redefine the loss vector $\mathsf{loss}_i \stackrel{\text{def}}{=} \nabla f(Bh_{i,L}; y_i^*) \in \mathbb{R}^d$ (where the gradient is with respect to z). Note that if $f(z;y) = \frac{1}{2}\|z-y\|^2$ is the ℓ_2 loss, then this notion coincides with Section 5.2. We assume that $f(z;y)$ is 1-Lipscthiz (upper) smooth with respect to z.[17]

All the results in Section 5.8, 5.9 and 5.10 remain unchanged. Section 5.11 also remains unchanged, except we need to restate Theorem 5.11.1 with respect to this new notation:

$$\|\nabla_{W_\ell} F_i(\overrightarrow{W})\|_F^2 \le O\Big(\frac{\|\,\mathsf{loss}_i\,\|^2}{d} \times m\Big) \qquad \|\nabla_{W_\ell} F(\overrightarrow{W})\|_F^2 \le O\Big(\frac{\|\,\mathsf{loss}\,\|^2}{d} \times mn\Big)$$
$$\|\nabla_{W_L} F(\overrightarrow{W})\|_F^2 \ge \Omega\Big(\frac{\max_{i\in[n]}\|\,\mathsf{loss}_i\,\|^2}{dn/\delta} \times m\Big)\ .$$

Section 5.12 also remains unchanged, except that we need to replace the precise definition of ℓ_2 loss in (5.14) with the semi-smoothness condition:

$$\begin{aligned} F_i(\overrightarrow{W}) = f(Bh_{i,L}; y_i^*) &\le f(B\hbar_{i,L}; y_i^*) + \langle \nabla f(B\hbar_{i,L}, y_i^*), B(h_{i,L} - \hbar_{i,L})\rangle + \frac{1}{2}\|B(h_{i,L} - \hbar_{i,L})\|^2 \\ &= F_i(\overrightarrow{\breve{W}}) + \langle \breve{\mathsf{loss}}_i, B(h_{i,L} - \hbar_{i,L})\rangle + \frac{1}{2}\|B(h_{i,L} - \hbar_{i,L})\|^2 \end{aligned} \tag{5.26}$$

[17] That is, $f(z+z';y) \le f(z) + \langle \nabla f(z;y), z'\rangle + \frac{1}{2}\|z'\|^2$.

and the rest of the proof remains unchanged.

As for the final convergence theorem of gradient descent, we can replace (5.20) with

$$F(\overrightarrow{W}^{(t+1)}) \le F(\overrightarrow{W}^{(t)}) - \Omega\Big(\frac{\eta\delta m}{dn^2}\Big) \cdot \| \mathsf{loss}^{(t)} \|^2 \ . \tag{5.27}$$

This means many things:

- If the loss is nonconvex but satisfies the Polyak-Łojasiewicz condition $\|\nabla f(z;y)\|^2 \ge \sigma(f(z;y) - f(z^*;y))$, then in $T = \Omega\Big(\frac{dn^2}{\eta\delta m\sigma}\Big) = O\big(\frac{n^6L^2}{\delta^2\sigma}\log\frac{1}{\epsilon}\big)$ iterations, GD can find a point $\overrightarrow{W}^{(T)}$ with $\| \mathsf{loss}^{(T)} \| \le \epsilon$. It suffices to choose $m \ge \widetilde{\Omega}\big(\operatorname{poly}(n, L, \delta^{-1}) \cdot d\sigma^{-2}\big)$ for same reason as before.

- If the loss is nonconvex but bounded (say, $|f(z;y)| \le O(1)$), then in $T = O\Big(\frac{dn^2}{\eta\delta m\epsilon^2}\Big) = O\big(\frac{n^6L^2}{\delta^2\epsilon^2}\big)$ iterations, we can find a point $\overrightarrow{W}^{(T)}$ with $\| \mathsf{loss}^{(T)} \| \le \epsilon$. If suffices to choose $m \ge \widetilde{\Omega}\big(\operatorname{poly}(n, L, \delta^{-1}) \cdot d\epsilon^{-1}\big)$.)

- If the loss is convex and its minimizer has bounded norm, meaning there exists z^* so that $f(z^*;y) = \min_z f(z;y)$ and $\|z - z^*\| \le D$. Then, by convexity

  $$f(z;y) - f(z^*;y) \le \langle \nabla f(z;y), z - z^* \rangle \le D\|\nabla f(z;y)\|$$

  Putting this into (5.27), we have (here $\overrightarrow{W}^* = \operatorname{argmin}_{\overrightarrow{W}} F_i(\overrightarrow{W})$ for all $i \in [n]$)

  $$\begin{aligned} F(\overrightarrow{W}^{(t+1)}) - F(\overrightarrow{W}^*) &\le F(\overrightarrow{W}^{(t)}) - F(\overrightarrow{W}^*) - \Omega\Big(\frac{\eta\delta m}{dn^2D^2}\Big) \cdot \sum_{i\in[n]} \big(F_i(\overrightarrow{W}^{(t)}) - F_i(\overrightarrow{W}^*)\big)^2 \\ &\le F(\overrightarrow{W}^{(t)}) - F(\overrightarrow{W}^*) - \Omega\Big(\frac{\eta\delta m}{dn^3D^2}\Big) \cdot \big(F(\overrightarrow{W}^{(t)}) - F(\overrightarrow{W}^*)\big)^2 \ . \end{aligned}$$

  This implies (see for instance the classical calculation steps in [Nes04]) that after $T = O\Big(\frac{dn^3D^2}{\eta\delta m\epsilon}\Big) = O\big(\frac{n^7L^2D^2}{\delta^2\epsilon}\big)$ iterations, we can have $F(\overrightarrow{W}^{(T)}) - F(\overrightarrow{W}^*) \le \epsilon$. The amount of over-parameterization needed is $m \ge \widetilde{\Omega}\big(\operatorname{poly}(n, L, \delta^{-1}) \cdot d\log\epsilon^{-1}\big)$.

- If the loss is cross entropy $f(z;y) = \frac{e^{z_y}}{\sum_{i=1}^{d} e^{z_i}}$ for classification, then $\|\nabla f(z;y)\| < 1/4$ implies perfect classification.[18] Thus, we have 100% training accuracy in $T = O\big(\frac{n^6 L^2}{\delta^2}\big)$ iterations. If suffices to choose $m \geq \widetilde{\Omega}\big(\operatorname{poly}(n, L, \delta^{-1}) \cdot d\big)$

[18] Recall $\frac{\partial f(z;y)}{z_y} = p_y(1-p_y)$ where $p_j = \frac{e^{z_j}}{\sum_{i=1}^{d} e^{z_i}}$. If $p_y > 1/2$, then z correctly predicts the target label y because $p_y > p_j$ for $j \neq z$.

5.17 Extension to Convolutional Neural Networks

There are numerous versions of convolutional neural networks (CNNs) that are used in practice. To demonstrate the capability of applying our techniques to such convolutional settings, in this section, we study a simple enough CNN for the ℓ_2 regression task.

A Simple CNN Model We assume that for the input layer (corresponding to A) and for each hidden layer $\ell = 1, 2, \ldots, L-1$ (corresponding to $W_1, \ldots, W_{L-1}$), there are $\mathfrak{d}$ positions each consisting of m channels. (Each position can be thought as a pixel of an image in computer vision tasks.) We assume the last hidden layer $\ell = L$ (corresponding to W_L) and the output layer (corresponding to B) are fully connected. We assume for each $j \in [\mathfrak{d}]$, there exists a set $Q_j \subseteq [\mathfrak{d}]$ of fixed cardinality $q \in [\mathfrak{d}]$ so that the value at position j in any convolutional layer is completely determined by positions $k \in Q_j$ of the previous layer.

Assumption 5.17.1. *We assume that $(Q_1, \ldots, Q_{\mathfrak{d}})$ give rise to a q-regular bipartite graph: each Q_j has exactly q entries and each $k \in [\mathfrak{d}]$ appears in exactly q different sets Q_j.*

(In vision tasks, if 3×3 kernels are used then $|Q_j| = 9$. We ignore the padding issue for simplicity.)

The output of each convolutional layer $\ell = 0, 1, 2, \ldots, L-1$ is represented by a $\mathfrak{d}m$-dimensional vector $h_\ell = (h_{\ell,1}, \ldots, h_{\ell,\mathfrak{d}})$ where each $h_{\ell,j} \in \mathbb{R}^m, \forall j \in [\mathfrak{d}]$. In the input layer and each $j \in [\mathfrak{d}]$, we assume

$$h_{0,j} = \phi\big(A_j x_{Q_j}\big) \in \mathbb{R}^m$$

where $x_{Q_j} \in \mathbb{R}^q$ denotes the concatenation of x_k for all $k \in Q_j$ given input $x \in \mathbb{R}^{\mathfrak{d}}$, and $A_j \in \mathbb{R}^{m \times q}$ is randomly initialized at $\mathcal{N}(0, \frac{2}{\sqrt{qm}})$ per entry. For notational simplicity, we

define matrix $A \in \mathbb{R}^{\mathfrak{d}m \times \mathfrak{d}}$ so that it satisfies $h_1 = \phi\big(Ax\big)$. Each row of A has q non-zero entries.

For each layer $\ell = 1, \ldots, L-1$ and each $j \in [\mathfrak{d}]$, we assume

$$h_{\ell,j} = \phi\big(W_{\ell,j} h_{\ell-1,Q_j} + \tau \cdot \mathbf{b}_{\ell,j}\big) \in \mathbb{R}^m$$

where $h_{\ell-1,Q_j} \in \mathbb{R}^{qm}$ denotes the concatenation of $h_{\ell-1,k}$ for all $k \in Q_j$, the weights $W_{\ell,j} \in \mathbb{R}^{m \times (qm)}$ and the bias the $\mathbf{b}_{\ell,j} \in \mathbb{R}^m$ are randomly initialized at $\mathcal{N}(0, \frac{2}{qm})$ per entry, and τ is a small parameter (say, $\tau = \frac{\delta^2}{10\mathfrak{d}L}$) for bias. For notational simplicity, we define matrix $W_\ell \in \mathbb{R}^{\mathfrak{d}m \times \mathfrak{d}m}$ and vector $\mathbf{b}_\ell \in \mathbb{R}^{\mathfrak{d}m}$ so that it satisfies $h_\ell = \phi\big(W_\ell h_{\ell-1} + \tau \mathbf{b}_\ell\big)$, and define vector $g_\ell \stackrel{\text{def}}{=} W_\ell h_{\ell-1} + \tau \mathbf{b}_\ell \in \mathbb{R}^{\mathfrak{d}m}$. Note that each row of W_ℓ has qm non-zero entries.

We assume the last layer W_L and the output layer B are simply fully connected (say without bias). That is, each entry of $W_L \in \mathbb{R}^{\mathfrak{d}m \times \mathfrak{d}m}$ is from $\mathcal{N}(0, \frac{2}{qm})$, and of $B \in \mathbb{R}^{d \times \mathfrak{d}m}$ is from $\mathcal{N}(0, \frac{1}{d})$.

We denote by $h_{i,\ell}$ the value of h_ℓ when the input vector is x_i, and define $g_{i,\ell}$, $D_{i,\ell}$ in the same way as before.

5.17.1 Changes in the Proofs

If one is willing to loose polynomial factors in L and $\mathfrak{d}$ in the final complexity, then changes to each of the lemmas of this paper is very little.[19]

Changes to Section 5.8 The first main result is Lemma 5.8.1: $\|h_{i,\ell}\|$ is in $[1-\epsilon, 1+\epsilon]$ with high probability. In the CNN case, for every $j \in [\mathfrak{d}]$, recalling that $h_{i,\ell,j} = \phi(W_{\ell,j} h_{i,\ell-1,Q_j} + \tau \mathbf{b}_\ell)$. Applying Fact 5.8.2, we have that $\frac{qm\|h_{i,\ell,j}\|^2}{2(\|h_{i,\ell-1,Q_j}\|^2+\tau^2)}$ is distributed as χ^2_ω distribution with $\omega \sim \mathcal{B}(m, \frac{1}{2})$. Due to the concentration of χ^2 distribution and the concentration of binomial distribution, $\|h_{i,\ell,j}\|^2$ is extremely close to $\frac{\|h_{i,\ell-1,Q_j}\|^2+\tau^2}{q}$ (a careful argument of this can be found in the proof of Lemma 5.8.1). Summing this up over all $j \in [\mathfrak{d}]$, and using Assumption 5.17.1, we have $\|h_{i,\ell,j}\|^2$ is concentrated at $\|h_{i,\ell-1}\|^2 + \frac{\tau^2 \mathfrak{d}}{q}$. Applying induction, we have $\|h_{i,\ell}\|$ is in $[1-\epsilon, 1+\epsilon]$ with probability at least $1 - e^{-\Omega(m\epsilon^2/L^2)}$, as long as $\tau^2 \le \frac{\epsilon q}{10\mathfrak{d}L}$.[20]

The changes to Lemma 5.8.3 and Lemma 5.8.4 are the same as above, but we loose some polynomial factors in L (because we are not careful in the argument above). For instance, the intermediate bound in Lemma 5.8.3a becomes $\|W_b D_{i,b-1} W_{b-1} \cdots D_{i,a} W_a\|_2 \le O(L)$.

As for the δ-separateness Lemma 5.8.5, we need to redefine the notion of δ-separateness between $h_{i,\ell}$ and $h_{j,\ell}$:

$$\sum_{k\in[\mathfrak{d}]} \left\| (I - \tfrac{h_{i,\ell,k} h_{i,\ell,k}^\top}{\|h_{i,\ell,k}\|^2}) h_{j,\ell,k} \right\|^2 \ge \Omega(\delta^2) \tag{5.28}$$

[19] We acknowledge the existence of more careful modifications to avoid loosing too many such factors, but do not present such result for the simplicity of this paper.

[20] We note that in all of our applications of Lemma 5.8.1, the minimal choice of ϵ is around δ^3 from the proof of δ-separateness. Therefore, choosing $\tau = \frac{\delta^2}{10\mathfrak{d}L}$ is safe. We are aware of slightly more involved proofs that are capable of handling much larger values of τ.

Then, denoting by $\widehat{h}_k = h_{i,\ell-1,k}/\|h_{i,\ell-1,k}\|$, we have

$$h_{j,\ell,k} = \phi(W_{\ell,k} h_{j,\ell-1,Q_j} + \tau \mathbf{b}_{\ell,k}) = \phi\Big(\vec{g}_1 + \Big(\sum_{z\in Q_k} \|(I - \widehat{h}_z \widehat{h}_z^\top) h_{j,\ell-1,z}\|^2\Big)^{1/2} \vec{g}_2\Big)$$

where $\vec{g}_2 \sim \mathcal{N}(0, \frac{2}{qm} I)$ is independent of the randomness of $h_{i,\ell,k}$ once $A, W_1, \ldots, W_{\ell-1}$ are fixed. One can use this to replace (5.6) and the rest of the proof follows.

Changes to Section 5.9 The first main result is Lemma 5.9.1, and we discuss necessary changes here to make it work for CNN. The first change in the proof is to replace $2c_1 L^{1.5}$ with $2c_1 L^2$ due to the above additional factor from Lemma 5.8.3a. Next, call that the proof of Lemma 5.9.1 relied on Claim 5.9.2 and Claim 5.9.4:

- For Claim 5.9.2, we can replace the definition of x with $x = D'(\widetilde{W}\widetilde{h} + \tau\mathbf{b} + g')$ for $\mathbf{b} \in \mathcal{N}(0, \frac{2}{qm} I)$. This time, instead of using the randomness of $\widetilde{W}$ like in the old proof (because $\widetilde{W}$ is no longer a full matrix), we use the randomness of $\tau\mathbf{b}$. The new statement becomes

  $$\|x\|_0 \le O\Big(\frac{\mathfrak{d}m}{\tau^{2/3}} \|g_1'\|^{2/3} + \frac{1}{\tau} \|g_2'\|_\infty (\mathfrak{d}m)^{3/2}\Big) \quad \text{and} \quad \|x\| \le O\Big(\|g_1'\| + \frac{1}{\sqrt{\tau}} \|g_2'\|_\infty^{3/2} (\mathfrak{d}m)^{3/4}\Big) \ .$$

  and its proof is by re-scaling x by $\frac{1}{\tau}$ and then applying the old proof (with dimension m replaced with $\mathfrak{d}m$).

- For Claim 5.9.4, it becomes $\|y_1\| \le O\big(\sqrt{qs/m} \log m\big)$ and $\|y_2\|_\infty \le \frac{2\sqrt{\log m}}{\sqrt{qm}}$.

After making all of these changes, we loose at most some polynomial factors in L and $\mathfrak{d}$ for the new statement of Lemma 5.9.1:

(a) $\|D'_{i,\ell}\|_0 \le m\omega^{2/3} \operatorname{poly}(L, \mathfrak{d})$ and $\|D'_{i,\ell} g_{i,\ell}\| \le \omega \operatorname{poly}(L, \mathfrak{d})$.

(b) $\|g'_{i,\ell}\|, \|h'_{i,\ell}\| \leq \omega \operatorname{poly}(L, \mathfrak{d})\sqrt{\log m}$.

Finally, the statements of Lemma 5.9.5 and Lemma 5.9.6 only loose polynomial factors in L and $\mathfrak{d}$.

Changes to Section 5.10 The norm upper bound part is trivial to modify so we only focus on the gradient norm lower bound. Since we have assumed W_L to be fully connected, the gradient on W_L is the same as before:

$$\widehat{\nabla}^{\vec{\mathsf{v}}}_{[W_L]_k} F(\overrightarrow{W}) = \sum_{i=1}^{n} \langle B_k, \mathsf{v}_i \rangle \cdot h_{i,L-1} \cdot \mathbb{1}_{(W_L h_{i,L-1})_k \geq 0}$$

Since we still have δ-separateness (5.28), one can verify for $\ell = L-1$,

$$\|h_{i,\ell} - h_{j,\ell}\|^2 = \sum_{k\in[\mathfrak{d}]} \|h_{i,\ell,k} - h_{j,\ell,k}\|^2 \geq \sum_{k\in[\mathfrak{d}]} \left\| (I - \frac{h_{i,\ell,k} h_{i,\ell,k}^\top}{\|h_{i,\ell,k}\|^2}) h_{j,\ell,k} \right\|^2 \geq \Omega(\delta^2) \ .$$

Since $\|h_{i,\ell}\| \approx 1$ and $\|h_{j,\ell}\| \approx 1$, this gives back the old definition of δ-separateness: $(I - h_{i,\ell} h_{i,\ell}^\top / \|h_{i,\ell}\|^2) h_{j,\ell}$ has norm at least $\Omega(\delta)$. Therefore, the entire rest of Section 5.10 follows as before.

Final Theorem Since Section 5.11 and 5.12 rely on previous sections, they do not need to be changed (besides some polynomial factor blowup in L and $\mathfrak{d}$). Our final theorem becomes

Theorem 5.17.2 (CNN). *Let $m \geq \widetilde{\Omega}\big(\operatorname{poly}(n, L, \mathfrak{d}, \delta^{-1}) \cdot d\big)$. For the convolutional neural network defined in this section, with probability at least $1 - e^{-\Omega(\log^2 m)}$ over the random initialization, GD and SGD respectively need at most $T = \frac{\operatorname{poly}(n,L,\mathfrak{d})}{\delta^2} \log \frac{1}{\epsilon}$ and $T = \frac{\operatorname{poly}(n,L,\mathfrak{d}) \cdot \log^2 m}{\delta^2} \log \frac{1}{\epsilon}$ iterations to find a point $F(\overrightarrow{W}) \leq \epsilon$.*

5.18 Extension to Residual Neural Networks

Again as we have discussed in Section 5.18, there are numerous versions of residual neural networks that are used in practice. To demonstrate the capability of applying our techniques to residual settings, in this section, we study a simple enough residual network for the ℓ_2 regression task (without convolutional layers).

A Simple Residual Model We consider an input layer $h_0 = \phi(Ax)$, $L-1$ residual layers $h_\ell = \phi(h_{\ell-1} + \tau W_\ell h_{\ell-1})$ for $\ell = 1, 2, \ldots, L-1$, a fully-connected layer $h_L = \phi(W_L h_{L-1})$ and an output layer $y = Bh_L$. We assume that $h_0, \ldots, h_L \in \mathbb{R}^m$ and the entries of $W_\ell \in \mathbb{R}^{m \times m}$ are from $\mathcal{N}(0, \frac{2}{m})$ as before. We choose $\tau = \frac{1}{\Omega(L \log m)}$ which is similar as previous work [ZLSD18].

We denote by $g_0 = Ax$, $g_\ell = h_{\ell-1} + \tau W_\ell h_{\ell-1}$ for $\ell = 1, 2, \ldots, L-1$ and $g_L = W_L h_{L-1}$. For analysis, we use $h_{i,\ell}$ and $g_{i,\ell}$ to denote the value of h_ℓ when the input vector is x_i, and $D_{i,\ell}$ the diagonal sign matrix so that $[D_{i,\ell}]_{k,k} = \mathbb{1}_{(g_{i,\ell})_k \geq 0}$.

5.18.1 Changes in the Proofs

Conceptually, we need to replace all the occurrences of W_ℓ with $(I + \tau W_\ell)$ for $\ell = 1, 2, \ldots, L-1$. Many of the proofs in the residual setting becomes much simpler when residual links are present. The main property we shall use is that the spectral norm

$$\|(I + \tau W_a) D_{i,a+1} \cdots D_{i,b} (I + \tau W_b)\|_2 \le 1.01 \tag{5.29}$$

for any $L - 1 \ge a \ge b \ge 1$ with our choice of τ.

Changes to Section 5.8 For Lemma 5.8.1, ignoring subscripts in i for simplicity, we can combine the old proof with (5.29) to derive that $\|h_\ell\| \le 1.02$ for every i and ℓ. We also have $\|h_\ell\| \ge \frac{1}{\sqrt{20}}$ by the following argument.

- Fact 5.8.2 says each coordinate of h_0 follows i.i.d. from a distribution which is 0 with half probability, and $|\mathcal{N}(0, \frac{2}{m})|$ with half probability. Therefore, with high probability, at least $m/4$ of the coordinates $k \in [m]$ will satisfy $|(h_0)_k| \ge \frac{0.6}{\sqrt{m}}$. Denote this set as $M_0 \subseteq [m]$.

- In the following layer $\ell = 1$, $(h_\ell)_k \ge (h_{\ell-1})_k - \tau |(W_\ell h_{\ell-1})_k|$. Since $W_\ell h_{\ell-1} \sim \mathcal{N}(0, \frac{2\|h_{\ell-1}\|^2}{m} I)$ and $\|h_{\ell-1}\| \le 1.02$, we know with high probability, at least $1 - \frac{1}{10L}$ fraction of the coordinates in M_0 will satisfy $|(W_\ell h_{\ell-1})_k| \le O(\frac{\log L}{\sqrt{m}})$. Therefore, for each of these $(1 - \frac{1}{10L})|M_0|$ coordinates, we have $(h_\ell)_k \ge (h_{\ell-1})_k - \frac{1}{10L}$ by our choice of τ. Denote this set as $M_1 \subseteq M_0$, then we have $(h_\ell)_k \ge \frac{0.6}{\sqrt{m}} - \frac{1}{10L\sqrt{m}}$ for each $k \in M_1$.

- Continuing this argument for $\ell = 2, 3, \ldots, L-1$, we know that every time we move from $M_{\ell-1}$ to M_ℓ, its size shrinks by a factor $1 - \frac{1}{10L}$, and the magnitude of $(h_\ell)_k$ for

$k \in M_\ell$ decreases by $\frac{1}{10L\sqrt{m}}$. Putting this together, we know $\|h_\ell\|^2 \geq (\frac{0.6}{\sqrt{m}} - \frac{1}{10\sqrt{m}})^2 \cdot (1 - \frac{1}{10L})^L \cdot \frac{m}{4} \geq \frac{1}{20}$ for all $\ell = 1, 2, \ldots, L-1$. The proof of the last layer h_L is the same as the old proof.

Lemma 5.8.3 is not needed anymore because of (5.29). Lemma 5.8.4 becomes trivial to prove using (5.29): for instance for Lemma 5.8.4a, we have $\|D_{i,L}W_L D_{i,L-1}(I + \tau W_{L-1}) \cdots D_{i,a}(I + \tau W_a)u\| \leq O(\|u\|)$ and thus $\|BD_{i,L}W_L D_{i,L-1}(I+\tau W_{L-1}) \cdots D_{i,a}(I+\tau W_a)u\| \leq O\big(\frac{\sqrt{s \log m}}{\sqrt{d}}\big)\|u\|$ for all s-sparse vectors u.

Lemma 5.8.5 needs the following changes in the same spirit as our changes to Lemma 5.8.1. With probability at least $1 - e^{-\Omega(\log^2 m)}$ it satisfies $\|W_\ell h_{i,\ell}\|_\infty \leq O(\frac{\log m}{\sqrt{m}})$ for all $i \in [n]$ and $\ell \in L$. In the following proof we condition on this event happens.[21] Consider $i, j \in [n]$ with $i \neq j$.

- In the input layer, since $\|x_i - x_j\| \geq \delta$, the same Claim 5.8.6 shows that, with high probability, there are at least $\frac{3}{4}m$ coordinates $k \in [m]$ with $|(h_{i,0} - h_{j,0})_k| \geq \frac{\delta}{10\sqrt{m}}$. At the same time, at least $\frac{3}{4}m$ coordinates $k \in [m]$ will satisfy $(h_{i,0})_k \geq \frac{1}{10\sqrt{m}}$ and $(h_{j,0})_k \geq \frac{1}{10\sqrt{m}}$. Denote $M_0 \subseteq [m]$ as the set of coordinates k satisfying both properties. We have $|M_0| \geq \frac{m}{2}$ and $\sum_{k \in M_0} |(h_{i,0} - h_{j,0})_k| \geq \frac{\delta}{20}\sqrt{m}$.

- In the following layer $\ell = 1$, we have

$$(h_{i,\ell} - h_{j,\ell})_k = \phi((h_{i,\ell-1})_k + \tau(W_\ell h_{i,\ell-1})_k) - \phi((h_{j,\ell-1})_k + \tau(W_\ell h_{j,\ell-1})_k)$$

[21] For simplicity, we only show how to modify Lemma 5.8.5 with success probability $1 - e^{-\Omega(\log^2 m)}$ because that is all we need to the downstream application of Lemma 5.8.5. If one is willing to be more careful, the success probability can be much higher.

Using $\|W_\ell h_{i,\ell}\|_\infty \le O(\frac{\log m}{\sqrt{m}})$ and our choice of τ, we know for every $k \in M_0$, it satisfies $(h_{i,\ell})_k \ge \frac{1}{10\sqrt{m}} - \frac{1}{100L\sqrt{m}}$ and $(h_{j,\ell})_k \ge \frac{1}{10\sqrt{m}} - \frac{1}{100L\sqrt{m}}$. Therefore, the ReLU activation becomes identity for such coordinates $k \in M_0$ and

$$\Delta_k \stackrel{\text{def}}{=} (h_{i,\ell} - h_{j,\ell})_k = (h_{i,\ell-1} - h_{j,\ell-1})_k + \tau(W_\ell(h_{i,\ell-1} - h_{j,\ell-1}))_k \ .$$

Let $s_k = 1$ if $(h_{i,\ell-1} - h_{j,\ell-1})_k \ge 0$ and $s_k = -1$ otherwise. Then,

$$\sum_{k\in M_0} |\Delta_k| \ge \sum_{k\in M_0} s_k \cdot \Delta_k = \sum_{k\in M_0} |(h_{i,\ell-1} - h_{j,\ell-1})_k| + \tau \cdot s_k(W_\ell(h_{i,\ell-1} - h_{j,\ell-1}))_k$$

Note that when $h_{i,\ell-1}$ and $h_{j,\ell-1}$ are fixed, the values $s_k(W_\ell(h_{i,\ell-1} - h_{j,\ell-1}))_k$ are independent Gaussian with mean zero. This means, with probability at least $1 - e^{-\Omega(\log^2 m)}$, the summation $\sum_{k\in M_0} s_k(W_\ell(h_{i,\ell-1} - h_{j,\ell-1}))_k$ is at most $O(\log m)$ in absolute value. Putting this into the above equation, we have

$$\sum_{k\in M_0} |\Delta_k| \ge \sum_{k\in M_0} |(h_{i,\ell-1} - h_{j,\ell-1})_k| - O(\tau \log m) \ge \frac{\delta}{20}\sqrt{m} - O(\tau \log m) \ .$$

- Continuing this process for $\ell = 2, 3, \ldots, L-1$, we can conclude that $\sum_{k\in M_0} |(h_{i,L-1} - h_{j,L-1})_k| \ge \frac{\delta}{30}\sqrt{m}$ and therefore $\|h_{i,L-1} - h_{j,L-1}\| \ge \Omega(\delta^2)$. This is the same statement as before that we shall need for the downstream application of Lemma 5.8.5.

Changes to Section 5.9 Lemma 5.9.1 becomes easy to prove with all the L factors disappear for the following reason. Fixing i and ignoring the subscript in i, we have for $\ell = 1, 2, \ldots, L-1$:

$$\begin{aligned} h'_\ell &= D''_\ell\big((I + \tau W_\ell + \tau W'_\ell)h_{\ell-1} - (I + \tau W_\ell)\widetilde{h}_{\ell-1}\big) \\ &= D''_\ell\big((I + \tau W_\ell)h'_{\ell-1} + \tau W'_\ell h_{\ell-1}\big) \end{aligned}$$

For some diagonal matrix $D''_\ell \in \mathbb{R}^{m\times m}$ with diagonal entries in $[-1,1]$ (see Proposition 5.12.3). By simple spectral norm of matrices bound we have

$$\|h'_\ell\| \le (1+\tau\|W_\ell\|_2+\tau\|W'_\ell\|_2)\|h'_{\ell-1}\|+\tau\|W'_\ell\|_2\|\widetilde{h}_{\ell-1}\| \le (1+\frac{1}{10L})\|h'_{\ell-1}\|+O(\tau\omega) \le \cdots \le O(\tau\omega)$$

This implies $\|h'_\ell\|, \|g'_\ell\| \le O(\tau\omega)$ for all $\ell \in [L-1]$, and combining with the old proof we have $\|h'_L\|, \|g'_L\| \le O(\omega)$.

As for the sparsity $\|D'_\ell\|_0$, because $\widetilde{g}_\ell = \widetilde{h}_{\ell-1} + \tau\widetilde{W}_\ell\widetilde{h}_{\ell-1} \sim \mathcal{N}\big(\widetilde{h}_{\ell-1}, \frac{2\tau^2\|\widetilde{h}_{\ell-1}\|^2}{m}\big)$ and $\|g'_\ell\| \le O(\tau\omega)$, applying essentially the same Claim 5.9.2, we have $\|D'_\ell\|_0 \le O(m\omega^{2/3})$ for every $\ell = 1, 2, \ldots, L-1$. One can similarly argue that $\|D'_L\|_0 \le O(m\omega^{2/3})$.

Next, Lemma 5.9.5 and Lemma 5.9.6 become trivial to prove (recall we have to change $\widetilde{W}_\ell$ with $I + \tau\widetilde{W}_\ell$ for $\ell < L$) and the L factor also gets improved.

Changes to Section 5.10 The proofs of this section require only notational changes.

Final Theorem Since Section 5.11 and 5.12 rely on previous sections, they do not need to be changed (besides improving polynomial factors in L). Our final theorem becomes

Theorem 5.18.1 (ResNet). *Let $m \ge \widetilde{\Omega}\big(\operatorname{poly}(n, L, \delta^{-1}) \cdot d\big)$. For the residual neural network defined in this section, with probability at least $1 - e^{-\Omega(\log^2 m)}$ over the random initialization, GD needs at most $T = O\big(\frac{n^6L^2}{\delta^2}\log\frac{1}{\epsilon}\big)$ iterations and SGD needs at most $T = O\big(\frac{n^7L^2\log^2 m}{b\delta^2}\log\frac{1}{\epsilon}\big)$ iterations to find a point $F(\overrightarrow{W}) \le \epsilon$.*

Chapter 6

Convergence result of Recurrent Neural Network

In this chapter, we focus on recurrent neural networks (RNNs) which are multi-layer networks widely used in natural language processing. They are harder to analyze than feedforward neural networks, because the *same* recurrent unit is repeatedly applied across the entire time horizon of length L, which is analogous to feedforward networks of depth L. We show when the number of neurons is sufficiently large, meaning polynomial in the training data size and in L, then SGD is capable of minimizing the regression loss in the linear convergence rate. This gives theoretical evidence of how RNNs can memorize data.

More importantly, in this paper we build general toolkits to analyze multi-layer networks with ReLU activations. For instance, we prove why ReLU activations can prevent exponential gradient explosion or vanishing, and build a perturbation theory to analyze first-order approximation of multi-layer networks.

6.1 Introduction

Neural networks have been one of the most powerful tools in machine learning over the past a few decades [KSH12, GMH13, LHP+15, AAA+16, HZRS16, SHM+16, SSS+17]. The multi-layer structure of neural network gives it supreme power in expressibility and learning performance. However, it raises complexity concerns: the training objective is generally *non-convex* and *non-smooth*. In practice, local-search algorithms such as stochastic gradient descent (SGD) are capable of finding global optima, at least on the training data [ZBH+17, GVS15]. How SGD avoids local minima for such objectives remains an open theoretical question since [GVS15].

In recent years, there have been a number of theoretical results aiming at a better understanding of this phenomenon. Many of them focus on two-layer (thus one-hidden-layer) neural networks and assume that the inputs are random Gaussian or sufficiently close to Gaussian [BG17, Son17, Tia17, LY17, DLT+18, GLM17, PRSZ18, ZSJ+17, ZSD17]. Some study deep neural networks but assuming the activation function is linear [HM17, ACGH18, BHL18]. Some study the convex task of training essentially only the last layer of the network [Dal17]. On the technique side, some of these results try to understand the gradient dynamics [Son17, Tia17, BG17, LY17, Dal17, BGMSS18, DLT+18, PRSZ18, ZSJ+17, ZSD17, VW18], while others focus on the geometry properties of the training objective [GLM17, SS18, FB17, ZL17, HM17].

More recently, [SS18] provided evidence that, even when inputs are standard Gaussians, two-layer neural networks can indeed have spurious local minima, and suggested that *over-parameterization* (i.e., increasing the number of neurons) may be the key in avoiding spurious local minima. [LL18] showed that, for two-layer networks with the cross-entropy

loss, in the over-parametrization regime, gradient descent (GD) is capable of finding nearly-global optimal solutions on the training data. This result was later extended to the ℓ_2 loss by [DZPS19].

In this paper, we show GD and SGD are capable of training multi-layer neural networks (with ReLU activation) to global minima on any non-degenerate training data set. Furthermore, the running time is polynomial in the number of layers and the number of data points. Since there are many different types of multi-layer networks (convolutional, feedforward, recurrent, etc.), in this present paper, we focus on recurrent neural networks (RNN) as our choice of multi-layer networks, and feedforward networks are only its "special case" (see for instance a follow-up work [AZLS19]).

Recurrent Neural Networks Among different architectures of neural networks, one of the *least* theoretically-understood structure is the recurrent one [Elm90]. A recurrent neural network recurrently applies the same network unit to a sequence of input tokens, such as a sequence of words in a language sentence. RNN is particularly useful when there are long-term, non-linear interactions between input tokens in the same sequence. These networks are widely used in practice for natural language processing, language generation, machine translation, speech recognition, video and music processing, and many other tasks [MKB+10, MKB+11, SSN12, KB13, SSB14, SVL14, CVMBB14, CGCB14]. On the theory side, while there are some attempts to show that an RNN is more expressive than a feedforward neural network [KNO18], when and how an RNN can be efficiently learned has little theoretical explanation.

In practice, RNN is usually trained by simple local-search algorithms such as SGD.

However, unlike shallow networks, the training process of RNN often runs into the trouble of vanishing or exploding gradient [SMH11]. That is, the value of the gradient becomes exponentially small or large in the time horizon, even when the training objective is still constant. [1] In practice, one of the popular ways to resolve this is by the long short term memory (LSTM) structure [HS97]. However, one can also use rectified linear units (ReLUs) as activation functions to avoid vanishing or exploding gradient [SBS+17]. In fact, one of the earliest adoptions of ReLUs was on applications of RNNs for this purpose twenty years ago [Hah98, SA96].

Since the RNN structure was proposed, a large number of variations have been designed over past decades, including LSTM [HS97], Bidirectional RNN [SP97], Bidirectional LSTM [GS05], gate recurrent unit [CVMG+14], statistical recurrent unit [OPS17], Fourier recurrent unit [ZLSD18]. For a more detailed survey, we refer the readers to [SBS+17].

[1] Intuitively, an RNN recurrently applies the same network unit for L times if the input sequence is of length L. When this unit has "operator norm" larger than one or smaller than one, the final output can possibly exponentially explode or vanish in L. More importantly, when one back propagates through time —which intuitively corresponds to applying the reverse unit multiple times— the gradient can also vanish or explode. Controlling the operator norm of a non-linear operator can be quite challenging.

6.1.1 Our Question

In this paper, we study the following general question

- *Can ReLU provably stabilize the training process and avoid vanishing/exploding gradient?*
- *Can RNN be trained close to zero training error* efficiently *under mild assumptions?*

Remark 6.1.1. When there is no activation function, RNN is known as *linear dynamical system*. Hardt, Ma and Recht [HMR18] first proved the convergence of finding global minima for such linear dynamical systems. Followups in this line of research include [HSZ17, HLS+18].

Motivations One may also want to study whether RNN can be trained close to zero test error. However, unlike feedforward networks, the training error, or the ability to memorize examples, may actually be desirable for RNN. After all, many tasks involving RNN are related to memories, and certain RNN units are even referred to memory cells. Since RNN applies the same network unit to all input tokens in a sequence, the following question can possibly of its own interest:

- *How does RNN learn mappings (say from token 3 to token 7) without destroying others?*

Another motivation is the following. An RNN can be viewed as a space constraint, differentiable Turing machine, except that the input is only allowed to be read in a fixed order. It was shown in [SS91] that all Turing machines can be simulated by fully-connected recurrent networks built of neurons with non-linear activations. In practice, RNN is also used as a tool to build neural Turing machines [GWD14], equipped with a grand goal of

automatically learning an algorithm based on the observation of the inputs and outputs. To this extent, we believe the task of understanding the *trainability* as a first step towards understanding RNN can be meaningful on its own.

Our Result To present the simplest result, we focus on the classical Elman network with ReLU activation:

$$h_\ell = \phi(W \cdot h_{\ell-1} + Ax_\ell) \in \mathbb{R}^m \qquad \text{where } W \in \mathbb{R}^{m\times m},\ A \in \mathbb{R}^{m\times d_x}$$
$$y_\ell = B \cdot h_\ell \in \mathbb{R}^d \qquad \text{where } B \in \mathbb{R}^{d\times m}$$

We denote by ϕ the ReLU activation function: $\phi(x) = \max(x, 0)$. We note that (fully-connected) feedforward networks are only "special cases" to this by replacing W with W_ℓ for each layer.[2]

We consider a regression task where each sequence of inputs consists of vectors $x_1, \ldots, x_L \in \mathbb{R}^{d_x}$ and we perform least-square regression with respect to $y_1^*, \ldots, y_L^* \in \mathbb{R}^d$. We assume there are n training sequences, each of length L. We assume the training sequences are δ-separable (say vectors x_1 are different by relative distance $\delta > 0$ for every pairs of training sequences). Our main theorem can be stated as follows

Theorem 6.1.1. *If the number of neurons $m \geq \mathrm{poly}(n, d, L, \delta^{-1}, \log \epsilon^{-1})$ is polynomially large, we can find weight matrices W, A, B where the RNN gives ϵ training error*

- *if gradient descent (GD) is applied for $T = \Omega\big(\frac{\mathrm{poly}(n,d,L)}{\delta^2} \log \frac{1}{\epsilon}\big)$ iterations, starting from random Gaussian initializations; or*

[2]Most of the technical lemmas of this paper remain to hold (and become much simpler) once W is replaced with W_ℓ. This is carefully treated by [AZLS19].

- *if (mini-batch or regular) stochastic gradient descent (SGD) is applied for*

$$T = \Omega\big(\frac{\text{poly}(n, d, L)}{\delta^2} \log \frac{1}{\epsilon}\big)$$

iterations, starting from random Gaussian initializations.[3]

(To present the simplest possible result, we have not tried to tighten the polynomial dependency with respect to n, d and L. We only tightened the dependency with respect to δ and ϵ.)

Our Contribution We summarize our contributions as follows.

- We believe this is the first proof of convergence of GD/SGD for training the *hidden layers* of recurrent neural networks (or even for any multi-layer networks of more than two layers) when activation functions are present.[4]

- Our results provide arguably the first theoretical evidence towards the empirical finding of [GVS15] on multi-layer networks, regarding the ability of SGD to avoid (spurious) local minima. Our theorem does not exclude the existence of bad local minima

[3] At a first glance, one may question how it is possible for SGD to enjoy a logarithmic time dependency in ϵ^{-1}; after all, even when minimizing strongly-convex and Lipschitz-smooth functions, the typical convergence rate of SGD is $T \propto 1/\epsilon$ as opposed to $T \propto \log(1/\epsilon)$. We quickly point out there is no contradiction here if the stochastic pieces of the objective enjoy a *common* global minimizer. In math terms, suppose we want to minimize some function $f(x) = \frac{1}{n}\sum_{i=1}^n f_i(x)$, and suppose x^* is the global minimizer of convex functions $f_1(x), \ldots, f_n(x)$. Then, if $f(x)$ is σ-strongly convex, and each each $f_i(x)$ is L-Lipschitz smooth, then SGD —moving in negative direction of $\nabla f_i(x)$ for a random $i \in [n]$ per step— can find ϵ-minimizer of this function in $O\big(\frac{L^2}{\sigma^2} \log \frac{1}{\epsilon}\big)$ iterations.

[4] Our theorem holds even when A, B are at random initialization and only the hidden weight matrix W is trained. This is much more difficult to analyze than the convex task of training only the last layer B [Dal17]. Training only the last layer can significantly reduce the learning power of (recurrent or not) neural networks in practice.

- We build new technical toolkits to analyze multi-layer networks with ReLU activation, which have now found many applications [AZLS19, ALL18c, AL19a, CG19]. For instance, combining this paper with new techniques, one can derive guarantees on testing error for RNN in the PAC-learning language [AL19a].

Extension: Deep RNN Elman RNN is also referred to as three-layer RNN, and one may also study the convergence of RNNs with more hidden layers. This is referred to as deep RNN [SBS+17]. Our theorem also applies to deep RNNs (by combining this paper together with [AZLS19]).

Extension: Loss functions For simplicity, in this paper we have adopted the ℓ_2 regression loss. Our results generalize to other Lipschitz smooth (but possibly nonconvex) loss functions, by combining with the techniques of [AZLS19].

6.1.2 Other Related Works

Another relevant work is [BGMSS18] where the authors studied over-paramterization in the case of two-layer neural network under a linear-separable assumption.

Instead of using randomly initialized weights like this paper, there is a line of work proposing algorithms using weights generated from some "tensor initialization" process [ABGM14, SA15, JSA15, Tia17, ZSJ+17].

There is huge literature on using the mean-field theory to study neural networks [MMN18, YS17, DFS16, XBSD+18, LBN+17, YS18, CPS18, PW17, PB17, PSG17, PLR+16, SGGSD17]. At a high level, they study the network dynamics at random initialization when the number of hidden neurons grow to infinity, and use such initialization theory to predict performance after training. However, they do not provide theoretical convergence rate for the training process (at least when the number of neurons is finite).

6.2 Notations and Preliminaries

We denote by $\|\cdot\|_2$ (or sometimes $\|\cdot\|$) the Euclidean norm of vectors, and by $\|\cdot\|_2$ the spectral norm of matrices. We denote by $\|\cdot\|_\infty$ the infinite norm of vectors, $\|\cdot\|_0$ the sparsity of vectors or diagonal matrices, and $\|\cdot\|_F$ the Frobenius norm of matrices. Given matrix W, we denote by W_k or w_k the k-th row vector of W. We denote the row ℓ_p norm for $W \in \mathbb{R}^{m\times d}$ as

$$\|W\|_{2,p} \stackrel{\text{def}}{=} \left(\sum_{i\in[m]} \|w_i\|_2^p\right)^{1/p}. \tag{6.1}$$

By definition, $\|W\|_{2,2} = \|W\|_F$.

We use $\mathcal{N}(\mu,\sigma)$ to denote Gaussian distribution with mean μ and variance σ; or $\mathcal{N}(\mu,\Sigma)$ to denote Gaussian vector with mean μ and covariance Σ. We use $\mathbb{1}_{event}$ to denote the indicator function of whether *event* is true. We denote by e_k the k-th standard basis vector. We use $\phi(\cdot)$ to denote the ReLU function, namely $\phi(x) = \max\{x,0\} = \mathbb{1}_{x\geq 0}\cdot x$. Given univariate function $f\colon \mathbb{R}\to\mathbb{R}$, we also use f to denote the same function over vectors: $f(x) = (f(x_1),\dots,f(x_m))$ if $x\in\mathbb{R}^m$.

Given vectors $v_1,\dots,v_n\in\mathbb{R}^m$, we define $U = \mathsf{GS}(v_1,\dots,v_n)$ as their Gram-Schmidt orthonormalization. Namely, $U = [\widehat{v}_1,\dots,\widehat{v}_n]\in\mathbb{R}^{m\times n}$ where

$$\widehat{v}_1 = \frac{v_1}{\|v_1\|} \quad \text{and} \quad \text{for } i\geq 2\text{:} \quad \widehat{v}_i = \frac{\prod_{j=1}^{i-1}(I-\widehat{v}_j\widehat{v}_j^\top)v_i}{\left\|\prod_{j=1}^{i-1}(I-\widehat{v}_j\widehat{v}_j^\top)v_i\right\|}.$$

Note that in the occasion that $\prod_{j=1}^{i-1}(I-\widehat{v}_j\widehat{v}_j^\top)v_i$ is the zero vector, we let $\widehat{v}_i$ be an arbitrary unit vector that is orthogonal to $\widehat{v}_1,\dots,\widehat{v}_{i-1}$.

6.2.1 Elman Recurrent Neural Network

We assume n training inputs are given: $(x_{i,1}, x_{i,2}, \ldots, x_{i,L}) \in \left(\mathbb{R}^{d_x}\right)^L$ for each input $i \in [n]$. We assume n training labels are given: $(y^*_{i,1}, y^*_{i,2}, \ldots, y^*_{i,L}) \in \left(\mathbb{R}^{d}\right)^L$ for each input $i \in [n]$. Without loss of generality, we assume $\|x_{i,\ell}\| \leq 1$ for every $i \in [n]$ and $\ell \in [L]$. Also without loss of generality, we assume $\|x_{i,1}\| = 1$ and its last coordinate $[x_{i,1}]_{d_x} = \frac{1}{\sqrt{2}}$ for every $i \in [n]$.[5]

We make the following assumption on the input data :

Assumption 6.2.1. *$\|x_{i,1} - x_{j,1}\| \geq \delta$ for some parameter $\delta \in (0, 1]$ and every pair of $i \neq j \in [n]$.*

Given weight matrices $W \in \mathbb{R}^{m \times m}$, $A \in \mathbb{R}^{m \times d_x}$, $B \in \mathbb{R}^{d \times m}$, we introduce the following notations to describe the evaluation of RNN on the input sequences. For each $i \in [n]$ and $j \in [L]$:

$$h_{i,0} = 0 \in \mathbb{R}^m \qquad g_{i,\ell} = W \cdot h_{i,\ell-1} + Ax_{i,\ell} \in \mathbb{R}^m$$
$$y_{i,\ell} = B \cdot h_{i,\ell} \in \mathbb{R}^d \qquad h_{i,\ell} = \phi(W \cdot h_{i,\ell-1} + Ax_{i,\ell}) \in \mathbb{R}^m$$

A very important notion that this entire paper relies on is the following:

Definition 6.2.1. For each $i \in [n]$ and $\ell \in [L]$, let $D_{i,\ell} \in \mathbb{R}^{m \times m}$ be the diagonal matrix where

$$(D_{i,\ell})_{k,k} = \mathbf{1}_{(W \cdot h_{i,\ell-1} + Ax_{i,\ell})_k \geq 0} = \mathbf{1}_{(g_{i,\ell})_k \geq 0} \ .$$

As a result, we can write $h_{i,\ell} = D_{i,\ell} W h_{i,\ell-1}$.

[5] If it only satisfies $\|x_{i,1}\| \leq 1$ one can pad it with an additional coordinate to make $\|x_{i,1}\| = 1$ hold. As for the assumption $[x_{i,1}]_{d_x} = \frac{1}{\sqrt{2}}$, this is equivalent to adding a bias term $\mathcal{N}(0, \frac{1}{m})$ for the first layer.

We consider the following random initialization distributions for W, A and B.

Definition 6.2.2. We say that W, A, B are at random initialization, if the entries of W and A are i.i.d. generated from $\mathcal{N}(0, \frac{2}{m})$, and the entries of $B_{i,j}$ are i.i.d. generated from $\mathcal{N}(0, \frac{1}{d})$.

Throughout this paper, for notational simplicity, we refer to index ℓ as the ℓ-th *layer* of RNN, and $h_{i,\ell}$, $x_{i,\ell}$, $y_{i,\ell}$ respectively as the hidden neurons, input, output on the ℓ-th layer. We acknowledge that in certain literatures, one may regard Elman network as a three-layer RNN.

Assumption 6.2.2. *We assume $m \geq \mathrm{poly}(n, d, L, \frac{1}{\delta}, \log \frac{1}{\epsilon})$ for some sufficiently large polynomial.*

Without loss of generality, we assume $\delta \leq \frac{1}{CL^2 \log^3 m}$ for some sufficiently large constant C (if this is not satisfied one can decrease δ). Throughout the paper except the detailed appendix, we use $\widetilde{O}$, $\widetilde{\Omega}$ and $\widetilde{\Theta}$ notions to hide polylogarithmic dependency in m. To simplify notations, we denote by

$$\rho \stackrel{\text{def}}{=} nLd \log m \quad \text{and} \quad \varrho \stackrel{\text{def}}{=} nLd\delta^{-1} \log(m/\epsilon) \ .$$

6.2.2 Objective and Gradient

For simplicity, we only optimize over the weight matrix $W \in \mathbb{R}^{m \times m}$ and let A and B be at random initialization. As a result, our ℓ_2-regression objective is a function over W:[6]

$$f(W) \stackrel{\text{def}}{=} \sum_{i=1}^{n} f_i(W) \quad \text{and} \quad f_i(W) \stackrel{\text{def}}{=} \frac{1}{2} \sum_{\ell=2}^{L} \| \mathsf{loss}_{i,\ell} \|_2^2 \quad \text{where} \quad \mathsf{loss}_{i,\ell} \stackrel{\text{def}}{=} B h_{i,\ell} - y^*_{i,\ell} \ .$$

Using chain rule, one can write down a closed form of the (sub-)gradient:

Fact 6.2.3. *For $k \in [m]$, the gradient with respect to W_k (denoted by ∇_k) and the full gradient are*

$$\nabla_k f(W) = \sum_{i=1}^{n} \sum_{a=2}^{L} \sum_{\ell=1}^{a-1} (\mathsf{Back}_{i,\ell+1\to a}^\top \cdot \mathsf{loss}_{i,a})_k \cdot h_{i,\ell} \cdot \mathbf{1}_{\langle W_k, h_{i,\ell}\rangle + \langle A_k, x_{i,\ell+1}\rangle \geq 0}$$

$$\nabla f(W) = \sum_{i=1}^{n} \sum_{a=2}^{L} \sum_{\ell=1}^{a-1} D_{i,\ell+1} \big(\mathsf{Back}_{i,\ell+1\to a}^\top \cdot \mathsf{loss}_{i,a} \big) \cdot h_{i,\ell}^\top$$

where for every $i \in [n]$, $\ell \in [L]$, and $a = \ell+1, \ell+2, \ldots, L$:

$$\mathsf{Back}_{i,\ell\to\ell} \stackrel{\text{def}}{=} B \in \mathbb{R}^{d \times m} \quad \textit{and} \quad \mathsf{Back}_{i,\ell\to a} \stackrel{\text{def}}{=} B D_{i,a} W \cdots D_{i,\ell+1} W \in \mathbb{R}^{d \times m} \ .$$

[6] The index ℓ starts from 2, because $B h_{i,1} = B\phi(A x_{i,1})$ remains constant if we are not optimizing over A and B.

6.3 Our Results

Our main results can be formally stated as follows.

Theorem 6.3.1 (GD). *Suppose* $\eta = \widetilde{\Theta}\big(\frac{\delta}{m}\operatorname{poly}(n,d,L)\big)$ *and* $m \geq \operatorname{poly}(n,d,L,\delta^{-1},\log\epsilon^{-1})$. *Let* $W^{(0)}, A, B$ *be at random initialization. With high probability over the randomness of* $W^{(0)}, A, B$, *if we apply gradient descent for* T *steps* $W^{(t+1)} = W^{(t)} - \eta\nabla f(W^{(t)})$, *then it satisfies*

$$f(W^{(T)}) \leq \epsilon \quad \text{for} \quad T = \widetilde{\Omega}\big(\frac{\operatorname{poly}(n,d,L)}{\delta^2}\log\frac{1}{\epsilon}\big).$$

Theorem 6.3.2 (SGD). *Suppose* $\eta = \widetilde{\Theta}\big(\frac{\delta}{m}\operatorname{poly}(n,d,L)\big)$ *and* $m \geq \operatorname{poly}(n,d,L,\delta^{-1},\log\epsilon^{-1})$. *Let* $W^{(0)}, A, B$ *be at random initialization. If we apply stochastic gradient descent for* T *steps* $W^{(t+1)} = W^{(t)} - \eta\nabla f_i(W^{(t)})$ *for a random index* $i \in [n]$ *per step, then with high probability (over* $W^{(0)}, A, B$ *and the randomness of SGD), it satisfies*

$$f(W^{(T)}) \leq \epsilon \quad \text{for} \quad T = \widetilde{\Omega}\big(\frac{\operatorname{poly}(n,d,L)}{\delta^2}\log\frac{1}{\epsilon}\big).$$

In both cases, we essentially have *linear convergence rates.* [7] Notably, our results show that the dependency of the number of layers L, is *polynomial.* Thus, even when RNN is applied to sequences of long input data, it does not suffer from exponential gradient explosion or vanishing (e.g., $2^{\Omega(L)}$ or $2^{-\Omega(L)}$) through the entire training process.

Main Technical Theorems Our main Theorem 6.17.1 and Theorem 6.18.1 are in fact natural consequences of the following two technical theorems. They both talk about the

[7] We remark here that the $\widetilde{O}$ notation may hide additional polynomial dependency in $\log\log\epsilon^{-1}$. This is not necessary, at the expense of slightly complicating the proofs, as shown by follow up [AZLS19].

first-order behavior of RNNs when the weight matrix W is sufficiently close to some random initialization.

The first theorem is similar to the classical Polyak-Łojasiewicz condition [Pol63, Loj63], and says that $\|\nabla f(W)\|_F^2$ is at least as large as the objective value.

Theorem 6.3.3. *With high probability over random initialization $\widetilde{W}, A, B$, it satisfies*

$$\forall W \in \mathbb{R}^{m\times m} \text{ with } \|W - \widetilde{W}\|_2 \le \frac{\mathrm{poly}(\varrho)}{\sqrt{m}}:$$

$$\begin{aligned} \|\nabla f(W)\|_F^2 &\ge \frac{\delta}{\mathrm{poly}(\rho)} \times m \times f(W) \ , \\ \|\nabla f(W)\|_F^2, \|\nabla f_i(W)\|_F^2 &\le \mathrm{poly}(\rho) \times m \times f(W) \ . \end{aligned}$$

The second theorem shows a special "semi-smoothness" property of the objective.

Theorem 6.3.4. *With high probability over random initialization $\widetilde{W}, A, B$, it satisfies for every $\breve{W} \in \mathbb{R}^{m\times m}$ with $\|\breve{W} - \widetilde{W}\| \le \frac{\mathrm{poly}(\varrho)}{\sqrt{m}}$, and for every $W' \in \mathbb{R}^{m\times m}$ with $\|W'\| \le \frac{\tau_0}{\sqrt{m}}$,*

$$f(\breve{W} + W') \le f(\breve{W}) + \langle \nabla f(\breve{W}), W' \rangle + \mathrm{poly}(\varrho) m^{1/3} \cdot \sqrt{f(W)} \cdot \|W'\|_2 + \mathrm{poly}(\rho) m \|W'\|_2^2 \ .$$

At a high level, the convergence of GD and SGD are careful applications of the two technical theorems above: indeed, Theorem 6.15.2 shows that as long as the objective value is high, the gradient is large; and Theorem 6.16.1 shows that if one moves in the (negative) gradient direction, then the objective value can be sufficiently decreased. These two technical theorems together ensure that GD/SGD does not hit any saddle point or (bad) local minima along its training trajectory. This was practically observed by [GVS15] and a theoretical justification was open since then.

An Open Question We did not try to tighten the polynomial dependencies of (n, d, L) in the proofs. When m is sufficiently large, we make use of the randomness at initialization to argue that, *for all the points* within a certain radius from initialization, for instance Theorem 6.15.2 holds. In practice, however, the SGD can create additional randomness as time goes; also, in practice, it suffices for those points on the SGD trajectory to satisfy Theorem 6.15.2. Unfortunately, such randomness can — in principle — be correlated with the SGD trajectory, so we do not know how to use that in the proofs. Analyzing such correlated randomness is certainly beyond the scope of this paper, but can possibly explain why in practice, the size of m needed is not that large.

6.3.1 Conclusion

Overall, we provide the first proof of convergence of GD/SGD for non-linear neural networks that have more two layers. We show with overparameterization GD/SGD can avoid hitting any (bad) local minima along its training trajectory. This was practically observed by [GVS15] and a theoretical justification was open since then. We present our result using recurrent neural networks (as opposed to the simpler feedforward networks [AZLS19]) in this very first paper, because memorization in RNN could be of independent interest. Also, our result proves that RNN can learn mappings from different input tokens to different output tokens *simultaneously* using the same recurrent unit.

Last but not least, we build new tools to analyze multi-layer networks with ReLU activations that could facilitate many new research on deep learning. For instance, our techniques in Section 6.5 provide a general theory for why ReLU activations avoid exponential exploding (see e.g. (6.2), (6.5)) or exponential vanishing (see e.g. (6.2), (6.4)); and our techniques in Section 6.6 give a general theory for the stability of multi-layer networks against adversarial weight perturbations, which is at the heart of showing the semi-smoothness Theorem 6.16.1, and used by all the follow-up works [AZLS19, ALL18c, AL19a, CG19].

6.4 Proof Sketch

The main difficulty of this paper is to prove Theorem 6.15.2 and 6.16.1, and we shall sketch the proof ideas in Section 6.5 through 6.8. In such high-level discussions, we shall put our emphasize on

- how to avoid exponential blow up in L, and
- how to deal with the issue of randomness dependence across layers.

We genuinely hope that this high-level sketch can (1) give readers a clear overview of the proof without the necessity of going to the appendix, and (2) appreciate our proof and understand why it is necessarily long.[8]

[8]For instance, proving gradient norm lower bound in Theorem 6.15.2 for a single neuron $k \in [m]$ is easy, but how to apply concentration across neurons? Crucially, due to the recurrent structure these quantities are never independent, so we have to build necessary probabilistic tools to tackle this. If one is willing to ignore such subtleties, then our sketched proof is sufficiently short and gives a good overview.

6.5 Basic Properties at Random Initialization

In this section we derive basic properties of the RNN when the weight matrices W, A, B are all *at random initialization*. The corresponding precise statements and proofs are in Section 6.11.

The first one says that the forward propagation neither explodes or vanishes, that is,

$$\frac{1}{2} \leq \|h_{i,\ell}\|_2, \|g_{i,\ell}\|_2 \leq O(L) \ . \tag{6.2}$$

Intuitively, (6.2) very reasonable. Since the weight matrix W is randomly initialized with entries i.i.d. from $\mathcal{N}\left(0, \frac{2}{m}\right)$, the norm $\|Wz\|_2$ is around $\sqrt{2}$ for any fixed vector z. Equipped with ReLU activation, it "shuts down" roughly half of the coordinates of Wz and reduces the norm $\|\phi(Wz)\|$ to one. Since in each layer ℓ, there is an additional unit-norm signal $x_{i,\ell}$ coming in, we should expect the final norm of hidden neurons to be at most $O(L)$.

Unfortunately, the above argument cannot be directly applied since the weight matrix W is reused for L times so there is no fresh new randomness across layers. Let us explain how we deal with this issue carefully, because it is at the heart of *all* of our proofs in this paper. Recall, each time W is applied to some vector $h_{i,\ell}$, it only uses "one column of randomness" of W. Mathematically, letting $U_\ell \in \mathbb{R}^{m \times n\ell}$ denote the column orthonormal matrix using Gram-Schmidt

$$U_\ell \stackrel{\text{def}}{=} \mathsf{GS}\left(h_{1,1}, \ldots, h_{n,1}, h_{1,2}, \ldots, h_{n,2}, \ldots, h_{1,\ell}, \ldots, h_{n,\ell}\right) \ ,$$

we have $Wh_{i,\ell} = WU_{\ell-1}U_{\ell-1}^\top h_{i,\ell} + W(I - U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell}$.

- The second term $W(I-U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell}$ has new randomness independent of the previous layers.[9]

- The first term $WU_{\ell-1}U_{\ell-1}^\top h_{i,\ell}$ relies on the randomness of W in the directions of $h_{i,a}$ for $a<\ell$ of the previous layers. We cannot rely on the randomness of this term, because when applying inductive argument till layer ℓ, the randomness of $WU_{\ell-1}$ is already used.

  Fortunately, $WU_{\ell-1}\in\mathbb{R}^{m\times n(\ell-1)}$ is a rectangular matrix with $m\gg n(\ell-1)$ (thanks to overparameterization!) so one can bound its spectral norm by roughly $\sqrt{2}$. This ensures that no matter how $h_{i,\ell}$ behaves (even arbitrarily correlated with $WU_{\ell-1}$), the norm of the first term cannot be too large. It is crucial here that $WU_{\ell-1}$ is a *rectangular* matrix, because for a square random matrix such as W, its spectral norm is 2 and using that, the forward propagation bound will exponentially blow up.

This summarizes the main idea for proving $\|h_{i,\ell}\|\le O(L)$ in (6.2); the lower bound $\frac{1}{2}$ is similar. Our next property says in each layer, the amount of "fresh new randomness" is non-negligible:

$$\|(I-U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell}\|_2\ge\widetilde{\Omega}(\frac{1}{L^2})\ . \tag{6.3}$$

This relies on a more involved inductive argument than (6.2). At high level, one needs to show that in each layer, the amount of "fresh new randomness" reduces only by a factor at most $1-\frac{1}{10L}$.

[9] More precisely, letting $v=(I-U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell}$, we have $W(I-U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell}=\big(W\frac{v}{\|v\|}\big)\|v\|$. Here, $W\frac{v}{\|v\|}$ is a random Gaussian vector in $\mathcal{N}(0,\frac{2}{m}I)$ and is *independent* of all $\{h_{i,a}\mid i\in[n],a<\ell\}$.

Using (6.2) and (6.3), we obtain the following property about the data separability:

$$(I - U_\ell U_\ell^\top)h_{i,\ell+1} \text{ and } (I - U_\ell U_\ell^\top)h_{j,\ell+1} \text{ are } (\delta/2)\text{-separable, } \forall i, j \in [n] \text{ with } i \neq j \quad (6.4)$$

Here, we say two vectors x and y are δ-separable if $\left\|(I - yy^\top/\|y\|_2^2)x\right\| \geq \delta$ and vice versa. Property (6.4) shows that the separability information (say on input token 1) *does not diminish* by more than a polynomial factor even if the information is propagated for L layers.

We prove (6.4) by induction. In the first layer $\ell = 1$ we have $h_{i,1}$ and $h_{j,1}$ are δ-separable which is a consequence of Assumption 6.2.1. If having fresh new randomness, given two δ separable vectors x, y, one can show that $\phi(Wx)$ and $\phi(Wy)$ are also $\delta(1-o(\frac{1}{L}))$-separable. Again, in RNN, we do not have fresh new randomness, so we rely on (6.3) to give us reasonably large fresh new randomness. Applying a careful induction helps us to derive that (6.4) holds for all layers.[10]

Intermediate Layers and Backward Propagation Training neural network is not only about forward propagation. We also have to bound intermediate layers and backward propagation.

The first two results we derive are the following. For every $\ell_1 \geq \ell_2$ and diagonal

[10]This is the only place that we rely on Assumption 6.2.1. This assumption is somewhat necessary in the following sense. If $x_{i,\ell} = x_{j,\ell}$ for some pair $i \neq j$ for all the first ten layers $\ell = 1, 2, \ldots, 10$, and if $y^*_{i,\ell} \neq y^*_{i,\ell}$ for even just one of these layers, then there is no hope in having the training objective decrease to zero. Of course, one can make more relaxed assumption on the input data, involving both $x_{i,\ell}$ and $y^*_{i,\ell}$. While this is possible, it complicates the statements so we do not present such results in this paper.

matrices D' of sparsity $s \in [\rho^2, m^{0.49}]$:

$$\|WD_{i,\ell_1} \cdots D_{i,\ell_2} W\|_2 \le O(L^3) \tag{6.5}$$

$$\|D'WD_{i,\ell_1} \cdots D_{i,\ell_2} WD'\|_2 \le \widetilde{O}(\sqrt{s}/\sqrt{m}) \tag{6.6}$$

Intuitively, one cannot use spectral bound argument to derive (6.5) or (6.6): the spectral norm of W is 2, and even if ReLU activations cancel half of its mass, the spectral norm $\|DW\|_2$ remains to be $\sqrt{2}$. When stacked together, this grows exponential in L.

Instead, we use an analogous argument to (6.2) to show that, for each fixed vector z, the norm of $\|WD_{i,\ell_1} \cdots D_{i,\ell_2} Wz\|_2$ is at most $O(1)$ with extremely high probability $1 - e^{-\Omega(m/L^2)}$. By standard ϵ-net argument, $\|WD_{i,\ell_1} \cdots D_{i,\ell_2} Wz\|_2$ is at most $O(1)$ for all $\frac{m}{L^3}$-sparse vectors z. Finally, for a possible dense vector z, we can divide it into L^3 chunks each of sparsity $\frac{m}{L^3}$. Finally, we apply the upper bound for L^3 times. This proves (6.5). One can use similar argument to prove (6.6).

Remark 6.5.1. We did not try to tighten the polynomial factor here in L. We conjecture that proving an $O(1)$ bound may be possible, but that question itself may be a sufficiently interesting random matrix theory problem on its own.

The next result is for back propagation. For every $\ell_1 \ge \ell_2$ and diagonal matrices D' of sparsity $s \in [\rho^2, m^{0.49}]$:

$$\|BD_{i,\ell_1} \cdots D_{i,\ell_2} WD'\|_2 \le \widetilde{O}(\sqrt{s}) \tag{6.7}$$

Its proof is in the same spirit as (6.6), with the only difference being the spectral norm of B is around $\sqrt{m/d}$ as opposed to $O(1)$.

6.6 Stability After Adversarial Perturbation

In this section we study the behavior of RNN after adversarial perturbation. The corresponding precise statements and proofs are in Section 6.12.

Letting $\widetilde{W}, A, B$ be at random initialization, we consider some matrix $W = \widetilde{W} + W'$ for $\|W'\|_2 \leq \frac{\text{poly}(\varrho)}{\sqrt{m}}$. Here, W' may depend on the randomness of $\widetilde{W}, A$ and B, so we say it can be *adversarially* chosen. The results of this section will later be applied essentially twice:

- Once for those updates generated by GD or SGD, where W' is how much the algorithm has moved away from the random initialization.
- The other time (see Section 6.7.3) for a technique that we call "randomness decomposition" where we decompose the true random initialization W into $W = \widetilde{W} + W'$, where $\widetilde{W}$ is a "fake" random initialization but identically distributed as W. Such technique at least traces back to smooth analysis [ST04].

To illustrate our high-level idea, from this section on (so in Section 6.6, 6.7 and 6.8)

we ignore the polynomial dependency in ϱ and *hide it in the big-O notion.*

We denote by $\widetilde{D}_{i,\ell}$, $\widetilde{g}_{i,\ell}$, $\widetilde{h}_{i,\ell}$ respectively the values of $D_{i,\ell}$, $g_{i,\ell}$ and $h_{i,\ell}$ determined by $\widetilde{W}$ and A at random initialization; and by $D_{i,\ell} = \widetilde{D}_{i,\ell} + D'_{i,\ell}$, $g_{i,\ell} = \widetilde{g}_{i,\ell} + g'_{i,\ell}$ and $h_{i,\ell} = \widetilde{h}_{i,\ell} + h'_{i,\ell}$ respectively those determined by $W = \widetilde{W} + W'$ after the adversarial perturbation.

Forward Stability Our first, and most technical result is the following:

$$\|g'_{i,\ell}\|_2, \|h'_{i,\ell}\|_2 \leq O(m^{-1/2}) \ , \quad \|D'_{i,\ell}\|_0 \leq O(m^{2/3}) \quad \text{and} \quad \|D'_{i,\ell} g_{i,\ell}\|_2 \leq O(m^{-1/2}) \ . \tag{6.8}$$

Intuitively, one may hope to prove (6.8) by induction, because we have (ignoring subscripts in i)

$$g'_{\ell'} = \underbrace{W' D_{\ell'-1} g_{\ell'-1}}_{①} + \underbrace{\widetilde{W} D'_{\ell'-1} g_{\ell'-1}}_{②} + \underbrace{\widetilde{W} \widetilde{D}_{\ell'-1} g'_{\ell'-1}}_{③} \ .$$

The main issue here is that, the spectral norm of $\widetilde{W}\widetilde{D}_{\ell'-1}$ in ③ is greater than 1, so we cannot apply naive induction due to exponential blow up in L. Neither can we apply techniques from Section 6.5, because the changes such as $g_{\ell'-1}$ can be *adversarial*.

In our actual proof of (6.8), instead of applying induction on ③, we recursively expand ③ by the above formula. This results in a total of L terms of ① type and L terms of ② type. The main difficulty is to bound a term of ② type, that is:

$$\big\|\widetilde{W}\widetilde{D}_{\ell_1} \cdots \widetilde{D}_{\ell_2+1} \widetilde{W} D'_{\ell_2} g_{\ell_2}\big\|_2$$

Our argument consists of two conceptual steps.

1. Suppose $g_{\ell_2} = \widetilde{g}_{\ell_2} + g'_{\ell_2} = \widetilde{g}_{\ell_2} + g'_{\ell_2,1} + g'_{\ell_2,2}$ where $\|g'_{\ell_2,1}\|_2 \le m^{-1/2}$ and $\|g'_{\ell_2,2}\|_\infty \le m^{-1}$, then we argue that $\|D'_{\ell_2} g_{\ell_2}\|_2 \le O(m^{-1/2})$ and $\|D'_{\ell_2} g_{\ell_2}\|_0 \le O(m^{2/3})$.

2. Suppose $x \in \mathbb{R}^m$ with $\|x\|_2 \le m^{-1/2}$ and $\|x\|_0 \le m^{2/3}$, then we show that $y = \widetilde{W}\widetilde{D}_{\ell_1} \cdots \widetilde{D}_{\ell_2+1}\widetilde{W}x$ can be written as $y = y_1 + y_2$ with $\|y_1\|_2 \le O(m^{-2/3})$ and $\|y_2\|_\infty \le O(m^{-1})$.

The two steps above enable us to perform induction without exponential blow up. Indeed, they together enable us to go through the following logic chain:

$$\left.\begin{array}{l} \|\cdot\|_2 \le m^{-1/2} \text{ and } \|\cdot\|_\infty \le m^{-1} \\ \|\cdot\|_2 \le m^{-2/3} \text{ and } \|\cdot\|_\infty \le m^{-1} \end{array}\right. \begin{array}{c} \overset{(1)}{\Longrightarrow} \\ \overset{}{\Longleftarrow}_{(2)} \end{array} \left.\right\} \|\cdot\|_2 \le m^{-1/2} \text{ and } \|\cdot\|_0 \le m^{2/3}$$

Since there is a gap between $m^{-1/2}$ and $m^{-2/3}$, we can make sure that all blow-up factors are absorbed into this gap, using the property that m is polynomially large. This enables us to perform induction to prove (6.8) without exponential blow-up.

Intermediate Layers and Backward Stability Using (6.8), and especially using the sparsity $\|D'\|_0 \le m^{2/3}$ from (6.8), one can apply the results in Section 6.5 to derive the following stability bounds for intermediate layers and backward propagation:

$$\left\|D_{i,\ell_1}W\cdots D_{i,\ell_2}W - \widetilde{D}_{i,\ell_1}\widetilde{W}\cdots\widetilde{D}_{i,\ell_2}\widetilde{W}\right\|_2 \le O(L^7) \tag{6.9}$$

$$\left\|BD_{i,\ell_1}W\cdots D_{i,\ell_2}W - B\widetilde{D}_{i,\ell_1}\widetilde{W}\cdots\widetilde{D}_{i,\ell_2}\widetilde{W}\right\|_2 \le O\big(m^{1/3}\big)\ . \tag{6.10}$$

Special Rank-1 Perturbation For technical reasons, we also need two bounds in the special case of $W' = yz^\top$ for some unit vector z and sparse y with $\|y\|_0 \le \mathrm{poly}(\varrho)$. We prove that, for this type of rank-one adversarial perturbation, it satisfies for every $k \in [m]$:

$$|((\widetilde{W}+W')h'_{i,\ell})_k| \le O\big(m^{-2/3}\big) \tag{6.11}$$

$$\left\|BD_{i,\ell_1}W\cdots D_{i,\ell_2}We_k - B\widetilde{D}_{i,\ell_1}\widetilde{W}\cdots\widetilde{D}_{i,\ell_2}\widetilde{W}e_k\right\|_2 \le O\big(m^{-1/6}\big) \tag{6.12}$$

6.7 Proof Sketch of Theorem 6.15.2: Polyak-Łojasiewicz Condition

The upper bound in Theorem 6.15.2 is easy to prove (based on Section 6.5 and 6.6), but the lower bound (a.k.a. the Polyak-Łojasiewicz condition) is the most technically involved result to prove in this paper. We introduce the notion of "fake gradient". Given *fixed* vectors $\{\mathsf{loss}_{i,a}\}_{i\in[n],a\in\{2,\dots,L\}}$, we define

$$\widehat{\nabla}_k f(W) \stackrel{\text{def}}{=} \sum_{i=1}^{n}\sum_{\ell=1}^{L-1}(u_{i,\ell})_k \cdot h_{i,\ell} \cdot \mathbf{1}_{(g_{i,\ell+1})_k\geq 0} \tag{6.13}$$

where $u_{i,\ell} \stackrel{\text{def}}{=} \sum_{a=\ell+1}^{L} \mathsf{Back}_{i,\ell+1\to a}^\top \cdot \mathsf{loss}_{i,a}$. Note that if $\mathsf{loss}_{i,a} = Bh_{i,a} - y^*_{i,a}$ is the *true* loss vector, then $\widehat{\nabla}_k f(W)$ will be identical to $\nabla_k f(W)$ by Fact 6.2.3. Our main technical theorem is the following:

Theorem 6.7.1. *For every fixed vectors* $\{\mathsf{loss}_{i,a}\}_{i\in[n],a\in\{2,\dots,L\}}$*, if* W, A, B *are at* random initialization*, then with high probability*

$$\|\widehat{\nabla} f(W)\|_F^2 \geq \widetilde{\Omega}\left(\frac{\delta m}{\mathrm{poly}(\rho)}\right) \times \max_{i,\ell}\{\|\mathsf{loss}_{i,\ell}\|^2\} \ .$$

There are only two conceptually simple steps from Theorem 6.14.2 to Theorem 6.15.2 (see Section 6.15).

- First, one can use the stability lemmas in Section 6.6 to show that, the fake gradient $\|\widehat{\nabla} f(W+W')\|_F$ after adversarial perturbation W' (with $\|W'\|_2 \leq \frac{1}{\sqrt{m}}$) is also large.
- Second, one can apply ϵ-net and union bound to turn "fixed loss" into "for all loss". This allows us to turn the lower bound on the fake gradient into a lower bound on the true gradient $\|\nabla_k f(W+W')\|_F$.

Therefore, in the rest of this section, we only sketch the ideas behind proving Theorem 6.14.2.

Let $(i^*, \ell^*) = \text{argmax}_{i,\ell}\{\| \mathsf{loss}_{i,\ell} \|_2\}$ be the sample and layer corresponding to the largest loss. Recall W, A, B are at random initialization.

6.7.1 Indicator and Backward Coordinate Bounds

There are three factors in the notion of fake gradient (6.13): $(u_{i,\ell})_k \in \mathbb{R}$ the backward coordinate, $h_{i,\ell} \in \mathbb{R}^m$ the forward vector, and $\mathbf{1}_{(g_{i,\ell+1})_k \geq 0} \in \{0,1\}$ the indicator coordinate. We already know very well how the forward vector $h_{i,\ell}$ behaves from the previous sections. Let us provide bounds on the other two factors at the random initialization. (Details in Section 6.13.)

Our "backward coordinate bound" controls the value of $(u_{i,\ell})_k$: at random initialization,

$$\left|(u_{i^*,\ell^*})_k\right| \geq \frac{\|\mathsf{loss}_{i^*,\ell^*}\|_2}{\rho} \quad \text{for at least } 1 - o(1) \text{ fraction of } k \in [m] \tag{6.14}$$

The main idea behind proving (6.14) is to use the randomness of B. For a fixed $k \in [m]$, it is in fact not hard to show that $\left|(u_{i^*,\ell^*})_k\right|$ is large with high probability. Unfortunately, the randomness of B are shared for different coordinates k. We need to also bound the correlation between pairs of coordinates $k_1, k_2 \in [m]$, and resort to MiDiarmid inequality to provide a high concentration bound with respect to all the coordinates.

Our indicator coordinate bound controls the value $(g_{i,\ell+1})_k$ inside the indicator functions $\mathbf{1}_{(g_{i,\ell+1})_k \geq 0}$. It says, letting $\beta_+ \stackrel{\text{def}}{=} \frac{\delta}{\rho^2}$ and $\beta_- \stackrel{\text{def}}{=} \frac{\delta}{\rho^{10}}$, then at random initialization, for at least $\frac{\delta}{\mathrm{poly}(\rho)}$ *fraction* of the coordinates $k \in [m]$,

$$|(g_{i^*,\ell^*+1})_k| \leq \frac{\beta_-}{\sqrt{m}} \quad \text{and} \quad |(g_{i,\ell+1})_k| \geq \frac{\beta_+}{\sqrt{m}} \qquad \begin{array}{l} \text{for } i \neq i^* \text{ and } \ell = \ell^*, \text{ or} \\ \text{for } i \in [n] \text{ and } \ell > \ell^*. \end{array} \tag{6.15}$$

This should be quite intuitive to prove, in the following two steps.

- First, there are $\frac{\delta}{\mathrm{poly}(\rho)} m$ coordinates $k \in [m]$ with $|(g_{i^*,\ell^*+1})_k| \leq \frac{\beta_-}{\sqrt{m}}$.

To show this, we write $(g_{i^*,\ell^*+1})_k = (WU_{\ell^*}U_{\ell^*}h_{i^*,\ell^*} + Ax_{i^*,\ell^*+1})_k$, and prove that for every $z \in \mathbb{R}^{n\ell^*}$ with bounded norms (by ϵ-net), there are at least $\frac{\delta}{\mathrm{poly}(\rho)}m$ coordinates $k \in [m]$ with $|(WU_{\ell^*}z + Ax_{i^*,\ell^*+1})_k| \leq \frac{\beta_-}{\sqrt{m}}$. This is possible using the independence between WU_{ℓ^*} and A.

- Then, *conditioning* on the first event happens, we look at $|(g_{i,\ell+1})_k|$ for (1) each $i \neq i^*$ and $\ell = \ell^*$, or (2) each $i \in [n]$ and $\ell > \ell^*$. In both cases, even though the value of g_{i^*,ℓ^*+1} is fixed, we still have sufficient fresh new randomness (by invoking (6.4) for case (1) and (6.3) for case (2)). Such additional randomness can make sure that, with high probability (over the fresh new randomness), the value of $(g_{i,\ell+1})_k$ is larger than $\frac{\beta_+}{\sqrt{m}}$.

6.7.2 Thought Experiment: Adding Small Rank-One Perturbation

We now focus on a fixed coordinate $k \in [m]$ satisfying (6.15) and (6.14) in the Section 6.7.1, and denote by $v_{i^*,\ell^*} \stackrel{\text{def}}{=} \frac{(I-U_{\ell^*-1}U_{\ell^*-1}^\top)h_{i^*,\ell^*}}{\|(I-U_{\ell^*-1}U_{\ell^*-1}^\top)h_{i^*,\ell^*}\|}$.

For analysis purpose, imagine that we apply a small *random* perturbation W'_k to the already-randomly initialized matrix W, in the rank-one direction $e_k v_{i^*,\ell^*}^\top$. Namely, we set $W'_k = g \cdot e_k v_{i^*,\ell^*}^\top$ where $g \sim \mathcal{N}(0,\theta^2)$ and θ is a parameter satisfying $\frac{\beta_-}{\sqrt{m}} \ll \theta \ll \frac{\beta_+}{\sqrt{m}}$. Using the fact that k satisfies (6.15), one can show that[11]

(a) $\mathbf{1}_{(g_{i,\ell+1})_k \geq 0}$ stays the same with respect to perturbation W'_k, except for $i = i^*$ and $\ell = \ell^*$; and

(b) $\mathbf{1}_{(g_{i^*,\ell^*+1})_k \geq 0}$ can be 0 or 1 each with at least constant probability over W'_k.

At the same time, using the fact that k satisfies (6.14), one can show that

(c) $h_{i,\ell}$ and $(u_{i,\ell})_k$ does not change by much (owing to Section 6.6); and

(d) $|(u_{i^*,\ell^*+1})_k| \geq \frac{\|\mathsf{loss}_{i^*,\ell^*}\|_2}{\rho}$ is large (owing to (6.14)).

[11] Specifically,

- For every $\ell < \ell^*$, we have $(g_{i,\ell+1})_k$ is unchanged with respect to W'_k. This is because $g_{i,\ell+1}$ only depends on the randomness of WU_ℓ, but v_{i^*,ℓ^*} is orthogonal to the columns of U_ℓ.
- For $i = i^*$ and $i = \ell^*$, we have $(g_{i,\ell+1})_k$ will change sign with constant probability with respect to W'_k. This is because $\|W'_k\|$ is above $\frac{\beta_-}{\sqrt{m}}$ — the original $(g_{i,\ell+1})_k$ before perturbation.
- For any other i and ℓ, we have $(g_{i,\ell+1})_k$ will not change sign with high probability with respect to W'_k. This is because $\|W'_k\|$ is below $\frac{\beta_+}{\sqrt{m}}$ — the original $(g_{i,\ell+1})_k$ before perturbation.

Putting (a), (b), (c), and (d) together, we know for such specially chosen k, at least with constant probability over the random perturbation of W'_k,

$$\|\widehat{\nabla}_k f(W + W'_k)\|_F \geq \Omega\Big(\frac{\| \mathsf{loss}_{i^*,\ell^*} \|_2}{\rho}\Big) \ . \tag{6.16}$$

6.7.3 Real Proof: Randomness Decomposition and McDiarmid's Inequality

There are only two main differences between (6.16) and our desired Theorem 6.14.2. First, (6.16) gives a gradient lower bound at $W+W'_k$, while in Theorem 6.14.2 we need a gradient lower bound at random initialization W. Second, (6.16) gives a lower bound on $\widehat{\nabla}_k f(\cdot)$ with *constant probability* for a small fraction of good coordinates k, but in Theorem 6.14.2 we need a lower bound for the entire $\widehat{\nabla} f(\cdot)$.

Randomness Decomposition To fix the first issue, we resort to a randomness decomposition technique at least tracing back to the smooth analysis of [ST04]:

Proposition 6.7.2. *Given small constant $\theta \in (0,1)$ and m-dimensional random $g \sim \mathcal{N}(0, \frac{1}{m}I)$, we can rewrite $g = g_1 + g_3$ where g_1 follows from $\mathcal{N}(0, \frac{1}{m}I)$ and g_3 is very close to $\mathcal{N}(0, \frac{\theta^2}{m}I)$.*

(Note that there is no contradiction here because g_1 and g_3 shall be correlated.)

Proof. Let $g_1, g_2 \in \mathbb{R}^m$ be two independent random vectors sampled from $\mathcal{N}(0, \frac{1}{m}I)$. We can couple them and make sure $g = \sqrt{1-\theta^2}g_1 + \theta g_2$. We now choose $g_3 = \theta g_2 - (1-\sqrt{1-\theta^2})g_1$. Since $(1-\sqrt{1-\theta^2}) \le O(\theta^2)$, when θ is sufficiently small, we know that g_3 is close to being generated from distribution $\mathcal{N}(0, \frac{\theta^2}{m}I)$. □

Using Proposition 6.7.2, for each good coordinate k, instead of "adding" perturbation W'_k to W, we can instead decompose W into $W = W_0 + W'_k$, where W_0 is distributed in the same way as W. In other words, W_0 is also at random initialization. If this idea is carefully implemented, one can immediately turn (6.16) into

$$\|\widehat{\nabla}_k f(W)\|_F = \|\widehat{\nabla}_k f(W_0 + W'_k)\|_F \ge \Omega\Big(\frac{\|\,\mathsf{loss}_{i^*,\ell^*}\,\|_2}{\rho}\Big)\ . \tag{6.17}$$

Extended McDiarmid's Inequality To fix the second issue, one may wish to consider all the indices $k \in [m]$ satisfying (6.15) and (6.14). Since there are at least $\frac{\delta}{\mathrm{poly}(\rho)}$ fraction of such coordinates, if all of them satisfied (6.17), then we would have already proved Theorem 6.14.2. Unfortunately, neither can we apply Chernoff bound (because the events with different $k \in [m]$ are correlated), nor can we apply union bound (because the event occurs only with constant probability).

Our technique is to resort to (an extended probabilistic variant of) McDiarmid's inequality (see Section 6.10.6) in a very non-trivial way to boost the confidence.

Give any fixed subset N of cardinality $|N| = (\mathrm{poly}(\rho)/\delta)^2$, one can show that there again exists $\frac{\delta}{\mathrm{poly}(\rho)}$ fraction of coordinate $k \in N$ satisfying (6.15) and (6.14).[12] Now, instead of decomposing $W = W_0 + W'_k$, we decompose it as $W = W_1 + W'_N$ for $W'_N = u_N v_{i^*,\ell^*}^\top$ where u_N is only supported on coordinates $k \in N$. In other words, we *simultaneously* perturb in the directions of W'_k for all $k \in N$. Since this perturbation is small enough —i.e., $\|W'_N\|_2 \leq \frac{\mathrm{poly}(\rho)}{\sqrt{m}}$— one can show that (6.17) remains true, that is, for a large fraction of $k \in N$, with at least constant probability over W'_N:

$$\|\widehat{\nabla}_k f(W_1 + W'_N)\|_F \geq \Omega\Big(\frac{\|\,\mathsf{loss}_{i^*,\ell^*}\,\|_2}{\rho}\Big) \ . \tag{6.18}$$

In order to apply McDiarmid's, we next need to bound on the difference between $\|\widehat{\nabla}_k f(W_1 + W'_N)\|_F$ and $\|\widehat{\nabla}_k f(W_1 + W'_N + W''_j)\|_F$ for an arbitrary (but small) perturbation W''_j (in the direction of $e_j v_{i^*,\ell^*}^\top$). We show that,

$$\sum_{k\in[N]} \Big| \|\widehat{\nabla}_k(W_1 + W'_N)\|_2^2 - \|\widehat{\nabla}_k(W_1 + W'_N + W''_j)\|_2^2 \Big| \leq O\left(\rho^8 + \frac{|N|}{m^{1/6}}\right) \ . \tag{6.19}$$

[12] We use $(\mathrm{poly}(\rho))^2$ to emphasize that the first polynomial needs to be bigger than the second $\mathrm{poly}(\rho)$.

In other words, although there are $|N|$ difference terms, their total summation only grows in rate $\frac{|N|}{m^{1/6}}$ according to (6.19). After applying a variant of McDiarmid's inequality, we derive that with *high probability* over W'_N, it satisfies

$$\sum_{k\in N} \|\widehat{\nabla}_k f(W)\|_F^2 = \sum_{k\in N} \|\widehat{\nabla}_k f(W_1 + W'_N)\|_F^2 \geq \Omega\Big(\frac{\|\,\mathsf{loss}_{i^*,\ell^*}\,\|_2^2}{\mathrm{poly}(\rho)}|N|\Big)\ . \tag{6.20}$$

Finally, by sampling sufficiently many random sets N to cover the entire space $[m]$, we can show

$$\|\widehat{\nabla} f(W)\|_F^2 = \sum_{k\in[m]} \|\widehat{\nabla}_k f(W)\|_F^2 \geq \Omega\Big(\frac{\|\,\mathsf{loss}_{i^*,\ell^*}\,\|_2^2}{\mathrm{poly}(\rho)}m\Big)\ .$$

and therefore Theorem 6.14.2 holds.

6.8 Proof Sketch of Theorem 6.16.1: Objective Semi-Smoothness

The objective semi-smoothness Theorem 6.16.1 turns out to be much simpler to prove than Theorem 6.15.2. It only relies on Section 6.5 and 6.6, and does not need randomness decomposition or McDiarmid's inequality. (Details in Section 6.16.)

Recall that in Theorem 6.16.1, $\widetilde{W}, A, B$ are at random initialization. $\breve{W}$ is an adversarially chosen matrix with $\|\breve{W}-\widetilde{W}\| \le \frac{\mathrm{poly}(\varrho)}{\sqrt{m}}$, and W' is some other adversarial perturbation on top of $\breve{W}$, satisfying $\|W'\| \le \frac{\tau_0}{\sqrt{m}}$. We denote by

- $\widetilde{D}_{i,\ell}$, $\widetilde{g}_{i,\ell}$, $\widetilde{h}_{i,\ell}$ respectively the values of $D_{i,\ell}$, $g_{i,\ell}$, $h_{i,\ell}$ determined by weight matrix $\widetilde{W}$;
- $\breve{D}_{i,\ell}$, $\breve{g}_{i,\ell}$, $\hbar_{i,\ell}$, $\breve{\mathsf{loss}}_{i,\ell}$ respectively those of $D_{i,\ell}$, $g_{i,\ell}$, $h_{i,\ell}$ and $\mathsf{loss}_{i,\ell}$ at weight matrix $\breve{W}$; and
- $D_{i,\ell}$, $g_{i,\ell}$, $h_{i,\ell}$ respectively the values of $D_{i,\ell}$, $g_{i,\ell}$, $h_{i,\ell}$ at weight matrix $W = \breve{W} + W'$.

Our main tool is to derive the following strong formula for $h_{i,\ell} - \hbar_{i,\ell}$: there exist diagonal matrices $D''_{i,\ell} \in \mathbb{R}^{m\times m}$ with entries in $[-1,1]$ and sparsity $\|D''_{i,\ell}\|_0 \le O(m^{2/3})$ such that,

$$h_{i,\ell} - \hbar_{i,\ell} = \sum_{a=1}^{\ell-1} (\breve{D}_{i,\ell} + D''_{i,\ell})\breve{W}\cdots\breve{W}(\breve{D}_{i,a+1} + D''_{i,a+1})W'h_{i,a} \tag{6.21}$$

In particular, (6.21) implies $\|h_{i,\ell} - \hbar_{i,\ell}\| \le O(L^9)\|W'\|_2$ after careful linear-algebraic manipulations (esp. using (6.6)). The main take-away message from (6.21) is that, this difference $h_{i,\ell} - \hbar_{i,\ell}$ is proportional to the norm of the perturbation, $\|W'\|_2$, no matter how small it is. In contrast, in (6.2), we only derived a weak upper bound of the form $\|h_{i,\ell} - \widetilde{h}_{i,\ell}\| \le O(m^{-1/2})$. Nevertheless, the proof of (6.21) relies on (6.2), so we are not duplicating proofs.

Finally, we carefully derive that

$$\begin{aligned}
&f(\breve{W}+W')-f(W)-\langle\nabla f(W),W'\rangle \\
&=\sum_{i=1}^{n}\sum_{\ell=2}^{L}\breve{\mathsf{loss}}_{i,\ell}^{\top}B\left((h_{i,\ell}-\hbar_{i,\ell})-\sum_{a=1}^{\ell-1}\breve{D}_{i,\ell}\breve{W}\cdots\breve{W}\breve{D}_{i,a+1}W'\hbar_{i,a}\right)+\frac{1}{2}\|B(h_{i,\ell}-\hbar_{i,\ell})\|^2
\end{aligned} \tag{6.22}$$

and plug (6.21) into (6.22) to derive our final Theorem 6.16.1.

6.9 Roadmap of Later Proof Details

- Section 6.10 recalls some old lemmas and derives some new lemmas in probability theory.
- Section 6.11 serves for Section 6.5, the basic properties at random initialization.
- Section 6.12 serves for Section 6.6, the stability after adversarial perturbation.
- Section 6.13, 6.14 and 6.15 together serve for Section 6.7 and prove Theorem 6.15.2, the Polyak-Łojasiewicz condition and gradient upper bound. In particular:
  - Section 6.13 serves for Section 6.7.1 (the indicator and backward coordinate bounds).
  - Section 6.14 serves for Section 6.7.3 (the randomness decomposition and McDiarmid's inequality) and proves Theorem 6.14.2.
  - Section 6.15 shows how to go from Theorem 6.14.2 to Theorem 6.15.2.
- Section 6.16 serves for Section 6.8, the proof of Theorem 6.16.1, the objective semi-smoothness.
- Section 6.17 gives the final proof for Theorem 6.17.1, the GD convergence theorem.
- Section 6.18 gives the final proof for Theorem 6.18.1, the SGD convergence theorem.

Parameters We also summarize a few parameters we shall use in the proofs.

- In Definition 6.13.1, we shall introduce two parameters

$$\beta_+ \stackrel{\text{def}}{=} \frac{\delta}{\rho^2} \text{ and } \beta_- \stackrel{\text{def}}{=} \frac{\delta}{\rho^{10}}$$

to control the thresholds of indicator functions (recall Section 6.7.1).

- In Definition 6.14.2, we shall introduce parameter

$$\theta \in \left[\rho^4 \cdot \beta_-, \rho^{-3} \cdot \beta_+\right]$$

to describe how much randomness we want to decompose out of W (recall Section 6.7.2).

- In (6.60) of Section 6.14.4, we shall choose

$$N = \frac{\rho^{22}}{\beta_-^2}$$

which controls the size of the set N where we apply McDiarmid's inequality (recall Section 6.7.3).

6.10 Preliminaries on Probability Theory

The goal of this section is to present a list of probability tools.

- In Section 6.10.1, we recall how to swap randomness.
- In Section 6.10.2, we recall concentration bounds for the chi-square distribution.
- In Section 6.10.3, we proved a concentration bound of sum of squares of ReLU of Gaussians.
- In Section 6.10.4 and Section 6.10.5, we show some properties for random Gaussian vectors.
- In Section 6.10.6, we recall the classical McDiarmid's inequality and then prove a general version of it.

6.10.1 Swapping Randomness

Fact 6.10.1 (probability splitting)**.** *If $f(X,Y)$ holds with probability at least $1-\epsilon$, then*

- *with probability at least $1-\sqrt{\epsilon}$ (over randomness of X), the following event holds,*
  - *$f(X,Y)$ holds with probability at least $1-\sqrt{\epsilon}$ (over randomness of Y).*

In other words,

$$\Pr_X\left[\Pr_Y[f(X,Y)] \geq 1-\sqrt{\epsilon}\right] \geq 1-\sqrt{\epsilon}.$$

Fact 6.10.2 (swapping probability and expectation)**.** *If $\Pr_{X,Y}[f(X,Y) \geq a] \geq \epsilon$, then*

$$\Pr_X\left[\mathop{\mathbb{E}}_Y[f(X,Y)] \geq a\epsilon/2\right] \geq \epsilon/2.$$

Proof. We prove it by making a contradiction,

Suppose

$$\Pr_X\left[\mathop{\mathbb{E}}_Y[f(X,Y)] \leq a\epsilon/2\right] \geq 1-\epsilon/2,$$

which implies that

$$\Pr_{X,Y}[f(X,Y) \geq a|X] \leq \epsilon.$$

□

6.10.2 Concentration of Chi-Square Distribution

Lemma 6.10.3 (Lemma 1 on page 1325 of [LM00]). *Let $X \sim \mathcal{X}_k^2$ be a chi-squared distributed random variable with k degrees of freedom. Each one has zero mean and σ^2 variance. Then*

$$\Pr[X - k\sigma^2 \geq (2\sqrt{kt} + 2t)\sigma^2] \leq \exp(-t)$$
$$\Pr[k\sigma^2 - X \geq 2\sqrt{kt}\sigma^2] \leq \exp(-t)$$

One straightforward application is

Lemma 6.10.4. *Let $x_1, x_2, \cdots, x_n$ denote i.i.d. samples from $\mathcal{N}(0, \sigma^2)$. For any $b \geq 1$, we have*

$$\Pr\left[|\|x\|_2^2 - n\sigma^2| \geq \frac{n}{b}\sigma^2\right] \leq 2\exp(-n/(8b^2)).$$

Proof. We choose $t = k/(8b^2)$ in Lemma 6.10.3,

$$\Pr\left[\left|\|x\|_2^2 - n\sigma^2\right| \geq (\frac{2n}{\sqrt{8}b} + \frac{2n}{8b^2})\sigma^2\right] \leq 2\exp(-n/(8b^2)).$$

Since $\frac{2n}{\sqrt{8}b} + \frac{2n}{8b^2} \leq \frac{2n}{\sqrt{8}b} + \frac{2n}{8b} \leq n/b$. Thus,

$$\Pr\left[\left|\|x\|_2^2 - n\sigma^2\right| \geq \frac{n}{b}\sigma^2\right] \leq 2\exp(-n/(8b^2)),$$

which completes the proof. □

Lemma 6.10.5. *Let $x_1, x_2, \cdots, x_m$ denote i.i.d. samples from $\mathcal{N}(0, 1)$, and $y_i = \max\{x_i^2 - \log m, 0\}$. We have*

$$\Pr\left[\sum_{i=1}^{m} y_i \geq 2\sqrt{m}\right] \leq e^{-\Omega(\sqrt{m})} .$$

Proof. First of all, letting $g = \sqrt{\log m}$,

$$\mathbb{E}[y_i] = \int_g^\infty \frac{\exp\left(-\frac{x^2}{2}\right)(x-g)^2}{\sqrt{2\pi}}\,dx = \frac{1}{2}\left(g^2+1\right)\operatorname{erfc}\left(\frac{g}{\sqrt{2}}\right) - \frac{e^{-\frac{g^2}{2}}g}{\sqrt{2\pi}} \leq \frac{1}{e^{\frac{g^2}{2}}} = \frac{1}{\sqrt{m}}\ .$$

On the other hand, each random variable y_i is $O(1)$-subgaussian. By subgaussian concentration,

$$\Pr\left[\sum_{i=1}^m y_i \geq 2\sqrt{m}\right] \leq e^{-\Omega(\sqrt{m})}$$

□

6.10.3 Concentration of Sum of Squares of ReLU of Gaussians

Lemma 6.10.6 (Upper bound)**.** *Given n i.i.d. Gaussian random variables $x_1, x_2, \cdots, x_n \sim \mathcal{N}(0, \sigma^2)$, we have*

$$\Pr\left[\left(\sum_{i=1}^{n} \max(x_i, 0)^2\right)^{1/2} < (1+\epsilon)\sqrt{n/2}\sigma\right] \geq 1 - \exp(-\epsilon^2 n/100).$$

Proof. Using Chernoff bound, we know that with probability $1-\exp(-\epsilon^2 n/6)$, $\sum_{i=1}^{n} \max(x_i, 0)^2$ is a at most degree-$(1+\epsilon)\frac{n}{2}$ Chi-square random variable. Let us say this is the first event.

Using Lemma 6.10.3, we have

$$\begin{aligned}
& \Pr[X \geq k\sigma^2 + (2\sqrt{kt} + 2t)\sigma^2] \leq \exp(-t) \\
\implies & \Pr[X \geq k\sigma^2 + (2\epsilon k + 2\epsilon^2 k)\sigma^2] \leq \exp(-\epsilon^2 k) && \text{by choosing } t = \epsilon^2 k \\
\implies & \Pr[X \geq k(1+4\epsilon)\sigma^2] \leq \exp(-\epsilon^2 k) \\
\implies & \Pr\left[X \geq (1+\epsilon)(1+4\epsilon)\frac{n}{2}\sigma^2\right] \leq \exp(-\epsilon^2(1+\epsilon)n/2) && \text{by } k = (1+\epsilon)n/2
\end{aligned}$$

Thus, we have with probability at least $1 - \exp(-\epsilon^2 n/2)$,

$$X \leq (1+4\epsilon)^2 \frac{n}{2}\sigma^2.$$

Let the above event denote the second event.

By taking the union bound of two events, we have with probability $1 - 2\exp(-\epsilon^2 n/6)$

$$\left(\sum_{i=1}^{n} \max(x_i, 0)^2\right)^{1/2} \leq X \leq (1+4\epsilon)\frac{n}{2}\sigma$$

Then rescaling the ϵ, we get the desired result. □

Lemma 6.10.7 (Lower bound). *Given n i.i.d. Gaussian random variables $x_1, x_2, \cdots, x_n \sim \mathcal{N}(0, \sigma^2)$, we have*

$$\Pr\left[\left(\sum_{i=1}^{n} \max(x_i, 0)^2\right)^{1/2} > (1-\epsilon)\sqrt{n/2}\sigma\right] \geq 1 - \exp(\epsilon^2 n/100)$$

Proof. Using Chernoff bound, we know that with probability $1-\exp(-\epsilon^2 n/6)$, $\sum_{i=1}^{n} \max(x_i, 0)^2$ is a at most degree-$(1-\epsilon)\frac{n}{2}$ Chi-square random variable. Let us say this is the first event.

Using Lemma 6.10.3, we have

$$\begin{aligned}
& \Pr[X \leq k\sigma^2 - 2\sqrt{kt}\sigma^2] \leq \exp(-t) \\
\implies & \Pr[X \leq k\sigma^2 - 2\epsilon k\sigma^2] \leq \exp(-\epsilon^2 k) && \text{by choosing } t = \epsilon^2 k \\
\implies & \Pr[X \leq k\sigma^2(1-2\epsilon)] \leq \exp(-\epsilon^2 k) \\
\implies & \Pr\left[X \leq (1-\epsilon)(1-2\epsilon)\frac{n}{2}\sigma^2\right] \leq \exp(-\epsilon^2(1-\epsilon)n/2) && \text{by } k = (1-\epsilon)n/2
\end{aligned}$$

Thus, we have with probability at least $1 - \exp(-\epsilon^2 n/4)$,

$$X \geq (1-2\epsilon)^2 \frac{n}{2}\sigma^2.$$

Let the above event denote the second event.

By taking the union bound of two events, we have with probability at least $1 - 2\exp(-\epsilon^2 n/6)$,

$$\left(\sum_{i=1}^{n} \max(x_i, 0)^2\right)^{1/2} \geq X \geq (1-2\epsilon)\frac{n}{2}\sigma.$$

Then rescaling the ϵ, we get the desired result. □

Combining Lemma 6.10.7 and Lemma 6.10.6, we have

Lemma 6.10.8 (Two sides bound)**.** *Given n i.i.d. Gaussian random variables $x_1, x_2, \cdots, x_n \sim \mathcal{N}(0, \sigma^2)$, let $\phi(a) = \max(a, 0)^2$. We have*

$$\Pr_x \left[\|\phi(x)\|_2 \in ((1-\epsilon)\sqrt{n/2}\sigma, (1+\epsilon)\sqrt{n/2}\sigma) \right] \geq 1 - 2\exp(-\epsilon^2 n/100)$$

Corollary 6.10.9 (Two sides bound for single matrix)**.** *Let $x \in \mathbb{R}^n$ denote a fixed vector. Given a random Gaussian matrix $A \in \mathbb{R}^{m \times n}$ where each entry is i.i.d. sampled from $\mathcal{N}(0, 2\sigma^2/m)$.*

$$\Pr_A [\|\phi(Ax)\|_2 \in ((1-\epsilon)\|x\|_2\sigma, (1+\epsilon)\|x\|_2\sigma)] \geq 1 - 2\exp(-\epsilon^2 m/100).$$

Proof. For each $i \in [m]$, let $y_i = (Ax)_i$. Then $y_i \sim \mathcal{N}(0, \widetilde{\sigma}^2)$, where $\widetilde{\sigma}^2 = 2\sigma^2/m \cdot \|x\|_2^2$. Using Corollary 6.10.8, we have

$$\Pr_y \left[\|\phi(y)\|_2 \in ((1-\epsilon)\sqrt{m/2}\widetilde{\sigma}, (1+\epsilon)\sqrt{m/2}\widetilde{\sigma}) \right] \geq 1 - 2\exp(-\epsilon m/100)$$

which implies

$$\Pr_y [\|\phi(y)\|_2 \in ((1-\epsilon)\|x\|_2\sigma, (1+\epsilon)\|x\|_2\sigma)] \geq 1 - 2\exp(-\epsilon^2 m/100).$$

Since $y = Ax$, thus we complete the proof. □

Corollary 6.10.10 (Two sides bound for multiple matrices)**.** *Let $x_1, x_2, \cdots, x_k$ denote k fixed vectors where $x_i \in \mathbb{R}^{n_i}$. Let $x = [x_1^\top \ x_2^\top \ \cdots \ x_k^\top]^\top \in \mathbb{R}^n$ where $n = \sum_{i=1}^k n_i$. Let $A_1, A_2, \cdots A_k$ denote k independent random Gaussian matrices where each entry of $A_i \in \mathbb{R}^{m \times n_i}$ is i.i.d. sampled from $\mathcal{N}(0, 2\sigma_i^2/m)$ for each $i \in [k]$. Let $A = [A_1 \ A_2 \ \cdots \ A_k]$. We have*

$$\Pr_A \left[\|\phi(Ax)\|_2 \in \left((1-\epsilon) \left(\sum_{i=1}^k \|x_i\|_2^2 \sigma_i^2 \right)^{1/2}, (1+\epsilon) \left(\sum_{i=1}^k \|x_i\|_2^2 \sigma_i^2 \right)^{1/2} \right) \right] \geq 1 - 2\exp(-\epsilon^2 m/100).$$

Proof. It is similar as Corollary 6.10.9. □

Fact 6.10.11 (see e.g. [AZLS19])**.** *Let $h, q \in \mathbb{R}^p$ be fixed vectors and $h \neq 0$, $W \in \mathbb{R}^{m \times p}$ be random matrix with i.i.d. entries $W_{i,j} \sim \mathcal{N}(0, \frac{2}{m})$, and vector $v \in \mathbb{R}^m$ defined as $v_i = \mathbf{1}_{\langle W_i, h+q \rangle \geq 0} \langle W_i, h \rangle$. Then,*

- *$|v_i|$ follows i.i.d. from the following distribution: with half probability $|v_i| = 0$, and with the other half probability $|v_i|$ follows from folded Gaussian distributions $|\mathcal{N}(0, \frac{2\|h\|^2}{m})|$.*
- *$\frac{m\|v\|^2}{2\|h\|^2}$ is in distribution identical to χ^2_ω (chi-square distribution of order ω) where ω follows from binomial distribution $\mathcal{B}(m, 1/2)$ (m trials each with success rate $1/2$).*

6.10.4 Gaussian Vector Percentile: Center

Fact 6.10.12. *Suppose $x \sim \mathcal{N}(0, \sigma^2)$ is a Gaussian random variable. For any $t \in (0, \sigma]$ we have*

$$\Pr[x \geq t] \in \left[\frac{1}{2}(1 - \frac{4}{5}\frac{t}{\sigma}), \frac{1}{2}(1 - \frac{2}{3}\frac{t}{\sigma})\right].$$

Similarly, if $x \sim \mathcal{N}(\mu, \sigma^2)$, for any $t \in (0, \sigma]$, we have

$$\Pr[|x| \geq t] \in \left[1 - \frac{4}{5}\frac{t}{\sigma}, 1 - \frac{2}{3}\frac{t}{\sigma}\right].$$

Lemma 6.10.13. *Let $x \sim \mathcal{N}(0, \sigma^2 I)$. For any $\alpha \in (0, 1/2)$, we have with probability at least $1 - \exp(-\alpha^2 m/100)$,*

- *there exists at least $\frac{1}{2}(1 - \alpha)$ fraction of i such that $x_i \geq 5\alpha\sigma/16$, and*
- *there exists at least $\frac{1}{2}(1 - \alpha)$ fraction of i such that $x_i \leq -5\alpha\sigma/16$.*

Proof. Let $c_1 = 4/5$. For each $i \in [m]$, we define random variable y_i as

$$y_i = \begin{cases} 1, & \text{if } x_i \geq \alpha\sigma/(4c_1); \\ 0, & \text{otherwise.} \end{cases}$$

Let $p = \Pr[y_i = 1]$. Using Fact 6.10.12 with $t = \alpha\sigma/(4c_1)$, we know that $p \geq \frac{1}{2}(1 - \alpha/4)$. Letting $Y = \sum_{i=1}^m y_i$, we have $\mu = \mathbb{E}[Y] = mp \geq \frac{1}{2}(1 - \alpha/4)m$. Using Chernoff bound, we have

$$\Pr[Y \leq (1 - \delta)\mu] \leq \exp(-\delta^2\mu/2).$$

Choosing $\delta = \frac{1}{4}\alpha$, we have

$$\Pr[Y \leq (1 - \alpha/4)\mu] \leq \exp(-\alpha^2\mu/32)$$

Further we have

$$\begin{aligned}
\Pr[Y \le \frac{1}{2}(1-\alpha)m] &\le \Pr[Y \le (1-\alpha/4)\frac{1}{2}(1-\alpha/4)m] && \text{by } (1-\alpha) \le (1-\alpha/4)^2 \\
&\le \Pr[Y \le (1-\alpha/4)\mu] && \text{by } \mu \ge \frac{1}{2}(1-\alpha/4)m \\
&= \Pr[Y \le (1-\delta)\mu] && \text{by } \delta = \alpha/4 \\
&\le \exp(-\alpha^2\mu/32) \\
&\le \exp(-\alpha^2\frac{1}{2}(1-\alpha/4)m/32) && \text{by } \mu \ge \frac{1}{2}(1-\alpha/4)m \\
&= \exp(-\alpha^2(1-\alpha/4)m/64)\ . && \square
\end{aligned}$$

We provide the definition of (α, σ)-good. Note that this definition will be used often in the later proof.

Definition 6.10.1 ((α, σ)-good)**.** Given $w \in \mathbb{R}^m$, we say w is (α, σ)-good if the following two conditions holding:

- there are at least $\frac{1}{2}(1-\alpha)$ fraction coordinates satisfy that $w_i \ge \alpha\sigma$; and
- there are at least $\frac{1}{2}(1-\alpha)$ fraction coordinates satisfy that $w_i \le -\alpha\sigma$.

Lemma 6.10.13 gives the following immediate corollary:

Corollary 6.10.14 (random Gaussian is $(\alpha, \sigma/4)$-good)**.** *Let $x \sim \mathcal{N}(0, \sigma^2 I)$. For any $\alpha \in (0, 1/2)$, we have with probability at least $1 - \exp(-\alpha^2 m/100)$ that x is $(\alpha, \sigma/4)$-good.*

Corollary 6.10.15. *Let $x_1, x_2, \cdots, x_k$ be k fixed vectors where $x_i \in \mathbb{R}^{n_i}$, and $A_1, A_2, \cdots, A_k$ be k independent random Gaussian matrices where each entry of $A_i \in \mathbb{R}^{m \times n_i}$ is i.i.d. sampled from $\mathcal{N}(0, \sigma_i^2)$ for each $i \in [k]$. Denote by $x = (x_1, \ldots, x_k) \in \mathbb{R}^n$ for $n = \sum_{i=1}^k n_i$, $A =$*

$[A_1, A_2, \cdots, A_k] \in \mathbb{R}^{m\times n}$, *and* $\sigma = \left(\sum_{i=1}^k \sigma_i^2 \|x_i\|_2^2\right)^{1/2}$. *For any fixed parameter* $\alpha \in (0, 1/2)$, *we have*

$$Ax = A_1x_1 + \cdots A_kx_k \text{ is } (\alpha, \sigma/4)\text{-good with probability at least } 1 - \exp(-\alpha^2 m/100).$$

Proof. It is clear that Ax follows from a Gaussian distribution $\mathcal{N}\big(0, \big(\sum_{i=1}^k \sigma_i^2 \|x_i\|_2^2\big) I\big)$, so we can directly apply Corollary 6.10.14. □

6.10.5 Gaussian Vector Percentile: Tail

Lemma 6.10.16. *Suppose $W \in \mathbb{R}^{m\times n}$ is a random matrix with entries drawn i.i.d. from $\mathcal{N}\big(0, \frac{2}{m}\big)$. Given $d \le s \le m$, with probability at least $1 - e^{-\Omega(s\log^2 m)}$, for all $x \in \mathbb{R}^n$, letting $y = Wx$, we can write $y = y_1 + y_2$ with*

$$\|y_1\| \le \frac{\sqrt{s}\log^2 m}{\sqrt{m}} \cdot \|x\| \quad \textit{and} \quad \|y_2\|_\infty \le \frac{\log m}{\sqrt{m}} \cdot \|x\| \ .$$

Proof of Lemma 6.10.16. Without loss of generality we only prove the result for $\|x\| = 1$.

Fixing any such x and letting $\beta = \frac{\log m}{2\sqrt{m}}$, we have $y_i \sim \mathcal{N}\big(0, \frac{2}{m}\big)$ so for every $p \ge 1$, by Gaussian tail bound

$$\Pr[|y_i| \ge \beta p] \le e^{-\Omega(\beta^2 p^2 m)} \ .$$

Since $\beta^2 p^2 m \ge \beta^2 m \gg \Omega(\log m)$, we know that if $|y_i| \ge \beta p$ occurs for q/p^2 indices i out of $[m]$, this cannot happen with probability more than

$$\binom{m}{q/p^2} \times \left(e^{-\Omega(\beta^2 p^2 m)}\right)^{q/p^2} \le e^{\frac{q}{p^2}\left(O(\log m) - \Omega(\beta^2 p^2 m)\right)} \le e^{-\Omega(\beta^2 q m)} \ .$$

In other words,

$$\Pr\left[\left|\{i \in [m] \colon |y_i| \ge \beta p\}\right| > q/p^2\right] \le e^{-\Omega(\beta^2 q m)} \ .$$

Finally, by applying union bound over $p = 1, 2, 4, 8, 16, \ldots$ we have with probability $\ge 1 - e^{-\Omega(\beta^2 q m)} \cdot \log q$,

$$\sum_{i\colon |y_i| \ge \beta} y_i^2 \le \sum_{k=0}^{\lceil \log q \rceil} (2^{k+1}\beta)^2 \left|\left\{i \in [m] \colon |y_i| \ge 2^k \beta\right\}\right| \le \sum_{k=0}^{\lceil \log q \rceil} (2^{k+1}\beta)^2 \cdot \frac{q}{2^{2k}} \le 4q\beta^2 \log q \ . \tag{6.23}$$

In other words, vector y can be written as $y = y_1 + y_2$ where $\|y_2\|_\infty \le \beta$ and $\|y_1\|^2 \le 4q\beta^2 \log q$.

At this point, we can choose $q = \frac{s \log^2 m}{m\beta^2} = 4s$ so the above event happens with probability at least $1 - e^{-\Omega(\beta^2 qm)} \geq 1 - e^{-\Omega(s \log^2 m)}$. Finally, applying standard ϵ-net argument over all unit vectors $x \in \mathbb{R}^n$, we have for each such $x \in \mathbb{R}^n$, we can decompose $y = Wx$ into $y = y_1 + y_2$ where

$$\|y_2\|_\infty \leq 2\beta = \frac{\log m}{\sqrt{m}} \text{ and } \|y_1\|^2 \leq \frac{8s \log^3 m}{m} \ . \qquad \square$$

6.10.6 McDiarmid's Inequality and An Extension

We state the standard McDiarmid's inequality,

Lemma 6.10.17 (McDiarmid's inequality)**.** *Consider independent random variables $x_1, \cdots, x_n \in \mathcal{X}$ and a mapping $f : \mathcal{X}^n \to \mathbb{R}$. If for all $i \in [n]$ and for all $y_1, \cdots, y_n, y_i' \in \mathcal{X}$, the function f satisfies*

$$|f(y_1, \cdots, y_{i-1}, y_i, y_{i+1}, \cdots, y_n) - f(y_1, \cdots, y_{i-1}, y_i', y_{i+1}, \cdots, y_n)| \leq c_i.$$

Then

$$\Pr[f(x_1, \cdots, x_n) - \mathbb{E}\, f \geq t] \geq \exp(\frac{-2t^2}{\sum_{i=1}^n c_i^2}),$$
$$\Pr[f(x_1, \cdots, x_n) - \mathbb{E}\, f \leq -t] \geq \exp(\frac{2t^2}{\sum_{i=1}^n c_i^2}).$$

We prove a more general version of McDiarmid's inequality,

Lemma 6.10.18 (McDiarmid extension)**.** *Let $w_1, \ldots, w_N$ be independent random variables and*

$f \colon (w_1, \ldots, w_N) \mapsto [0, 1]$. Suppose it satisfies:

- $\mathbb{E}_{w_1,\ldots,w_N}[f(w_1, \ldots, w_N)] \geq \mu$, *and*
- *With probability at least $1 - p$ over $w_1, \ldots, w_N$, it satisfies*

$$\forall k \in [N], \forall w_k'' \colon\ |f(w_{-k}, w_k) - f(w_{-k}, w_k'')| \leq c \tag{6.24}$$

Then, $\Pr[f(w_1, \ldots, w_N) \geq \mu/2] \geq 1 - N^2\sqrt{p} - e^{\Omega(\frac{-\mu^2}{N(c^2+p)})}$.

Proof of Lemma 6.10.18. For each $t \in [N]$, we have with probability at least $1 - \sqrt{p}$ over $w_1, \ldots, w_t$, it satisfies

$$\Pr_{w_{t+1},\ldots,w_N}[\forall k \in [N], \forall w_k'' \colon |f(w_{-k}, w_k) - f(w_{-k}, w_k'')| \le c] \ge 1 - \sqrt{p} \ .$$

Define those $(w_1, \ldots, w_t)$ satisfying the above event to be $K_{\le t}$.

Define random variable X_t (which depends only on $w_1, \ldots, w_t$) as

$$X_t := \mathop{\mathbb{E}}_{w_{>t}}[f(\vec{w}) \mid w_{\le t}] \mathbb{1}_{(w_{\le 1},\ldots,w_{\le t}) \in K_{\le 1} \times \cdots \times K_{\le t}} + N(1 - \mathbb{1}_{(w_{\le 1},\ldots,w_{\le t}) \in K_{\le 1} \times \cdots \times K_{\le t}})$$

For every t and fixed $w_1, \ldots, w_{t-1}$.

- If $(w_{\le 1}, \ldots, w_{<t}) \notin K_{\le 1} \times \cdots \times K_{<t}$, then $X_t = X_{t-1} = N$.
- If $(w_{\le 1}, \ldots, w_{<t}) \in K_{\le 1} \times \cdots \times K_{<t}$,
  - If $w_{\le t} \notin K_{\le t}$, then $X_t - X_{t-1} = N - \cdots \ge 0$.
  - If $w_{\le t} \in K_{\le t}$, then

    $$X_t - X_{t-1} = \mathop{\mathbb{E}}_{w_{>t}}[f(w_{<t}, w_t, w_{>t}) \mid w_{\le t}] - \mathop{\mathbb{E}}_{w_{\ge t}}[f(w_{<t}, w_t, w_{>t}) \mid w_{<t}]$$

    Recall from our assumption that, with probability at least $1 - \sqrt{p}$ over w_t and $w_{>t}$, it satisfies

    $$\forall w_t'' \colon |f(w_{<t}, w_t'', w_{>t}) - f(w_{<t}, w_t, w_{>t})| \le c$$

    Taking expectation over w_t and $w_{>t}$, we have

    $$\forall w_t'' \colon \mathop{\mathbb{E}}_{w_{>t}}[f(w_{<t}, w_t'', w_{>t})] - \mathop{\mathbb{E}}_{w_{\ge t}}[f(w_{<t}, w_t, w_{>t})] \ge -(c + \sqrt{p})$$

    This precisely means $X_t - X_{t-1} \ge c + \sqrt{p}$.

In sum, we have just shown that $X_t - X_{t-1} \geq -(c + \sqrt{p})$ always holds. By applying martingale concentration (with one-sided bound),

$$\Pr[X_N - X_0 \leq -t] \leq \exp\left(\frac{-t^2}{N(c+\sqrt{p})^2}\right)$$

Notice that $X_0 = \mu$ so if we choose $t = \mu/2$, we have

$$\Pr[X_N \geq \mu/2] \geq 1 - \exp\left(\frac{-\mu^2}{N(c+\sqrt{p})^2}\right)$$

Recalling

$$X_N := f(\vec{w})\mathbb{1}_{(w_{\leq 1},\ldots,w_{\leq t}) \in K_{\leq 1} \times \cdots \times K_{\leq t}} + N(1 - \mathbb{1}_{(w_{\leq 1},\ldots,w_{\leq t}) \in K_{\leq 1} \times \cdots \times K_{\leq t}})$$

and we have $X_N = f(w_1, \ldots, w_N)$ with probability at least $1 - N\sqrt{p}$ (and $X_N = N$ with the remaining probabilities). Together, we have the desired theorem.

□

6.11 Basic Properties at Random Initialization

Recall that the recursive update equation of RNN can be described as follows

$$\begin{aligned} h_{i,0} &= 0 && \forall i \in [n] \\ h_{i,\ell} &= \phi(W \cdot h_{i,\ell-1} + Ax_{i,\ell}) && \forall i \in [n], \forall \ell \in [L] \\ y_{i,\ell} &= B \cdot h_{i,\ell} && \forall i \in [n], \forall \ell \in [L] \end{aligned}$$

Throughout this section, we assume that matrices $W \in \mathbb{R}^{m \times m}$, $A \in \mathbb{R}^{m \times d_x}$, $B \in \mathbb{R}^{d \times m}$ are at their random initialization position: each entry of W and A is sampled i.i.d. from $\mathcal{N}(0, \frac{2}{m})$ and each entry of B is sampled i.i.d. from $\mathcal{N}(0, \frac{1}{d})$. We recall

Definition 6.11.1. For each $i \in [n]$ and $\ell \in [L]$, let $D_{i,\ell} \in \mathbb{R}^{m \times m}$ be the diagonal matrix where

$$(D_{i,\ell})_{k,k} = \mathbf{1}_{(W \cdot h_{i,\ell-1} + Ax_{i,\ell})_k \geq 0} = \mathbf{1}_{(g_{i,\ell})_k \geq 0} \ .$$

As a result, we can write $h_{i,\ell} = D_{i,\ell} W h_{i,\ell-1}$.

We introduce two notations that shall repeatedly appear in our proofs.

Definition 6.11.2 (U_ℓ)**.** Let $U_\ell \in \mathbb{R}^{m \times n\ell}$ denote the column orthonormal matrix using Gram-Schmidt

$$U_\ell \stackrel{\text{def}}{=} \mathsf{GS}\left(h_{1,1}, \ldots, h_{n,1}, h_{1,2}, \ldots, h_{n,2}, \ldots, h_{1,\ell}, \ldots, h_{n,\ell}\right)$$

Definition 6.11.3 ($v_{i,\ell}$)**.** For each $i \in [n]$, $\ell \in [L]$, we define vector $v_{i,\ell} \in \mathbb{R}^m$ as

$$v_{i,\ell} = \frac{(I - U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell}}{\|(I - U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell}\|_2}$$

Roadmap

- Section 6.11.1 proves that the forward propagation $\|h_{i,\ell}\|_2$ neither vanishes nor explodes.
- Section 6.11.2 gives a lower bound on the projected forward propagation $\|(I-U_\ell U_\ell^\top)h_{i,\ell+1}\|_2$.
- Section 6.11.3 proves that for two data points $i, j \in [n]$, the projected forward propagation $(I - U_\ell U_\ell^\top)h_{i,\ell+1}$ and $(I - U_\ell U_\ell^\top)h_{j,\ell+1}$ are separable from either other.
- Section 6.11.4 and Section 6.11.5 prove that the consecutive intermediate layers, in terms of spectral norm, do not explode (for full and sparse vectors respectively).
- Section 6.11.6 proves that the backward propagation does not explode.

6.11.1 Forward Propagation

Our first result of this section is on showing upper and lower bounds on the forward propagation.

Lemma 6.11.1 (c.f. (6.2))**.** *With probability at least* $1 - \exp(-\Omega(m/L^2))$ *over the random initialization* W, A *(see Definition 6.2.2), it satisfies*

$$\forall i \in [n], \quad \forall \ell \in \{0, 1, \ldots, L-1\} \quad : \quad (1 - 1/(4L))^\ell \leq \|h_{i,\ell+1}\|_2 \leq 2\ell + 4.$$
$$\|g_{i,\ell+1}\|_2 \leq 4\ell + 8.$$

We prove Lemma 6.11.1 by induction on $\ell \in [L]$. We only prove the $h_{i,\ell+1}$ part and the $g_{i,\ell+1}$ part is completely analogous.

For the base case $\ell = 0$, we have $\|x_{i,1}\|_2 = 1$ and $h_{i,1} = \phi(Ax_{i,1})$. Using Corollary 6.10.10 we have $1-1/4L \leq \|h_{i,1}\|_2 \leq 1+1/4L$ with probability at least $1-\exp(-\Omega(-m/L^2))$. We proceed the proof for the case of $\ell \geq 1$, assuming that Lemma 6.11.1 already holds for $0, 1, \ldots, \ell - 1$. We first show

Claim 6.11.2. *With probability at least* $1 - \exp(-\Omega(m/L^2))$ *over* W *and* A*,*

$$\forall i \in [n] \colon \|h_{i,\ell+1}\|_2 \leq (1 + 1/L)(\|h_{i,\ell}\|_2 + 1)$$

Note if Claim 6.11.2 holds for all $\ell = 0, 1, \ldots, \ell - 1$, then we must have $\|h_{i,\ell}\|_2 \leq (1 + 1/L)^\ell \|h_{i,0}\|_2 + \sum_{i=1}^{\ell} (1 + 1/L)^i = (1 + 1/L)^\ell + \sum_{i=1}^{\ell} (1 + 1/L)^i \leq 2\ell + 4$.

Proof of Claim 6.11.2. Recall the definition of $h_{i,\ell} \in \mathbb{R}^m$, we have

$$\|h_{i,\ell+1}\|_2 = \|\phi(W \cdot h_{i,\ell} + Ax_{i,\ell+1})\|_2$$

We can rewrite vector $Wh_{i,\ell} \in \mathbb{R}^m$ as follows

$$\begin{aligned} Wh_{i,\ell} &= WU_{\ell-1}U_{\ell-1}^\top h_{i,\ell} + W(I - U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell} \\ &= WU_{\ell-1}U_{\ell-1}^\top h_{i,\ell} + W\frac{(I - U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell}}{\|(I - U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell}\|_2} \cdot \|(I - U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell}\|_2 \\ &= WU_{\ell-1}U_{\ell-1}^\top h_{i,\ell} + Wv_{i,\ell} \cdot \|(I - U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell}\|, \end{aligned}$$

where the last step follows by definition of $v_{i,\ell}$ (See Definition 6.11.3). Define $z_1 \in \mathbb{R}^{n(\ell-1)}$, $z_2 \in \mathbb{R}$, $z_3 \in \mathbb{R}^d$ as follows

$$z_1 = U_{\ell-1}^\top h_{i,\ell}, \quad z_2 = \|(I - U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell}\|_2, \quad z_3 = x_{i,\ell+1}. \tag{6.25}$$

Then

$$\begin{aligned} \|z_1\|_2^2 + z_2^2 + \|z_3\|_2^2 &= \|U_{\ell-1}^\top h_{i,\ell}\|_2^2 + \|(I - U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell}\|_2^2 + \|x_{i,\ell+1}\|_2^2 \\ &= \|h_{i,\ell}\|_2^2 + \|x_{i,\ell+1}\|_2^2 \leq \|h_{i,\ell}\|_2^2 + 1 \ . \end{aligned} \tag{6.26}$$

We can thus rewrite

$$\begin{aligned} Wh_{i,\ell} + Ax_{i,\ell+1} &= WU_{\ell-1}z_1 + Wv_{i,\ell}z_2 + Az_3 \\ &= \begin{bmatrix} M_1 & M_2 & M_3 \end{bmatrix} \cdot \begin{bmatrix} z_1 \\ z_2 \\ z_3 \end{bmatrix} \\ &= M \cdot z, \end{aligned}$$

where the last step follows by defining $M \in \mathbb{R}^{m \times (n(\ell-1)+1+d)}$ as follows,

$$M = \begin{bmatrix} M_1 & M_2 & M_3 \end{bmatrix} = \begin{bmatrix} WU_{\ell-1} & Wv_{i,\ell} & A \end{bmatrix} \tag{6.27}$$

We stress here that the entries of M_1, M_2, M_3 are i.i.d. from $\mathcal{N}(0, \frac{2}{m})$.[13] We have $\|h_{i,\ell+1}\| = \|\phi(Wh_{i,\ell} + Ax_{i,\ell+1})\| = \|\phi(M \cdot z)\|$.

Next, applying Corollary 6.10.10, we know that if z_1, z_2, z_3 are fixed (instead of defined as in (6.25)), then, letting Choosing $\epsilon = 1/2L$, we have

$$\Pr_M \left[\|h_{i,\ell+1}\| \leq (1+\epsilon) \cdot \sqrt{\|z_1\|_2^2 + z_2^2 + \|z_3\|_2^2} \right] \geq 1 - \exp(-\Omega(\epsilon^2 m)) \ .$$

To move from fixed choices of z_1 and z_2 to *all* choices of z_1 and z_2, we perform a standard ϵ-net argument. Since the dimension of z_1 and z_2 are respectively $n(\ell-1)$ and 1, the size of ϵ-net for z_1 and z_2 is at most $e^{O(nL \log L)}$. Thus, with probability at least $1 - e^{O(nL \log L + \log n)} \cdot \exp(-\Omega(\epsilon^2 m)) \geq 1 - \exp(-\Omega(\epsilon^2 m))$ we have: for all $z_1 \in \mathbb{R}^{n(\ell-1)}$ and $z_2 \in \mathbb{R}$ satisfying $\|z_1\| \leq 2L + 4$ and $0 \leq z_2 \leq 2L + 4$, and fixed $z_3 = x_{i,\ell+1}$,

$$\|h_{i,\ell+1}\| \leq (1+2\epsilon) \cdot \sqrt{\|z_1\|_2^2 + z_2^2 + \|z_3\|_2^2}.$$

In particular, since we have "for all" quantifies on z_1 and z_2 above, we can substitute the choice of z_1 and z_2 in (6.25) (which may depend on the randomness of W and A). This, together with (6.26), gives

$$\Pr \left[\|h_{\ell+1}\|_2 \leq (1+\epsilon) \cdot \sqrt{\|h_{i,\ell}\|_2^2 + 1} \right] \geq 1 - \exp(-\Omega(\epsilon^2 m)) \ . \qquad \square$$

Similarly, we can prove a lower bound

[13] Indeed, after Gram-Schmidt we can write $U_{\ell-1} = [\widehat{h}_1, \ldots, \widehat{h}_{n(\ell-1)}]$, where each $\widehat{h}_j$ only depends on the randomness of A and $W[\widehat{h}_1, \ldots, \widehat{h}_{j-1}]$. In other words, conditioning on any choice of A and $W[\widehat{h}_1, \ldots, \widehat{h}_{j-1}]$, we still have $W\widehat{h}_j$ is an independent Gaussian vector from $\mathcal{N}(0, \frac{2}{m}I)$. Similarly, $v_{i,\ell}$ may depend on the randomness of A and $WU_{\ell-1}$, but conditioning on any choice of A and $WU_{\ell-1}$, we still have $Wv_{i,\ell}$ follows from $\mathcal{N}(0, \frac{2}{m}I)$. This proves that the entries of M_1, M_2, M_3 are independent.

Claim 6.11.3. *With probability at least* $1 - \exp(-\Omega(m/L^2))$ *over* W *and* A,

$$\|h_{i,\ell+1}\|_2 \geq (1 - \frac{1}{4L})\|h_{i,\ell}\|_2.$$

Proof. We can define z_1, z_2, z_3 in the same way as (6.25). This time, we show a lower bound

$$\|z_1\|_2^2 + z_2^2 + \|z_3\|_2^2 \geq \|z_1\|_2^2 + z_2^2 = \|h_{i,\ell}\|_2^2. \tag{6.28}$$

Applying Corollary 6.10.10, we know if z_1, z_2, z_3 are fixed (instead of defined as in (6.25)), then choosing $\epsilon = 1/8L$,

$$\Pr\left[\|h_{i,\ell+1}\| \geq (1-\epsilon) \cdot \sqrt{\|z_1\|_2^2 + z_2^2 + \|z_3\|_2^2}\right] \geq 1 - \exp(-\Omega(\epsilon^2 m)) \ ..$$

Again, after applying ϵ-net, we know with probability at least $1 - e^{O(nL\log L + \log n)} \cdot \exp(-\Omega(\epsilon^2 m)) \geq 1 - \exp(-\Omega(\epsilon^2 m))$, for all $z_1 \in \mathbb{R}^{n(\ell-1)}$ and $z_2 \in \mathbb{R}$ satisfying $\|z_1\| \leq 2L + 4$ and $0 \leq z_2 \leq 2L + 4$, and fixed $z_3 = x_{i,\ell+1}$,

$$\|h_{i,\ell+1}\|_2 \geq (1-\epsilon) \cdot \sqrt{\|z_1\|_2^2 + z_2^2 + \|z_3\|_2^2}.$$

Substituting the choice of z_1, z_2, z_3 in (6.25), and the lower bound (6.28), we have

$$\Pr\left[\|h_{i,\ell+1}\| \geq (1-\epsilon) \cdot \|h_{i,\ell}\|_2\right] \geq 1 - \exp(-\Omega(\epsilon^2 m)).$$

Choosing $\epsilon = 1/(4L)$ gives the desired statement. □

Finally, recursively applying Claim 6.11.2 and Claim 6.11.3 for all $\ell = 0, 1, \ldots, L-1$, we have with probability at least $1 - L^2 \exp(-\Omega(m/L^2)) \geq 1 - \exp(-\Omega(m/L^2))$, we have

$$\|h_{i,\ell}\|_2 \geq (1 - \frac{1}{4L})^\ell, \qquad \|h_{i,\ell}\|_2 \leq 2\ell + 4 \ .$$

This finishes the proof of Lemma 6.11.1. ■

6.11.2 Forward Correlation

This subsection proves the following lemma which, as discussed in Section 6.5, bounds how much "fresh new randomness" is left after propagating to layer ℓ.

Lemma 6.11.4 (c.f. (6.3))**.** *With probability at least $1 - e^{-\Omega(\sqrt{m})}$ over the random initialization W, A in Definition 6.2.2, letting U_ℓ be defined in Definition 6.11.2, we have*

$$\forall i \in [n], \forall \ell \in \{0, 1, \cdots, L-1\} \quad : \quad \|(I - U_\ell U_\ell^\top) h_{i,\ell+1}\|_2 \geq \frac{1}{2 \cdot 10^6 L^2 \log^3 m} \ .$$

To prove Lemma 6.11.4, we inductively (with the increasing order of ℓ) show for each $i \in [n]$, for each $\ell \in \{0, 1, \cdots, L-1\}$, we have

$$\|(I - U_\ell U_\ell^\top) h_{i,\ell+1}\|_2 \geq \xi_\ell \stackrel{\text{def}}{=} \frac{1}{10^6 L^2 \log^3 m}(1 - 2\alpha - \frac{1}{4L})^\ell \quad \text{where} \quad \alpha \stackrel{\text{def}}{=} \frac{1}{2 \cdot 10^4 L^2 \log^2 m} \ . \tag{6.29}$$

We first show (6.29) in the base case $\ell = 0$. Since U_0 is an empty matrix, we have $(I - U_0 U_0^\top) h_{i,1} = h_{i,1}$ so according to Lemma 6.11.1 we have $\|h_{i,1}\|_2 \geq (1 - 1/4L)$.

The remainder of the proof assumes (6.29) already holds for $\ell - 1$. We can write

$$h_{i,\ell+1} = \phi(W h_{i,\ell} + A x_{i,\ell+1}) = \phi(M_1 z_1 + M_2 z_2 + M_3 z_3).$$

where $M_1 \in \mathbb{R}^{m \times n(\ell-1)}$, $M_2 \in \mathbb{R}^{m \times 1}$, $M_3 \in \mathbb{R}^{m \times d}$ and $z_1 \in \mathbb{R}^{n(\ell-1)}$, $z_2 \in \mathbb{R}$, $z_3 \in \mathbb{R}^d$ are defined as

$$\begin{aligned} &M_1 = W U_{\ell-1} && M_2 = W v_{i,\ell} && M_3 = A \\ &z_1 = U_{\ell-1}^\top h_{i,\ell} && z_2 = \|(I - U_{\ell-1} U_{\ell-1}^\top) h_{i,\ell}\|_2 && z_3 = x_{i,\ell+1} \ . \end{aligned} \tag{6.30}$$

in the same way as (6.25) and (6.27) as in the proof of Lemma 6.11.1. We again have the entries of M_1, M_2, M_3 are i.i.d. from $\mathcal{N}(0, \frac{2}{m})$ (recall Footnote 13). For the quantity $M_2 z_2$, we can further decompose it as follows

$$Mz_2 = \nu \cdot (z_2 - c_5\alpha)_+ + \nu' z_2' \tag{6.31}$$

where $c_5 = \frac{1}{16 \log m}$ is some fixed parameter, ν and ν' denote two vectors that are independently generated from $\mathcal{N}(0, \frac{2I}{m})$, and

$$(z_2 - c_5\alpha)_+ = \begin{cases} 0, & \text{if } z_2 < c_5\alpha; \\ \sqrt{z_2^2 - c_5^2\alpha^2}, & \text{if } z_2 \geq c_5\alpha. \end{cases} \qquad z_2' = \begin{cases} z_2, & \text{if } z_2 < c_5\alpha; \\ c_5\alpha, & \text{if } z_2 \geq c_5\alpha. \end{cases}$$

It is clear that the two sides of (6.31) are identical in distribution (because $M_2 \sim \mathcal{N}(0, \frac{2I}{m})$ and $(z_2 - c_5\alpha)_+^2 + (z_2')^2 = z_2^2$).

Next, suppose z_1 and z_2 are fixed (instead of depending on the randomness of W and A) and satisfies[14]

$$\frac{1}{\sqrt{2}} \leq \|z_1\| \leq 2L + 6 \text{ and } |z_2| \leq 2L + 6. \tag{6.32}$$

We can apply Corollary 6.10.15 to obtain the following statement: with probability at least $1 - \exp(-\Omega(\alpha^2 m))$,

$$w \stackrel{\text{def}}{=} M_1 z_1 + \nu(z_2 - c_5\alpha)_+ + M_3 z_3$$

is $(\alpha, \sigma/4)$-good where $\sigma = \left(\frac{2}{m}\|z_1\|_2^2 + \frac{2}{m}((z_2 - c_5\alpha)_+)^2 + \frac{2}{m}\|z_3\|_2^2\right)^{1/2}$. Using $\|z_1\|_2^2 \geq 1/2$, we can lower bound σ^2 as

$$\sigma^2 \geq \frac{2}{m}(\|z_1\|_2^2 + z_2^2 - c_5^2\alpha^2) \geq \frac{2}{m}(\frac{1}{2} - c_5^2\alpha^2) \geq \frac{1}{2m} \ .$$

[14]Note that if z_1 and z_2 are random, then they satisfy such constraints by Lemma 6.11.1.

In other words, w is $(\alpha, \frac{1}{4\sqrt{2}\sqrt{m}})$-good. Next, applying standard ϵ-net argument, we have with probability at least $1 - \exp(-\Omega(\alpha^2 m))$, for all vectors $z_1 \in \mathbb{R}^{n(\ell-1)}$ and $z_2 \in \mathbb{R}$ satisfying (6.32), it satisfies w is $(\alpha, \frac{1}{8\sqrt{m}})$-good. This allows us to plug in the random choice of z_1 and z_2 in (6.30).

We next apply Lemma 6.11.5 with

$$w = M_1 z_1 + \nu(z_2 - c_5\alpha)_+ + M_3 z_3, \quad r = z_2', \quad v = \nu, \quad U = U_\ell.$$

(We can do so because the randomness of v is independent of the randomness of U_ℓ and w.) Lemma 6.11.5 tells us that, with probability at least $1 - \exp(-\Omega(\sqrt{m}))$ over the randomness of v,

$$\|(I - U_\ell U_\ell^\top) \cdot \phi(w + rv)\| \geq r(1 - 2\alpha) - \frac{\alpha^{1.5}}{4} \ .$$

By induction hypothesis, we know

$$r = z_2' \geq \min\{z_2, c_5\alpha\} \geq \min\{\xi_{\ell-1}, c_5\alpha\} \geq \xi_{\ell-1} \ ,$$

where the last step follows by $\xi_{\ell-1} \leq c_5\alpha$. Thus, we have

$$\|(I - U_\ell U_\ell^\top) \cdot \phi(w + rv)\| \geq r(1 - 2\alpha) - \frac{\alpha^{1.5}}{4} \geq \xi_{\ell-1}(1 - 2\alpha) - \frac{\alpha^{1.5}}{4} \geq \xi_{\ell-1}(1 - 2\alpha - \frac{1}{4L}) = \xi_\ell \ ,$$

where the last inequality uses $\alpha^{1.5} \leq \frac{\xi_{\ell-1}}{L}$.

■

6.11.2.1 Tools

Lemma 6.11.5. *Suppose $\alpha \in [\frac{1}{100L^4}, 1/2)$, $m \geq 4\widetilde{d}/\alpha$ and $r \in (0, \frac{\alpha}{16 \log m}]$. Suppose w is a fixed vector that is $(\alpha, \frac{1}{8\sqrt{m}})$-good (see Definition 6.10.1), and $U \in \mathbb{R}^{m \times \widetilde{d}}$ is a fixed column*

orthonormal matrix. Then, if $v \sim \mathcal{N}(0, \frac{2}{m}I)$*, with probability at least* $1 - \exp(-\Omega(\sqrt{m}))$*, it satisfies*

$$\|(I - UU^\top) \cdot \phi(w + rv)\| \geq r(1 - 2\alpha) - \frac{\alpha^{1.5}}{4} \ .$$

Proof. We split $w \in \mathbb{R}^m$ into three pieces $w = (w_1, w_2, w_3) \in \mathbb{R}^m$ with disjoint support such that:

- w_1 corresponds to the coordinates that are $\geq \alpha/8\sqrt{m}$,
- w_2 is the remaining, which corresponds to the coordinates that are within $(-\alpha/8\sqrt{m}, \alpha/8\sqrt{m})$.
- w_3 corresponds to the coordinates that are $\leq -\alpha/8\sqrt{m}$, and

We write $v = (v_1, v_2, v_3)$ according to the same partition. We consider the following three cases.

- For each index k in the first block, we have $\big(\phi(w_1 + rv_1)\big)_k \neq \big(w_1 + rv_1\big)_k$ only if $(rv_1)_k \leq -\alpha/8\sqrt{m}$. However, if this happens, we have

  $$0 \leq \big(\phi(w_1 + rv_1)\big)_k - \big(w_1 + rv_1\big)_k \leq \max\big\{\big(rv_1\big)_k - \alpha/8\sqrt{m}, 0\big\} \ .$$

  Applying Lemma 6.10.5, we know with probability at least $1 - e^{-\Omega(\sqrt{m})}$,

  $$\delta_1 \stackrel{\text{def}}{=} \phi(w_1 + rv_1) - \big(w_1 + rv_1\big) \quad \text{satisfies} \quad \|\delta_1\|^2 \leq 2\sqrt{m}\frac{2r^2}{m} \leq 4\alpha^2/\sqrt{m} \ .$$

- Similarly, for each index k in the third block, we have $\big(\phi(w_1 + rv_1)\big)_k \neq 0$ only if $(rv_1)_k \geq \alpha/8\sqrt{m}$. Therefore, we can similarly derive that

  $$\delta_3 \stackrel{\text{def}}{=} \phi(w_3 + rv_3) \quad \text{satisfies} \quad \|\delta_3\|^2 \leq 4\alpha^2/\sqrt{m} \ .$$

- For the second block, we claim that

$$\delta_2 \stackrel{\text{def}}{=} \phi(w_2 + rv_2) \quad \text{satisfies} \quad \|\delta_2\|_2 \leq \alpha^{3/2}/4 \ . \tag{6.33}$$

To prove (6.33), we use triangle inequality,

$$\|\phi(w_2 + rv_2)\|_2 \leq \|\phi(w_2)\|_2 + \|\phi(rv_2)\|_2$$

Since $\|\phi(w_2)\|_\infty \leq \alpha/8\sqrt{m}$ and the size of support of $\phi(w_2)$ is at most αm, we have

$$\|\phi(w_2)\|_2 \leq ((\alpha/8\sqrt{m})^2 \alpha m)^{1/2} \leq \frac{\alpha^{3/2}}{8}.$$

Since $v \sim \mathcal{N}(0, \frac{2}{m}I)$, and since the size of support of v_2 is at most αm, we have $\|v_2\| \leq 2\sqrt{\alpha}$ with probability at least $1 - e^{-\Omega(\alpha m)}$ (due to chi-square distribution concentration). Thus

$$\|\phi(rv_2)\|_2 = r \cdot \|\phi(v_2)\|_2 \leq \frac{\alpha}{16} \cdot 2\sqrt{\alpha} = \frac{\alpha^{3/2}}{8} \ .$$

Together, by triangle inequality we have $\|\phi(w_2 + rv_2)\| \leq \frac{\alpha^{3/2}}{4}$. This finishes the proof of (6.33).

Denoting by $\delta = (\delta_1, \delta_2, \delta_3)$, we have

$$\phi(w + rv) = w_1 + rv_1 + \delta.$$

Taking the norm on both sides,

$$\begin{aligned}
\|(I-UU^\top)\phi(w+rv)\| &= \|(I-UU^\top)(w_1+rv_1+\delta)\| \\
&\geq \|(I-UU^\top)(w_1+rv_1)\| - \|(I-UU^\top)\delta\| \\
&\qquad\qquad \text{(by triangle inequality)} \\
&\geq \|(I-UU^\top)(w_1+rv_1)\| - \|\delta\| \qquad (\text{by } \|(I-UU^\top)\delta\| \leq \|\delta\|) \\
&\geq \|(I-UU^\top)(w_1+rv_1)\| - \frac{\alpha^{3/2}}{4} - \frac{4\alpha}{m^{1/4}} \\
&\geq \|(I-UU^\top)(w_1+rv_1)\| - \frac{\alpha^{3/2}}{2} \\
&\geq \|(I-UU^\top)w_1+rv_1\| - r\|U^\top v_1\| - \frac{\alpha^{3/2}}{2} \ .
\end{aligned}$$

Now, since $U \in \mathbb{R}^{m\times\widetilde{d}}$, it is not hard to show that $\|U^\top v_1\|_2^2 \leq \frac{2\widetilde{d}}{m}$ with probability at least $1-\exp(-\Omega(m))$. Using $\frac{2\widetilde{d}}{m} \leq \frac{\alpha}{2}$ (owing to our assumption $m \geq 4\widetilde{d}/\alpha$), we have $r\|U^\top v_1\| \leq \frac{r\alpha}{2}$.

On the other hand, the random vector $z = (I-UU^\top)w_1+rv_1$ follows from distribution $\mathcal{N}(\mu, \frac{2r^2}{m})$ for some fixed vector $\mu = (I-UU^\top)w_1$ and has at least $\frac{m}{2}(1-\alpha)$ dimensions. By chi-square concentration, we have $\|z\| \geq r(1-3\alpha/2)$ with probability at least $1-e^{-\Omega(\alpha^2 m)}$. Putting these together, we have

$$\|(I-UU^\top)\phi(w+rv)\| \geq r(1-3\alpha/2) - \frac{r\alpha}{2} - \frac{\alpha^{3/2}}{2} = r(1-2\alpha) - \frac{\alpha^{3/2}}{2} \ .$$

□

6.11.3 Forward δ-Separateness

We first give the definition of δ-Separable,

Definition 6.11.4 (δ-separable vectors)**.** For any two vectors x, y, we say x and y are δ-separable if

$$\left\|(I - \frac{yy^\top}{\|y\|_2^2})x\right\| \geq \delta \quad \text{and} \quad \left\|(I - \frac{xx^\top}{\|x\|_2^2})y\right\| \geq \delta \ ..$$

We say a finite set X is δ-separable if for any two vectors $x, y \in X$, x and y are δ-separable.

The goal of this subsection is to prove the δ-separateness over all layers ℓ.

Lemma 6.11.6 (c.f. (6.4))**.** *Let $\{x_{i,1}\}_{i\in[n]}$ be δ-separable with $\delta \leq \frac{1}{10^6 L^2 \log^3 m}$. With probability at least $1 - e^{-\Omega(\sqrt{m})}$, for all $\ell = 0, 1, \ldots, L-1$, for all $i, j \in [n]$ with $i \neq j$, we have*

$$(I - U_\ell U_\ell^\top)h_{i,\ell+1} \text{ and } (I - U_\ell U_\ell^\top)h_{j,\ell+1} \text{ are } \frac{\delta}{2}\text{-separable.}$$

(Note that since we have assumed $\|x_{i,1} - x_{j,1}\| \geq \delta$ in Assumption 6.2.1 and assumed without loss of generality that $(x_{i,1})_{d_x} = \frac{1}{\sqrt{2}}$, it automatically satisfies that $\{x_{i,1}\}_{i\in[n]}$ is $O(\delta)$-separable.)

To prove Lemma 6.11.6, we inductively (with the increasing order of ℓ) show for each $i \in [n]$, for each $\ell \in \{0, 1, \cdots, L-1\}$, we have

$$(I - U_\ell U_\ell^\top)h_{i,\ell+1} \text{ and } (I - U_\ell U_\ell^\top)h_{j,\ell+1} \text{ are } \delta_\ell \text{ separable for } \delta_\ell \stackrel{\text{def}}{=} \delta(1 - 2\alpha - \frac{1}{4L})^\ell \quad (6.34)$$

where $\alpha \stackrel{\text{def}}{=} 16\delta \log m$.

We skip the base case and only prove (6.34) for $\ell \geq 1$ by assuming (6.34) already holds for $\ell - 1$.[15]

Claim 6.11.7. *For $i \neq j$, if $(I - U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell}$ and $(I - U_{\ell-1}U_{\ell-1}^\top)h_{j,\ell}$ are $\delta_{\ell-1}$-separable, then letting $U = [U_\ell, \widehat{h}]$ where $\widehat{h} = \frac{(I-U_\ell U_\ell^\top)h_{j,\ell+1}}{\|(I-U_\ell U_\ell^\top)h_{j,\ell+1}\|_2}$, we have*

$$\|(I - UU^\top)h_{i,\ell+1}\| \geq \delta_\ell = \delta_{\ell-1}(1 - 3\alpha) \ .$$

holds with probability at least $1 - \exp(-\Omega(\sqrt{m}))$.

Since it is easy to verify that

$$\left\| \left(I - \widehat{h}\widehat{h}^\top\right)(I - U_\ell U_\ell^\top)h_{i,\ell+1} \right\| = \|(I - UU^\top)h_{i,\ell+1}\|_2 \ ,$$

Claim 6.11.7 immediately implies (6.34) for layer ℓ, and thus finishes the proof of Lemma 6.11.6. Therefore, we only need to prove Claim 6.11.7 below.

Proof of Claim 6.11.7. Let $x = (I - U_{\ell-1}U_{\ell-1}^\top)h_{j,\ell}$ and $y = (I - U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell}$. If x and y are $\delta_{\ell-1}$-separable, we split y into two parts where y_1 is parallel to x and y_2 is orthogonal to x

$$y = y_1 + y_2, \quad y_1 = \frac{\langle x, y\rangle x}{\|x\|_2^2}, \quad y_2 = (I - xx^\top/\|x\|_2^2)y$$

This also implies that the randomness in y_1 is independent of the randomness in y_2.

It is easy to see that $\|y_1\|_2 = \frac{\langle x,y\rangle}{\|x\|_2}$, so we can rewrite Wy as follows

$$Wy = Wy_1 + Wy_2 = W\frac{\langle x, y\rangle x}{\|x\|_2^2} + Wy_2 = (\|y_1\|_2/\|x\|_2)Wx + Wy_2.$$

[15] The proof of the base case is a replication of Claim 6.11.7 and only simpler. Indeed, for the base case of $\ell = 0$, one can view $h_{i,\ell} = x_{i,1}$ and $h_{j,\ell} = x_{j,1}$, and view U_ℓ as an empty matrix. Then, the same analysis of Claim 6.11.7 but with slightly different notations will apply.

Therefore,

$$\begin{aligned} Wh_{i,\ell} + Ax_{i,\ell+1} &= WU_{\ell-1}U_{\ell-1}^\top h_{i,\ell} + W(I - U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell} + Ax_{i,\ell+1} \\ &= WU_{\ell-1}U_{\ell-1}^\top h_{i,\ell} + Wy + Ax_{i,\ell+1} && \text{(by definition of } y\text{)} \\ &= WU_{\ell-1}U_{\ell-1}^\top h_{i,\ell} + (\|y_1\|_2/\|x\|_2)Wx + Ax_{i,\ell+1} + Wy_2 \\ & && \text{(by rewritting } Wy\text{)} \\ &= M_1 z_1 + M_2 z_2 + M_3 z_3 + M_4 z_4 \end{aligned}$$

where

$$\begin{aligned} M_1 &= WU_{\ell-1} & M_2 &= W\frac{x}{\|x\|_2} & M_3 &= A & M_4 &= W\frac{y_2}{\|y_2\|_2} \\ z_1 &= U_{\ell-1}^\top h_{i,\ell} & z_2 &= \|y_1\|_2 & z_3 &= x_{i,\ell+1} & z_4 &= \|y_2\|_2 \ , \end{aligned} \tag{6.35}$$

and we know the entries of M_1, M_2, M_3, M_4 are i.i.d. from $\mathcal{N}(0, \frac{2}{m})$, owing to a similar treatment as Footnote 13. For the vector $M_4 z_4$, we further rewrite it as

$$M_4 z_4 = \nu \cdot (z_4 - c_5\alpha)_+ + \nu' z_4'$$

where $c_5 = \frac{1}{16 \log m}$ is a fixed parameter, and ν and ν' denote two vectors that are independently generated from the same distribution $\mathcal{N}(0, \frac{2}{m}I)$ as vector $M_4 \in \mathbb{R}^m$, and

$$(z_4 - c_5\alpha)_+ = \begin{cases} 0, & \text{if } z_4 < c_5\alpha; \\ \sqrt{z_4^2 - c_5^2\alpha^2}, & \text{if } z_4 \geq c_5\alpha. \end{cases} \qquad z_4' = \begin{cases} z_4, & \text{if } z_4 < c_5\alpha; \\ c_5\alpha, & \text{if } z_4 \geq c_5\alpha. \end{cases}$$

Together, we can write

$$\begin{aligned} (I - UU^\top)h_{i,\ell+1} &= (I - UU^\top)\phi(Wh_{i,\ell} + Ax_{i,\ell+1}) \\ &= (I - UU^\top)\phi(M_1 z_1 + M_2 z_2 + M_3 z_3 + M_4 z_4) \\ &= (I - UU^\top)\phi(M_1 z_1 + M_2 z_2 + M_3 z_3 + \nu \cdot (z_4 - c_5\alpha)_+ + \nu' z_4') \\ &= (I - UU^\top)\phi(w + \nu' z_4') \end{aligned}$$

where the last step follows by defining

$$w = M_1 z_1 + M_2 z_2 + M_3 z_3 + \nu \cdot (z_4 - c_5\alpha)_+ \ .$$

Our plan is to first use the randomness in w to argue that w is $(\alpha, \gamma/4\sqrt{m})$-good. Then we conditioned w is good, and prove that the norm of $(I - UU^\top)\phi(w + \nu' z_4')$ is lower bounded (using (6.11.5)).

Now, suppose that $z_1 \in \mathbb{R}^{n(\ell-1)}$, $z_2 \in \mathbb{R}$, and $z_4 \in \mathbb{R}$ are fixed (instead of computed based on the randomness of W and A), and satisfies[16]

$$\frac{1}{\sqrt{2}} \le \|z_1\| \le 2L + 6 \text{ and } |z_2|, |z_4| \le 2L + 6. \tag{6.36}$$

we can use Corollary 6.10.15 to obtain the following statement: w is $(\alpha, \sigma/4)$-good with probability at least $1 - \exp(-\Omega(\alpha^2 m))$ where $\sigma = \left(\frac{2}{m}\|z_1\|_2^2 + \frac{2}{m}z_2^2 + \frac{2}{m}\|z_3\|_2^2 + \frac{2}{m}(z_4^2 - c_5^2\alpha^2)\right)^{1/2}$. Using $\|z_1\|_2^2 \ge 1/2$, we can lower bound σ^2 as

$$\sigma^2 \ge \frac{2}{m}(\|z_1\|_2^2 + z_2^2 + z_4^2 - c_5^2\alpha^2) \ge \frac{2}{m}(\frac{1}{2} - c_5^2\alpha^2)$$

In other words, w is $(\alpha, \frac{1}{4\sqrt{2}\sqrt{m}})$-good. Next, applying standard ϵ-net argument, we have with probability at least $1 - \exp(-\Omega(\alpha^2 m))$, for all z_1, z_2, z_4 satisfying (6.36), it satisfies w is $(\alpha, \frac{1}{8\sqrt{m}})$-good. This allows us to plug in the random choice of z_1, z_2, z_4 in (6.35).

We apply Lemma 6.11.5 with the following setting

$$U = \left[U_\ell, \frac{(I - U_\ell U_\ell^\top)h_{j,\ell+1}}{\|(I - U_\ell U_\ell^\top)h_{j,\ell+1}\|_2}\right], \quad w = w, \quad v = \nu', \quad r = z_4' \in [0, c_5\alpha]$$

[16]Note that if z_1, z_2 and z_4 are random, then they satisfy such constraints by Lemma 6.11.1.

where w is $(\alpha, \gamma/8\sqrt{m})$-good. (We can do so because the randomness of v is independent of the randomness of U and w.) Lemma 6.11.5 tells us that, with probability at least $1 - \exp(-\Omega(\sqrt{m}))$ over the randomness of v,

$$\|(I - UU^\top) \cdot \phi(w + rv)\| \geq r(1 - 2\alpha) - \frac{\alpha^{1.5}}{4} \ .$$

By induction hypothesis, we know

$$r = z'_4 \geq \min\{z_4, c_5\alpha\} \geq \min\{\delta_{\ell-1}, c_5\alpha\} \geq \delta_{\ell-1} \ ,$$

where the last step follows by $\delta_{\ell-1} \leq c_5\alpha$. Thus, we have

$$\|(I - UU^\top) \cdot \phi(w + rv)\| \geq r(1 - 2\alpha) - \frac{\alpha^{1.5}}{4} \geq \delta_{\ell-1}(1 - 2\alpha) - \frac{\alpha^{1.5}}{4} \geq \delta_{\ell-1}(1 - 2\alpha - \frac{1}{4L}) = \delta_\ell \ ,$$

where the last inequality uses $\alpha^{1.5} \leq \frac{\delta_{\ell-1}}{L}$. □

6.11.4 Intermediate Layers: Spectral Norm

The following lemma bounds the spectral norm of (consecutive) intermediate layers.

Lemma 6.11.8 (c.f. (6.5))**.** *With probability at least* $1-\exp(-\Omega(m/L^2))$*, we have for all* $L \geq \ell_2 \geq \ell_1 \geq 0$ *and* $i \in [n]$

$$\left\| \prod_{\ell=\ell_2}^{\ell_1} D_{i,\ell} W \right\|_2 \leq O(L^3),$$

We start with an important claim whose proof is almost identical to Lemma 6.11.1.

Claim 6.11.9. *Given* $\ell > b \geq 1$*, given* $i \in [n]$*, and given* $z_{b-1} \in \mathbb{R}^m$ *a fixed vector, letting*

$$z_\ell = D_{i,\ell} W D_{i,\ell-1} \cdots D_{i,b} W z_{b-1} \ ,$$

we have with probability at least $1-\exp(-\Omega(m/L^2))$*, it satisfies* $\|z_\ell\|_2 \leq (1+1/L)^{\ell-b+1}\|z_{b-1}\|_2$.

Proof. Let U denote the following column orthonormal matrix using Gram-Schmidt (its first $n(\ell-1)$ columns coincide with $U_{\ell-1}$):

$$U \stackrel{\text{def}}{=} \mathsf{GS}\left(h_{1,1}, \ldots, h_{n,1}, h_{1,2}, \ldots, h_{n,2}, \ldots, h_{1,\ell-1}, \ldots, h_{n,\ell-1}, z_{b-1}, \cdots z_{\ell-1}\right) \ .$$

We can rewrite $\|z_\ell\|_2$ as follows:

$$\begin{aligned}
\|z_\ell\|_2 &= \|D_{i,\ell} W z_{\ell-1}\|_2 \\
&= \left\|\mathbf{1}_{W h_{i,\ell-1} + A x_{i,\ell} \geq 0} \cdot W z_{\ell-1}\right\|_2 \\
&= \left\|\mathbf{1}_{W U U^\top h_{i,\ell-1} + A x_{i,\ell} \geq 0} \cdot W U U^\top z_{\ell-1}\right\|_2 \\
&= \left\|\mathbf{1}_{My + Ax \geq 0} M z\right\|_2 .
\end{aligned}$$

where in the last step we have defined $M = WU$, $y = U^\top h_{i,\ell-1}$, $x = x_{i,\ell}$ and $z = U^\top z_{\ell-1}$. We stress here that the entries of M and A are i.i.d. from $\mathcal{N}(0, \frac{2}{m})$.[17]

Now, Claim 6.11.10 tells us for fixed $x \in \mathbb{R}^d$ and fixed $y, z \in \mathbb{R}^{n\ell+\ell-b}$, we have with probability $1 - \exp(-\Omega(m/L^2))$ (over the randomness of M, A),

$$\|\mathbf{1}_{My+Ax\geq 0} Mz\|_2 \leq \|z\|_2(1 + 1/2L) \ .$$

After taking ϵ-net over all possible y, z, we have that for fixed $x \in \mathbb{R}^d$ but all $y, z \in \mathbb{R}^{n\ell+\ell-b}$:

$$\|\mathbf{1}_{My+Ax\geq 0} Mz\|_2 \leq \|z\|_2(1 + 1/L) \ .$$

We can thus plug in the choice $y = U^\top h_{i,\ell-1}$ and $z = U^\top z_{\ell-1}$ (both of which may depend on the randomness of W and A). Using $\|z\|_2 \leq \|z_{\ell-1}\|_2$, we have

$$\|z_\ell\|_2 \leq \|z_{\ell-1}\|_2(1 + 1/L) \ .$$

Finally, taking union bound over all possible ℓ and applying induction, we have

$$\|z_\ell\|_2 \leq (1 + 1/L)^{\ell-b+1} \|z_{b-1}\|_2. \qquad \square$$

Now, to prove the spectral norm bound in Lemma 6.11.8, we need to go from "for each z_{b-1} (see Claim 6.11.9)" to "for all z_{b-1}". Since z_{b-1} has m dimensions, we cannot afford taking union bound over all possible z_{b-1} (or its ϵ-net).

To bypass this issue, we partition the coordinates of z_{b-1} into L^3 trunk (each of length m/L^3). We write $z_{b-1} = \sum_{j=1}^{L^3} (z_{b-1})_j$ where each $(z_{b-1})_j \in \mathbb{R}^m$ denotes a vector that only

[17] This follows from a similar argument as Footnote 13, taking into account the additional fact that each z_j may only depend on the randomness of A, $WU_{\ell-1}$, and $Wz_{b-1}, \ldots Wz_{j-1}$.

has non-zero entries on m/L^3 coordinates. For each $j \in [L^3]$, we have with probability $1 - \exp(-m/L^2)$,

$$\|(z_\ell)_j\|_2 \leq (1 + 1/L)^{\ell - b} \cdot \|(z_{b-1})_j\|_2 \leq 2\|(z_{b-1})_j\|_2 \ .$$

By applying an ϵ-net argument over all such possible (but sparse) $(z_{b-1})_j$, we have with probability at least $1 - 2^{O(m/L^3)} \exp(-\Omega(m/L^2)) \geq 1 - \exp(-\Omega(m/L^2))$, the above equation holds for all possible $(z_{b-1})_j$.

Next, taking a union bound over all $j \in [L^3]$, we have with probability at least $1 - \exp(-\Omega(m/L^2))$:

$$\forall z_{b-1} \in \mathbb{R}^m \colon \|z_\ell\|_2 \leq O(L^3)\|z_{b-1}\|_2 \ .$$

Taking a union bound over all ℓ, b, we complete the proof of Lemma 6.11.8. ■

6.11.4.1 Tools

Claim 6.11.10. *For fixed $x \in \mathbb{R}^d, y, z \in \mathbb{R}^k$. Let $M \in \mathbb{R}^{m \times k}$ and $A \in \mathbb{R}^{m \times d}$ denote random Gaussian matrices where each entry is i.i.d. sampled from $\mathcal{N}(0, 2/m)$. We have with probability at least $1 - \exp(-\Omega(m/L^2))$*

$$\|\mathbf{1}_{My + Ax \geq 0} \cdot Mz\|_2 \leq \|z\|_2(1 + 1/2L) \ .$$

Proof. Without loss of generality we assume $\|z\|_2 = 1$. We can rewrite My as follows

$$\begin{aligned} My &= M(zz^\top)y + M(I - zz^\top)y \\ &= Mz \cdot z^\top y + \frac{M(I - zz^\top)y}{\|(I - zz^\top)y\|_2} \cdot \|(I - zz^\top)y\|_2 \\ &= M_1 z_1 + M_2 z_2, \end{aligned}$$

where $M_1, M_2 \in \mathbb{R}^m$ and $z_1, z_2 \in \mathbb{R}$ are defined as follows

$$M_1 = Mz, \quad M_2 = \frac{M(I - zz^\top)y}{\|(I - zz^\top)y\|_2}$$
$$z_1 = z^\top y, \quad z_2 = \|(I - zz^\top)y\|_2$$

It is easy to see that M_1 is independent of M_2. We can rewrite

$$\|\mathbf{1}_{My+Ax\geq 0} \cdot Mz\|_2 = \|\mathbf{1}_{M_1 z_1 + M_2 z_2 + Ax \geq 0} \cdot M_1\|_2$$

Using Fact 6.10.11 together with concentration bounds (for binomial distribution and for chi-square distribution), we have with probability at least $1 - \exp(-\Omega(m/L^2))$,

$$\|\mathbf{1}_{M_1 z_1 + M_2 z_2 + Ax \geq 0} \cdot M_1\|_2 \leq \|z\|_2 (1 + 1/2L).$$

Thus, we complete the proof. □

6.11.5 Intermediate Layers: Sparse Spectral Norm

This section proves two results corresponding to the spectral norm of intermediate layers with respect to *sparse* vectors. We first show Lemma 6.11.11 and our Corollary 6.11.12 and 6.11.13 shall be direct applications of Lemma 6.11.11.

Lemma 6.11.11. *For every $k \in [m]$ and $t \geq 2$, with probability at least*

$$1 - nL^2 e^{O(k \log(m))}(e^{-\Omega(m/L^2)} + e^{-\Omega(nLt^2)})$$

it satisfies, for all $i \in [n]$, for all $L > \ell_2 \geq \ell_1 \geq 1$, for all k-sparse vectors $z, y \in \mathbb{R}^m$

$$\left| y^\top W \left(\prod_{\ell=\ell_2}^{\ell_1} D_{i,\ell} W \right) z \right| \leq \frac{5t\sqrt{nL}}{m^{1/2}} \cdot \|y\|_2 \cdot \|z\|_2.$$

Proof. Without loss of generality we assume $\|y\| = \|z\| = 1$. Fixing $\ell_2 \geq \ell_1$, fixing i, and fixing $z_{\ell_1 - 1} = z$, we have according to Claim 6.11.9, letting $z_{\ell_2} = D_{i,\ell_2} W D_{i,\ell_2 - 1} W \cdots D_{i,\ell_1} z_{\ell_1 - 1}$, then with probability at least $1 - e^{-\Omega(m/L^2)}$

$$\|z_{\ell_2}\|_2 \leq (1 + 1/L)^{\ell_2 - \ell_1 - 1} \|z_{\ell_1 - 1}\|_2 \leq 2 \ .$$

Applying ϵ-net over all k-sparse vectors z, we have with probability at least $1 - e^{O(k \log m)} e^{-\Omega(m/L^2)}$, it satisfies $\|z_{\ell_2}\|_2 \leq 3$ for all k-sparse z:

Similar to the proof of Lemma 6.11.8, we let U denote the following column orthonormal matrix using Gram-Schmidt:

$$U \stackrel{\text{def}}{=} \mathsf{GS}\left(h_{1,1}, \ldots, h_{n,1}, h_{1,2}, \ldots, h_{n,2}, \ldots, h_{1,\ell_2 - 1}, \ldots, h_{n,\ell_2 - 1}, z_{\ell_1 - 1}, \cdots z_{\ell_2}\right) \ ,$$

and we have

$$\left| y^\top W \left(\prod_{\ell=\ell_2}^{\ell_1} D_{i,\ell} W \right) z \right| = \left| y^\top W U U^\top z_{\ell_2} \right| \leq \left\| y^\top W U \right\| \cdot \|U^\top z_{\ell_2}\| \leq 3 \left\| y^\top W U \right\| \ .$$

Next, observe the entries of $WU \in \mathbb{R}^{m \times n(\ell_2-1)+(\ell_2-\ell_1+2)}$ are i.i.d. drawn from $\mathcal{N}(0, \frac{2}{m})$ (following a similar argument as Footnote 17). Therefore, if y is a fixed vector, then $y^\top WU$ is in distribution identical to a Gaussian vector $\mathcal{N}(0, \frac{2}{m}I)$ of $n(\ell_2-1)+(\ell_2-\ell_1+2) \le 2nL$ dimensions. By chi-square distribution tail bound (see Lemma 6.10.3), we have for $t \ge 2$:

$$\Pr[\|y^\top WU\|^2 \ge \frac{nLt^2}{m}] \le e^{-\Omega(nLt^2)} \ .$$

Applying ϵ-net over all k-sparse vectors y, we have with probability at least $1-e^{O(k\log m)}e^{-\Omega(nLt^2)}$, it satisfies $\|y^\top WU\|^2 \le \frac{2nLt^2}{m}$ for all k-sparse vectors y.

Conditioning on both events happen, we have

$$\left| y^\top W \left(\prod_{\ell=\ell_2}^{\ell_1} D_{i,\ell} W \right) z \right| \le 3\frac{\sqrt{2nL}t}{\sqrt{m}} \ .$$

Taking union bound over all possible i, ℓ_1, ℓ_2 we finish the proof. □

Choosing $k = s^2 m^{2/3}$ and $t = \frac{sm^{1/3}\log m}{5\sqrt{nL}}$ in Lemma 6.11.11, we have

Corollary 6.11.12 (c.f. (6.6)). *Let $s \in [m^{-1/4}, m^{1/6}]$ be a fixed real. With probability at least $1 - e^{-\Omega(s^2 m^{2/3}\log^2 m)}$, we have for all $i \in [n]$, for all $L > \ell_2 \ge \ell_1 \ge 1$, for all $s^2m^{2/3}$-sparse vectors $y, z \in \mathbb{R}^m$,*

$$\left| z^\top W \left(\prod_{\ell=\ell_2}^{\ell_1} D_{i,\ell} W \right) y \right| \le \frac{s\log m}{m^{1/6}} \cdot \|z\|_2 \cdot \|y\|_2.$$

Choosing $k = 1$ and $t = \frac{\sqrt{nLd}\log m}{5}$ in Lemma 6.11.11, we have

Corollary 6.11.13 (c.f. (6.6)). *Let $\rho = nLd\log m$. With probability at least $1-\exp(-\Omega(\rho^2))$, it satisfies for all $i \in [n]$, for all $L > \ell_2 \ge \ell_1 \ge 1$, and for all 1-sparse vectors $y, z \in \mathbb{R}^m$,*

$$\left| z^\top W \left(\prod_{\ell=\ell_2}^{\ell_1} D_{i,\ell} W \right) y \right| \le \frac{\rho}{m^{1/2}} \cdot \|z\|_2 \cdot \|y\|_2 \ .$$

6.11.6 Backward Propagation

This section proves upper bound on the backward propagation against *sparse* vectors. We first show Lemma 6.11.14 and our Corollary 6.11.15 and 6.11.16 shall be immediate corollaries.

Lemma 6.11.14. *For any $k \in [m]$, $t \geq 2$ and any $a \in \mathbb{R}^d$, with probability at least*

$$1 - nL^2 e^{O(k \log m)}(e^{-\Omega(m/L^2)} + e^{-\Omega(t^2)}),$$

over the randomness of W, A, B, we have for all $i \in [n]$, for all $L \geq \ell_2 \geq \ell_1 \geq 1$, and for all k-sparse $y \in \mathbb{R}^m$,

$$\left| a^\top B \left(\prod_{\ell=\ell_2}^{\ell_1} D_{i,\ell} W \right) y \right| \leq \frac{t}{\sqrt{d}} \cdot \|a\|_2 \cdot \|y\|_2.$$

Proof of Lemma 6.11.14. Using Claim 6.11.9, we know that for fixed $z_{\ell_1 - 1} = y$, letting

$$z_{\ell_2} = D_{i,\ell_2} W D_{i,\ell_2 - 1} W \cdots D_{i,\ell_1} W z_{\ell_1 - 1} \ ,$$

with probability at least $1 - \exp(-\Omega(m/L^2))$ we have

$$\|z_{\ell_2}\|_2 \leq (1 + 1/L)^{\ell_2 - \ell_1 + 1} \|z_{\ell_1 - 1}\|_2 \leq 3\|z_{\ell_1 - 1}\|_2.$$

Next, fixing vectors a and z_{ℓ_2} and letting B be the only source of randomness, we know $a^\top B z_{\ell_2}$ follows from $\mathcal{N}(0, \|a\|_2^2 \|z_{\ell_2}\|_2^2 / d)$. Then with probability at least $1 - \exp(-\Omega(t^2))$ over B,

$$|a^\top B z_{\ell_2}| \leq t \cdot \|a\|_2 \|z_{\ell_2}\|_2 / \sqrt{d}.$$

Taking a union of the above two events, we get with probability $1 - \exp(-\Omega(m/L^2)) - \exp(-\Omega(t^2))$,

$$|a^\top B z_{\ell_2}| \leq \frac{3t}{\sqrt{d}} \cdot \|a\|_2 \cdot \|y\|_2.$$

At this point, we apply ϵ-net argument for all k-sparse vectors $y \in \mathbb{R}^m$ (the size of which is at most $e^{O(k \log(m/k))}$). Taking a union bound over all such vectors in the ϵ-net, we have with probability at least

$$1 - \exp(O(d + k \log(m/k)))(\exp(-m/L^2) + \exp(-\Omega(t^2))) \ ,$$

for all k-sparse vector $y \in \mathbb{R}^m$,

$$|a^\top B z_{\ell_2}| \leq \frac{3t}{\sqrt{d}} \cdot \|a\|_2 \cdot \|y\|_2 \ .$$

Finally, we also take a union bound over all ℓ_2, ℓ_1 and i, and there are at most $O(nL^2)$ choices. □

Using Lemma 6.11.14 with $k = s^2 m^{2/3}$ and $t = s m^{1/3} \log m$, and taking union bound over all $a \in \mathbb{R}^d$, give

Corollary 6.11.15 (c.f. (6.7))**.** *Let $s \in [m^{-1/4}, m^{1/6}]$ be a fixed real. With probability at least $1 - \exp(-\Omega(s^2 m^{2/3} \log^2 m))$, we have for all $i \in [n]$, for all $L \geq \ell_2 \geq \ell_1 \geq 1$, for all $(s^2 \cdot m^{2/3})$-sparse $y \in \mathbb{R}^m$, for all $a \in \mathbb{R}^d$,*

$$\left| a^\top B \left(\prod_{\ell=\ell_2}^{\ell_1} D_{i,\ell} W \right) y \right| \leq (s m^{1/3} \log m) \cdot \|a\|_2 \cdot \|y\|_2 \ .$$

Using Lemma 6.11.14 with $k = 1$ and $t = nLd \log m$, and taking union bound over all $a \in \mathbb{R}^d$, give

Corollary 6.11.16 (c.f. (6.7))**.** *Let* $\rho = nLd \log m$*. With probability at least* $1 - \exp(-\Omega(\rho^2))$*, we have for all* $i \in [n]$*, for all* $L \geq \ell_2 \geq \ell_1 \geq 1$*, for all* 1*-sparse vector* $y \in \mathbb{R}^m$*, and for all* $a \in \mathbb{R}^d$*,*

$$\left| a^\top B \left(\prod_{\ell=\ell_2}^{\ell_1} D_{i,\ell} W \right) y \right| \leq \rho \cdot \|a\|_2 \cdot \|y\|_2.$$

6.12 Stability After Adversarial Perturbation

Throughout this section, we consider some random initialization $\widetilde{W}, A, B$, and some adversarially chosen perturbation $W' \in \mathbb{R}^{m\times m}$ which may depend on the randomness of $\widetilde{W}, A, B$. We introduce the following notations in this section

Definition 6.12.1.

$$\begin{aligned}
&\widetilde{g}_{i,0} = \widetilde{h}_{i,0} = 0 && g_{i,0} = h_{i,0} = 0 && \text{for } i \in [n]\\
&\widetilde{g}_{i,\ell} = \widetilde{W}\widetilde{h}_{i,\ell-1} + Ax_{i,\ell} && g_{i,\ell} = (\widetilde{W} + W')h_{i,\ell-1} + Ax_{i,\ell} && \text{for } i \in [n] \text{ and } \ell \in [L]\\
&\widetilde{h}_{i,\ell} = \phi(\widetilde{W}\widetilde{h}_{i,\ell-1} + Ax_{i,\ell}) && h_{i,\ell} = \phi((\widetilde{W} + W')h_{i,\ell-1} + Ax_{i,\ell}) && \text{for } i \in [n] \text{ and } \ell \in [L]\\
&h'_{i,\ell} = h_{i,\ell} - \widetilde{h}_{i,\ell} && g'_{i,\ell} = g_{i,\ell} - \widetilde{g}_{i,\ell} && \text{for } i \in [n] \text{ and } \ell \in [L]
\end{aligned}$$

Define diagonal matrices $\widetilde{D}_{i,\ell}$ and $D_{i,\ell}$ by letting

$$(\widetilde{D}_{i,\ell})_{k,k} = \mathbb{1}_{(\widetilde{g}_{i,\ell})_k \geq 0} \text{ and } (D_{i,\ell})_{k,k} = \mathbb{1}_{(g_{i,\ell})_k \geq 0}.$$

Accordingly, we let diagonal matrix $D'_{i,\ell} = D_{i,\ell} - \widetilde{D}_{i,\ell}$.

Roadmap

- Section 6.12.1 proves the stability at forward when the perturbation matrix W' has small spectral norm. It gives bounds on $\|g'_{i,\ell}\|_2$, $\|h'_{i,\ell}\|_2$, $\|D'_{i,\ell}\|_0$, and $\|D'_{i,\ell}g_{i,\ell}\|_2$.
- Section 6.12.2 proves the stability of intermediate layers. It gives bound on $\|\prod_{\ell=\ell_2}^{\ell_1} D_{i,\ell}\widetilde{W}\|_2$ and $\|\prod_{\ell=\ell_2}^{\ell_1} D_{i,\ell}W\|_2$.
- Section 6.12.3 analyzes the stability for backward. It bounds the difference $\|a^\top B(\prod_{\ell=\ell_2}^{\ell_1} \widetilde{D}_{i,\ell}\widetilde{W} - \prod_{\ell=\ell_2}^{\ell_1} D_{i,\ell}\widetilde{W})\|_2$.

- Section 6.12.4 considers a special type of rank-one perturbation matrix W', and provides stability bounds on the forward and backward propagation.

As discussed in Section 6.6, the results of Section 6.12.1, 6.12.2 and 6.12.3 shall be used twice, once for the final training updates (see Section 6.16), and once for the randomness decomposition (see Section 6.14). In contrast, the results of Section 6.12.4 shall only be used once in Section 6.14.

6.12.1 Forward

The goal of this section is to prove Lemma 6.12.1,

Lemma 6.12.1 (forward stability, c.f. (6.8))**.** *Letting* $\varrho = nLd\delta^{-1}\log(m/\epsilon)$*, for any* $\tau_0 \in \left[\varrho^{-100}, \varrho^{100}\right]$*, with probability at least* $1 - e^{-\Omega(L^6\tau_0^{4/3}m^{1/3})}$ *over the randomness of* $\widetilde{W}, A, B$*, for every* $W' \in \mathbb{R}^{m\times m}$ *with* $\|W'\|_2 \le \frac{\tau_0}{\sqrt{m}}$*, for every* $i \in [n]$ *and* $\ell \in [L]$*, we have*

(a) $\|g'_{i,\ell}\|_2, \|h'_{i,\ell}\|_2 \le O(L^6\tau_0)/m^{1/2}$ *,*

(b) $\|D'_{i,\ell}\|_0 \le O(L^{10/3}\tau_0^{2/3})\cdot m^{2/3}$ *, and*

(c) $\|D'_{i,\ell}g_{i,\ell}\|_2 \le O(L^5\tau_0)/m^{1/2}$ *.*

Proof of Lemma 6.12.1. Suppose $C > 1$ is a large enough constant so that the hidden constant in Lemma 6.11.8 can be C. We inductively prove that one can write $g'_{i,\ell} = g'_{i,\ell,1} + g'_{i,\ell,2}$ where

$$\begin{aligned}
&\text{I:}\quad \|g'_{i,\ell,1}\|_2 \le \tau_1\cdot\frac{1}{m^{1/2}} \quad \text{II:}\quad \|g'_{i,\ell,2}\|_\infty \le \tau_2\cdot\frac{1}{m} \quad \text{III:}\quad \|g'_{i,\ell}\|_2 \le \tau_3\cdot\frac{1}{m^{1/2}}\\
&\text{IV:}\quad \|D'_{i,\ell}\|_0 \le \tau_4\cdot m^{2/3} \quad \text{V:}\quad \|D'_{i,\ell}g_{i,\ell}\|_2 \le \tau_5\cdot\frac{1}{m^{1/2}} \quad \text{VI:}\quad \|h'_{i,\ell}\|_2 \le (\tau_3+\tau_5)\frac{1}{m^{1/2}}\ .
\end{aligned} \tag{6.37}$$

Above, we choose parameters

$$\tau_1 = 5CL^4(L+2)\tau_0 \qquad \tau_2 = 4L\tau_5\log m \qquad \tau_3 = \tau_1+\tau_2 \qquad \tau_4 = 10(\tau_1)^{2/3} \qquad \tau_5 = 3\tau_1\ .$$

We emphasize that all these parameters are polynomial in ϱ so negligible when comparing to m.

Throughout the proof, we focus on some fixed $i \in [n]$ without loss of generality, and one can always take a union bound at the end. We drop the subscript i for notational

simplicity. In order to prove (6.37), we first assume that it holds for all $1, 2, \ldots, \ell - 1$. In particular, we assume for all $\ell' \leq \ell - 1$,

$$\|g'_{\ell',1}\|_2 \leq \tau_1 \cdot \frac{1}{m^{1/2}} \quad \text{and} \quad \|g'_{\ell',2}\|_\infty \leq \tau_2 \cdot \frac{1}{m} \ .$$

A useful observation is $g'_{\ell'}$ can be split into three terms

$$g'_{\ell'} = \underbrace{W' D_{\ell'-1} g_{\ell'-1}}_{z_{\ell'-1,1}} + \underbrace{\widetilde{W} D'_{\ell'-1} g_{\ell'-1}}_{z_{\ell'-1,2}} + \underbrace{\widetilde{W} \widetilde{D}_{\ell'-1} g'_{\ell'-1}}_{z_{\ell'-1,3}} \ . \tag{6.38}$$

After recursively applying (6.38), we can write

$$g'_\ell = g'_{\ell,1} = \sum_{\ell_a=1}^{\ell-1} \left(\widetilde{W} \widetilde{D}_{\ell-1} \cdots \widetilde{W} \widetilde{D}_{\ell-\ell_a+1} \right) z_{\ell-\ell_a,1} + \left(\widetilde{W} \widetilde{D}_{\ell-1} \cdots \widetilde{W} \widetilde{D}_{\ell-\ell_a+1} \right) z_{\ell-\ell_a,2} \ . \tag{6.39}$$

Applying Claim 6.12.2, with probability at least $1 - e^{-\Omega(\tau_1^{4/3} m^{1/3})}$, we have for all $\ell' \leq \ell - 1$,

$$\|z_{\ell',1}\|_2 \leq \frac{\tau_0}{\sqrt{m}} \left(4\ell' + 8 + \frac{\tau_1 + \tau_2}{\sqrt{m}} \right) \tag{6.40}$$

Applying Claim 6.12.5, we have with probability at least $1 - e^{-\Omega(\tau_1^{4/3} m^{1/3})}$, one can write

$$\left(\widetilde{W} \widetilde{D}_{\ell-1} \cdots \widetilde{W} \widetilde{D}_{\ell-\ell_a+1} \right) z_{\ell-\ell_a,2} = z_{\ell-\ell_a,2^\sharp} + z_{\ell-\ell_a,2^\flat}$$

where

$$\|z_{\ell-\ell_a,2^\sharp}\|_2 \leq \frac{3\tau_5 \sqrt{\tau_4} \log^2 m}{m^{2/3}}, \quad \|z_{\ell-\ell_a,2^\flat}\|_\infty \leq \frac{4\tau_5 \log m}{m} \ . \tag{6.41}$$

As a result, we can define $g'_\ell = g'_{\ell,1} + g'_{\ell,2}$ for

$$g'_{\ell,1} = \sum_{\ell_a=1}^{\ell-1} \left(\widetilde{W} \widetilde{D}_{\ell-1} \cdots \widetilde{W} \widetilde{D}_{\ell-\ell_a+1} \right) z_{\ell-\ell_a,1} + z_{\ell-\ell_a,2^\sharp} \quad \text{and} \quad g'_{\ell,2} = \sum_{\ell_a=1}^{\ell-1} z_{\ell-\ell_a,2^\flat} \ .$$

We first bound $\|g'_{\ell,1}\|_2$,

$$\begin{aligned}\|g'_{\ell,1}\|_2 &\le \sum_{\ell_a=1}^{\ell-1} \|\widetilde{W}\widetilde{D}_{i,\ell-1}\cdots\widetilde{W}\widetilde{D}_{i,\ell-\ell_a+1}\|_2 \cdot \|z_{\ell-\ell_a,1}\|_2 + \|z_{\ell-\ell_a,2^\sharp}\|_2 \\ &\overset{①}{\le} \sum_{\ell_a=1}^{\ell} (CL^3\|z_{\ell-\ell_a,1}\|_2 + \|z_{\ell-\ell_a,2^\sharp}\|_2) \\ &\overset{②}{\le} CL^4\frac{\tau_0}{\sqrt{m}}\left(4L+8+\frac{\tau_1+\tau_2}{\sqrt{m}}\right) + L\frac{3\tau_5\sqrt{\tau_4}\log^2 m}{m^{2/3}} \\ &\le 5CL^4\cdot\frac{\tau_0(L+2)}{\sqrt{m}} \overset{③}{\le} \tau_1\frac{1}{\sqrt{m}} \ .\end{aligned}$$

Above, inequality ① follows from Lemma 6.11.8, inequality ② follows from (6.40) and (6.41), and ③ follows from our choice of $\tau_1 = 5CL^4(L+2)\tau_0$. We next bound $\|g'_{\ell,2}\|_\infty$,

$$\|g'_{\ell,2}\|_\infty \le \sum_{\ell_a=1}^{\ell-1} \|z_{\ell-\ell_a,2^\flat}\|_\infty \overset{①}{\le} L\cdot\frac{4\tau_5\log m}{m} \overset{②}{\le} \tau_2\frac{1}{m}$$

where inequality ① is due to (6.41), and ② follows from our choice of $\tau_2 = 4L\tau_5\log m$. Thus, we have showed I and II of (6.37):

$$\|g'_{\ell,1}\|_2 \le \tau_1\cdot\frac{1}{m^{1/2}} \quad \text{and} \quad \|g'_{\ell,2}\|_\infty \le \tau_2\cdot\frac{1}{m} \ .$$

They together further imply

$$\|g'_\ell\|_2 \le (\tau_1+\tau_2)\frac{1}{m^{1/2}} = \tau_3\frac{1}{m^{1/2}}$$

so III of (6.37) holds. IV and V of (6.37) are implied by Claim 6.12.3, and VI is implied because

$$\|h'_\ell\|_2 = \|\phi(g_\ell)-\phi(\widetilde{g}_\ell)\|_2 \le \|g_\ell-\widetilde{g}_\ell\|_2 \le \|g'_\ell\|_2 \ . \qquad \square$$

6.12.1.1 Tools

Claim 6.12.2. *Suppose* $g_{\ell-1} = \widetilde{g}_{\ell-1} + g'_{\ell-1} = \widetilde{g}_{\ell-1} + g'_{\ell-1,1} + g'_{\ell-1,2}$ *where*

$$\|g'_{\ell-1,1}\|_2 \le \frac{\tau_1}{\sqrt{m}} \quad \text{and} \quad \|g'_{\ell-1,2}\|_\infty \le \frac{\tau_2}{m} \ .$$

Then, we have with probability at least $1 - e^{-\Omega(m/L^2)}$

$$\|W' D_{\ell-1} g_{\ell-1}\|_2 \le \frac{\tau_0}{\sqrt{m}} \left(4\ell + 8 + \frac{\tau_1 + \tau_2}{\sqrt{m}} \right).$$

Proof of Claim 6.12.2. Using triangle inequality, we can calculate

$$\|W' D_{\ell-1} g_{\ell-1}\|_2 \le \|W'\|_2 \cdot \|D_{\ell-1}\|_2 \cdot (\|\widetilde{g}_{\ell-1}\|_2 + \|g'_{\ell-1,1}\|_2 + \|g'_{\ell-1,2}\|_2)$$

Using Lemma 6.11.1, we have $\|\widetilde{g}_{\ell-1}\| \le 4\ell + 8$. Using elementary calculation, we have

$$\|g'_{\ell-1,1}\|_2 + \|g'_{\ell-1,2}\|_2 \le \frac{\tau_1}{\sqrt{m}} + \sqrt{m}\frac{\tau_2}{m} \le \frac{\tau_1 + \tau_2}{\sqrt{m}}$$

Together we finish the proof. □

Claim 6.12.3. *With probability at least* $1 - e^{-\Omega(\tau_1^{4/3} m^{1/3})}$ *the following holds. Whenever*

$$\|g'_{\ell-1,1}\|_2 \le \tau_1 \cdot \frac{1}{m^{1/2}}, \quad \|g'_{\ell-1,2}\|_\infty \le \tau_2 \cdot \frac{1}{m} \ ,$$

then letting $\tau_4 = 10(\tau_1)^{2/3}$ *and* $\tau_5 = 3\tau_1$*, we have*

$$\|D'_{\ell-1} g_{\ell-1}\|_2 \le \tau_5 \cdot \frac{1}{m^{1/2}}, \quad \|D'_{\ell-1}\|_0 \le \tau_4 \cdot m^{2/3}$$

Proof of Claim 6.12.3. We choose parameters $\xi = \frac{(\tau_1)^{2/3}}{10^{1/3} m^{5/6}}$ and $\alpha = 10\xi\sqrt{m}$ in the proof. We have $\|g'_{\ell-1,2}\|_\infty \le \xi$.

First of all, using similar (but simpler) proof as Lemma 6.11.4, one can show with probability at least $1 - \exp(-\Omega(\alpha^2 m))$, the vector $\widetilde{g}_{\ell-1}$ is $(\alpha, \frac{1}{5\sqrt{m}})$-good (recall Definition 6.10.1).[18] This implies that $\widetilde{g}_{\ell-1}$ has at most $\alpha m = 10\xi m^{3/2}$ coordinates j satisfying $|(\widetilde{g}_{\ell-1})_j| \le \frac{\alpha}{5\sqrt{m}} = 2\xi$.

For each $j \in [m]$, if it satisfies $(D'_{\ell-1})_{j,j} \neq 0$, then the sign of $\widetilde{g}_{\ell-1}$ and $\widetilde{g}_{\ell-1} + g'_{\ell-1,1} + g'_{\ell-1,2}$ must differ on coordinate j. As a result:

$$|(g'_{\ell-1,1} + g'_{\ell-1,2})_j| > |(\widetilde{g}_{\ell-1})_j| \ .$$

Define $y = D'_{\ell-1} g_{\ell-1}$. There are two possibilities for such j with $(D'_{\ell-1})_{j,j} \neq 0$.

- Case 1: $|(\widetilde{g}_{\ell-1})_j| \le 2\xi$. Let such coordinates be $S_1 \subset [m]$, and we have $|S_1| \le 10\xi m^{3/2}$ using the above argument.

  Next, for each such $j \in S_1$, we must have $|y_j| = |(\widetilde{g}_{\ell-1} + g'_{\ell-1,1} + g'_{\ell-1,2})_j| \le |(g'_{\ell-1,1} +$

[18] Indeed,

$$\widetilde{g}_{\ell-1} = \widetilde{W}\widetilde{h}_{\ell-2} + Ax_{\ell-1} = M_1 z_1 + M_2 z_2.$$

where $M_1 \in \mathbb{R}^{m \times n(\ell-2)}$, $M_3 \in \mathbb{R}^{m \times d}$ and $z_1 \in \mathbb{R}^{n(\ell-1)}$, $z_3 \in \mathbb{R}^d$ are defined as

$$\begin{aligned} M_1 &= \widetilde{W} U_{\ell-2} & M_2 &= A \\ z_1 &= U_{\ell-2}^\top \widetilde{h}_{\ell-2} & z_2 &= x_{\ell-1} \ . \end{aligned} \tag{6.42}$$

The entries of M_1 and M_2 are i.i.d. from $\mathcal{N}(0, \frac{2}{m})$ (recall Footnote 13). Suppose z_1 and z_2 are fixed (instead of depending on the randomness of $\widetilde{W}$ and A) and satisfies $\frac{1}{\sqrt{2}} \le \|z_1\| \le 2L+6$. We can apply Corollary 6.10.15 to obtain the following statement: with probability at least $1 - \exp(-\Omega(\alpha^2 m))$, $\widetilde{g}_{\ell-1}$ is $(\alpha, \sigma/4)$-good where $\sigma^2 = \frac{2}{m}\|z_1\|_2^2 + \frac{2}{m}\|z_3\|_2^2 \ge \frac{1}{m}$. In other words, w is $(\alpha, \frac{1}{4\sqrt{m}})$-good. Applying standard ϵ-net argument, we have with probability at least $1 - \exp(-\Omega(\alpha^2 m))$, for all vectors $z_1 \in \mathbb{R}^{n(\ell-2)}$ satisfying $\frac{1}{\sqrt{2}} \le \|z_1\| \le 2L+6$, it satisfies $\widetilde{g}_{\ell-1}$ is $(\alpha, \frac{1}{5\sqrt{m}})$-good. This allows us to plug in the random choice of z_1 in (6.42), to conclude that $\widetilde{g}_{\ell-1}$ is $(\alpha, \frac{1}{5\sqrt{m}})$-good.

$g'_{\ell-1,2})_j| \le |(g'_{\ell-1,1})_j| + \xi$ so we can calculate the ℓ_2 norm of y on S_1:

$$\sum_{i\in S_1} y_j^2 \le 2\|g'_{\ell-1,1}\|^2 + 2\xi^2|S_1| \le \frac{2\tau_1^2}{m} + 20\xi^3 m^{3/2} = \frac{4\tau_1^2}{m} \ .$$

- Case 2: $|(\widetilde{g}_{\ell-1})_j| > 2\xi$. Let such coordinates be $S_2 \subset [m] \setminus S_1$. In this case we must have $|(g'_{\ell-1,1})_j| \ge |(\widetilde{g}_{\ell-1})_j| - |(g'_{\ell-1,2})_j| > 2\xi - \xi = \xi$. Therefore, $|S_2| \le \frac{\|g'_{\ell-1,1}\|_2^2}{\xi^2} \le \frac{\tau_1^2}{m\xi^2}$.

  Next, for each $j \in S_2$, we must have

$$|y_j| = |(\widetilde{g}_{\ell-1} + g'_{\ell-1,1} + g'_{\ell-1,2})_j| \le |(g'_{\ell-1,1} + g'_{\ell-1,2})_j| \le |(g'_{\ell-1,1})_j| + \xi/2 \le \frac{5}{4}|(g'_{\ell-1,1})_j| \ .$$

  and therefore

$$\sum_{j\in S_2} y_j^2 \le 2\sum_{j\in S_2} (g'_{\ell-1,1})_j^2 \le \frac{2\tau_1^2}{m} \ .$$

  In sum, we conclude that

$$\|D'_{\ell-1}\|_0 \le |S_1| + |S_2| \le 10\xi m^{3/2} + \frac{\tau_1^2}{m\xi^2} < 10(\tau_1)^{2/3} m^{2/3} = \tau_4 \cdot m^{2/3}$$

and

$$\|y\|_2 \le \frac{\sqrt{4\tau_1^2 + 2\tau_1^2}}{\sqrt{m}} \le \frac{3\tau_1}{\sqrt{m}} = \tau_5 \cdot \frac{1}{m^{1/2}} \ . \qquad \square$$

Claim 6.12.4. *With probability at least $1 - e^{-\Omega(\tau_4 m^{2/3}\log^2 m)}$, for all $L \ge \ell + 1 \ge b \ge 1$, for all*

$$x \in \mathbb{R}^m \quad \textit{with} \quad \|x\|_2 \le \frac{\tau_5}{\sqrt{m}} \quad \textit{and} \quad \|x\|_0 \le \tau_4 \cdot m^{2/3}$$

we have that the vector $y = \widetilde{W}\widetilde{D}_\ell\widetilde{W}\cdots\widetilde{D}_b\widetilde{W}x$ can be written as

$$y = y_1 + y_2 \quad \textit{where} \quad \|y_1\|_2 \le \frac{3\tau_5\sqrt{\tau_4}\log^2 m}{m^{2/3}} \quad \textit{and} \quad \|y_2\|_\infty \le \frac{4\tau_5 \log m}{m}$$

Proof of Claim 6.12.4. Let $s = \tau_4 \cdot m^{2/3}$ for notational simplicity. Let $z_{b-1} = x$ and assume for now that x is a fixed vector. Letting $z_\ell = \widetilde{D}_\ell \widetilde{W} \cdots \widetilde{D}_b z_{b-1}$, we have according to Claim 6.11.9, with probability at least $1 - \exp(-\Omega(m/L^2))$,

$$\|z_\ell\|_2 \le (1 + 1/L)^{\ell - b - 1} \|z_{b-1}\|_2 \le 3\|z_{b-1}\|_2.$$

Similar to the proof of Lemma 6.11.8, we let U denote the following column orthonormal matrix using Gram-Schmidt:

$$U \stackrel{\text{def}}{=} \mathsf{GS}\left(h_{1,1}, \ldots, h_{n,1}, h_{1,2}, \ldots, h_{n,2}, \ldots, h_{1,\ell-1}, \ldots, h_{n,\ell-1}, z_{b-1}, \cdots z_\ell\right) \ ,$$

and we have

$$\widetilde{W}\widetilde{D}_\ell\widetilde{W} \cdots \widetilde{D}_b\widetilde{W}x = \widetilde{W}UU^\top z_{\ell_2} \ .$$

Observe the entries of $\widetilde{W}U \in \mathbb{R}^{m \times n(\ell-1)+(\ell-b+2)}$ are i.i.d. drawn from $\mathcal{N}(0, \frac{2}{m})$ (following a similar argument as Footnote 17). Therefore, according to Lemma 6.10.16, we have can write $y = \widetilde{W}\widetilde{D}_\ell\widetilde{W} \cdots \widetilde{D}_b\widetilde{W}x$ as $y = y_1 + y_2$ with

$$\|y_1\| \le \frac{\sqrt{s}\log^2 m}{\sqrt{m}} \cdot \|U^\top z_{\ell_2}\| \quad \text{and} \quad \|y_2\|_\infty \le \frac{\log m}{\sqrt{m}} \cdot \|U^\top z_{\ell_2}\| \ .$$

Plugging in $\|U^\top z_\ell\|_2 \le \|z_\ell\|_2 \le 3\|z_{b-1}\|_2 = 3\|x\|_2 \le \frac{3\tau_5}{\sqrt{m}}$, we have

$$\|y_1\| \le \frac{3\tau_5\sqrt{s}\log^2 m}{m} \quad \text{and} \quad \|y_2\|_\infty \le \frac{3\tau_5 \log m}{m} \ .$$

Finally, taking ϵ-net over all s-sparse vectors x, we have the desired result. □

Combining Claim 6.12.3 and Claim 6.12.4, we have

Claim 6.12.5. *With probability at least* $1 - e^{-\Omega(\tau_1^{4/3} m^{1/3})}$*, whenever*

$$\|g'_{\ell-1,1}\|_2 \le \frac{\tau_1}{\sqrt{m}}, \qquad \|g'_{\ell-1,2}\|_\infty \le \frac{\tau_2}{m} \ ,$$

we have the vector $y = \widetilde{W}\widetilde{D}_\ell\widetilde{W} \cdots \widetilde{D}_b\widetilde{W}D'_{\ell-1}g_{\ell-1}$ *can be written as*

$$y = y_1 + y_2 \quad \textit{where} \quad \|y_1\|_2 \le \frac{3\tau_5\sqrt{\tau_4}\log^2 m}{m^{2/3}} \quad \textit{and} \quad \|y_2\|_\infty \le \frac{4\tau_5 \log m}{m}$$

6.12.2 Intermediate Layers

The goal of this subsection is to prove Lemma 6.12.6.

Lemma 6.12.6 (intermediate stability, c.f. (6.9))**.** *Letting $\varrho = nLd\log m$, for any $\tau_0 \in \left[\varrho^{-100}, \varrho^{100}\right]$, with probability at least $1 - e^{-\Omega(L^6\tau_0^{4/3}m^{1/3})}$ over the randomness of $\widetilde{W}, A, B$, for every $W' \in \mathbb{R}^{m\times m}$ with $\|W'\|_2 \le \frac{\tau_0}{\sqrt{m}}$, for every $i \in [n]$, for every $L \ge \ell_2 \ge \ell_1 \ge 1$, the following holds*

- $\left\|\prod_{\ell=\ell_2}^{\ell_1}(\widetilde{D}_{i,\ell} + D'_{i,\ell})\widetilde{W}\right\|_2 \le O(L^7)$.
- $\left\|\prod_{\ell=\ell_2}^{\ell_1}(\widetilde{D}_{i,\ell} + D'_{i,\ell})(\widetilde{W} + W')\right\|_2 \le O(L^7)$.

We show Claim 6.12.7 and then use it to prove Corollary 6.12.7.

Claim 6.12.7. *Let $s \in [m^{-1/4}, m^{1/8}]$ be any fixed real. With probability at least $1 - e^{-\Omega(s^2m^{2/3}\log^2 m)}$, it satisfies that for every $i \in [n]$, for every $L \ge \ell_2 \ge \ell_1 \ge 1$, if $D'_{i,\ell} \in \mathbb{R}^{m\times m}$ is an arbitrary diagonal matrix with entries in $\{-1, 0, 1\}$ of sparsity $\|D'_{i,\ell}\|_0 \le s^2m^{2/3}$ (for each $\ell = \ell_1, \ldots, \ell_2$), then*

$$\left\|\prod_{\ell=\ell_2}^{\ell_1}(\widetilde{D}_{i,\ell} + D'_{i,\ell})\widetilde{W}\right\|_2 \le O(L^7) \ .$$

Proof of Claim 6.12.7. We define set $\mathcal{C}$ as follows

$$\mathcal{C} = \left\{ \prod_{\ell=\ell_2}^{\ell_1}(D'_{i,\ell})^{c_\ell}(\widetilde{D}_{i,\ell})^{1-c_\ell}\widetilde{W} \;\middle|\; c_\ell \in \{0,1\}, \forall \ell \in [\ell_1, \ell_2] \right\}.$$

For ℓ, we define set $\mathcal{C}_\ell$ as follows

$$\mathcal{C}_\ell = \left\{ C \in \mathcal{C} \;\middle|\; D' \text{ appears } \ell \text{ times in } C \right\}$$

From Lemma 6.11.8, we can bound the $\ell = 0$ term

$$\left\| \sum_{C \in \mathcal{C}_\ell} C \right\|_2 \leq O(L^3).$$

For each $C \in \mathcal{C}_\ell$ with $\ell > 0$, we have

$$\|C\|_2 \leq O(L^3) \cdot \left(\frac{s \log m}{m^{1/6}} \right)^{\ell - 1} \cdot O(L^3)$$

where we apply Lemma 6.11.8 twice(one on the left, one on the right) and apply Corollary 6.11.12 $\ell - 1$ times. The probability of the above event is at least $1 - e^{\Omega(s^2 \cdot m^{2/3} \log^2 m)}$. Therefore, for each $\ell \in [\ell_2 - \ell_1]$, we can bound

$$\left\| \sum_{C \in \mathcal{C}_\ell} C \right\|_2 \leq O(L^6) \binom{\ell_2 - \ell_1}{\ell} \left(\frac{s \log m}{m^{1/6}} \right)^{\ell - 1}$$

which is at most $O(L^7)$ when $\ell = 1$ and $o(L^7)$ for $\ell > 1$ by our parameter choices. Putting it altogether,

$$\text{LHS} = \left\| \sum_{\ell=0}^{\ell_2 - \ell_1} \sum_{C \in \mathcal{C}_\ell} C \right\|_2 \leq \sum_{\ell=0}^{\ell_2 - \ell_1} \left\| \sum_{C \in \mathcal{C}_\ell} C \right\|_2 \leq O(L^3 + L^7) \qquad \square$$

Proof of Lemma 6.12.6. Applying Lemma 6.12.1c, we know with probability $\geq 1 - e^{-\Omega(L^6 \tau_0^{4/3} m^{1/3})}$ it satisfies $\|D'_{i,\ell}\|_0 \leq s^2 m^{2/3}$ for $s^2 = O(L^{10/3} \tau_0^{2/3})$. Therefore, applying Claim 6.12.7 we have

$$\left\| \prod_{\ell=\ell_2}^{\ell_1} (\widetilde{D}_{i,\ell} + D'_{i,\ell}) \widetilde{W} \right\|_2 \leq O(L^7) \ .$$

On the other hand, since $\|W'\| \leq \frac{\tau_0}{\sqrt{m}}$, we also have

$$\left\| \prod_{\ell=\ell_2}^{\ell_1} (\widetilde{D}_{i,\ell} + D'_{i,\ell}) (\widetilde{W} + W') \right\|_2 \leq O(L^7) \ .$$

by expanding out the $2^{\ell_2 - \ell_1 + 1}$ terms with respect to W'. $\square$

6.12.3 Backward

We state the main result in this section.

Lemma 6.12.8 (backward stability, c.f. (6.10)). *Letting $\varrho = nLd\log m$, for any $\tau_0 \in \left[\varrho^{-100}, \varrho^{100}\right]$, with probability at least $1 - e^{-\Omega(L^6\tau_0^{4/3}m^{1/3})}$ over the randomness of $\widetilde{W}, A, B$, for every $W' \in \mathbb{R}^{m\times m}$ with $\|W'\|_2 \le \frac{\tau_0}{\sqrt{m}}$, for every $1 \le \ell_1 \le \ell_2 \le L$, for every $i \in [n]$, the followings hold*

(a) $\left\|a^\top B\prod_{\ell=\ell_2}^{\ell_1}\widetilde{D}_{i,\ell}\widetilde{W} - a^\top B\prod_{\ell=\ell_2}^{\ell_1}D_{i,\ell}\widetilde{W}\right\|_2 \le O\big(\tau_0^{1/3}L^6\log m\cdot m^{1/3}\big)\cdot\|a\|_2.$

(b) $\left\|a^\top B\prod_{\ell=\ell_2}^{\ell_1}D_{i,\ell}\widetilde{W} - a^\top B\prod_{\ell=\ell_2}^{\ell_1}D_{i,\ell}W\right\|_2 \le O(\tau_0 L^{15})\cdot\|a\|_2.$

(c) $\left\|a^\top B\prod_{\ell=\ell_2}^{\ell_1}\widetilde{D}_{i,\ell}\widetilde{W} - a^\top B\prod_{\ell=\ell_2}^{\ell_1}\widetilde{D}_{i,\ell}W\right\|_2 \le O(\tau_0 L^{7})\cdot\|a\|_2.$

(d) $\left\|a^\top B\prod_{\ell=\ell_2}^{\ell_1}\widetilde{D}_{i,\ell}W - a^\top B\prod_{\ell=\ell_2}^{\ell_1}D_{i,\ell}W\right\|_2 \le O\big(\tau_0^{1/3}L^6\log m\cdot m^{1/3}\big)\cdot\|a\|_2.$

We first use Lemma 6.12.1 to derive that, with probability $\ge 1 - e^{-\Omega(L^6\tau_0^{4/3}m^{1/3})}$, $\|D'_{i,\ell}\|_0 \le s^2m^{2/3}$, for parameter $s = O(L^{5/3}\tau_0^{1/3})$. We prove the five statements separately.

Proof of Lemma 6.12.8a. Without loss of generality we assume $\|a\| = 1$. We define set $\mathcal{C}$ to be

$$\mathcal{C} = \left\{\prod_{\ell=\ell_2}^{\ell_1}(D'_{i,\ell})^{c_\ell}(\widetilde{D}_{i,\ell})^{1-c_\ell}\widetilde{W} \;\middle|\; c_{\ell_1},\ldots,c_{\ell_2}\in\{0,1\}\right\}.$$

For each $\ell \in [\ell_2 - \ell_1]$, we define set $\mathcal{C}_\ell$ to be

$$\mathcal{C}_\ell = \{C \in \mathcal{C} \mid D' \text{ appears } \ell \text{ times in } C\}.$$

Ignoring subscripts for the ease of presentation, by Corollary 6.11.15, we know

$$\|a^\top B\widetilde{D}\widetilde{W}\cdots\widetilde{D}\widetilde{W}D'\|_2 \le (s\log m)m^{1/3} \ .$$

By Corollary 6.11.12, we know

$$\left\|D'\widetilde{W}\widetilde{D}\cdots\widetilde{D}\widetilde{W}D'\right\|_2 \le (s\log m)m^{-1/6} \ .$$

Thus, for each ℓ and $C \in \mathcal{C}_\ell$,

$$\begin{aligned}\|a^\top BC\|_2 &\le \|a^\top B\widetilde{D}\widetilde{W}\cdots\widetilde{D}\widetilde{W}D'\|_2 \cdot \left\|D'\widetilde{W}\widetilde{D}\cdots\widetilde{D}\widetilde{W}D'\right\|_2^{\ell-1} \cdot \left\|D'\widetilde{W}\widetilde{D}\cdots\widetilde{D}\widetilde{W}\right\|_2 \\ &\le (s\cdot m^{1/3}\log m)\times(s\cdot m^{-1/6}\log m)^{\ell-1}\times O(L^3) \ .\end{aligned}$$

Finally, the LHS of the Lemma 6.12.8a becomes

$$\begin{aligned}\text{LHS} &= \left\|\sum_{\ell=1}^{\ell_2-\ell_1}\sum_{C\in\mathcal{C}_\ell} a^\top BC\right\|_2 \le \sum_{\ell=1}^{\ell_2-\ell_1}\sum_{C\in\mathcal{C}_\ell}\|a^\top BC\|_2 \\ &\le \sum_{\ell=1}^{\ell_2-\ell_1}\binom{\ell_2-\ell_1}{\ell}(s\cdot m^{1/3}\log m)\times(s\cdot m^{-1/6}\log m)^{\ell-1}\times O(L^3) \le O\big(L^4\cdot s\log m\cdot m^{1/3}\big) \ .\end{aligned}$$

□

Proof of Lemma 6.12.8b. Again we assume $\|a\| = 1$ without loss of generality. We define set $\mathcal{C}$ to be

$$\mathcal{C} = \left\{\prod_{\ell=\ell_2}^{\ell_1} D_{i,\ell}(W')^{c_\ell}\widetilde{W}^{1-c_\ell} \;\middle|\; c_{\ell_1},\ldots,c_{\ell_2}\in\{0,1\}\right\}$$

For each $\ell \in [\ell_2-\ell_1]$, we define set $\mathcal{C}_\ell$

$$\mathcal{C}_\ell = \{C\in\mathcal{C} \mid W' \text{ appears } \ell \text{ times in } C\} \ .$$

Ignoring subscripts for the ease of presentation, we have for each $C \in \mathcal{C}_\ell$,

$$\|a^\top BC\|_2 \le \|a^\top B\|_2 \cdot \|\widetilde{W}D \cdots \widetilde{W}D\|_2 \cdot \|W'\|_2 \cdot \left(\|D\widetilde{W} \cdots \widetilde{W}D\|_2 \|W'\|_2\right)^{\ell-1} \cdot \|D\widetilde{W} \cdots D\widetilde{W}\|_2 \tag{6.43}$$

$$\le O(\sqrt{m}L^7) \cdot \left(\frac{\tau_0}{\sqrt{m}}\right) \cdot \left(\frac{O(\tau_0 L^7)}{\sqrt{m}}\right)^{\ell-1} \cdot O(L^7) \ . \tag{6.44}$$

Above, we have used $\|W'\|_2 \le \frac{\tau_0}{\sqrt{m}}$, $\|\widetilde{W}D \cdots \widetilde{W}D\|_2 \le O(L^7)$ from Lemma 6.12.6, and $\|B\|_2 \le O(\sqrt{m})$ with high probability. Finally, by triangle inequality, the LHS of Lemma 6.12.8b becomes

$$\begin{aligned}
\text{LHS} &= \left\| \sum_{\ell=1}^{\ell_2-\ell_1} \sum_{C \in \mathcal{C}_\ell} a^\top BC \right\|_2 \le \sum_{\ell=1}^{\ell_2-\ell_1} \sum_{C \in \mathcal{C}_\ell} \left\| a^\top BC \right\|_2 \\
&\le \sum_{\ell=1}^{\ell_2-\ell_1} \binom{\ell_2-\ell_1}{\ell} O(\sqrt{m}L^7) \cdot \left(\frac{\tau_0}{\sqrt{m}}\right) \cdot \left(\frac{O(\tau_0 L^7)}{\sqrt{m}}\right)^{\ell-1} \cdot O(L^7) \\
&\le O(\tau_0 L^{15})
\end{aligned}$$

□

Proof of Lemma 6.12.8c. It is similar to the proof of Lemma 6.12.8b. □

Proof of Lemma 6.12.8d. It is similar to the proof of Lemma 6.12.8a. □

6.12.4 Special Rank-One Perturbation

We prove two lemmas regarding the special rank-one perturbation with respect to a coordinate $k \in [m]$. The first one talks about forward propagation.

Lemma 6.12.9 (c.f. (6.11))**.** *Let $\rho = nLd\log m$, $\varrho = nLd\delta^{-1}\log(m/\epsilon)$, $\tau_0 \in [\varrho^{-100}, \varrho^{50}]$, $N \in [1, \varrho^{100}]$. If $\widetilde{W}, A$ are at random initialization, then with probability at least $1 - e^{-\Omega(\rho^2)}$, for any rank-one perturbation $W' = yz^\top$ with $\|z\| = 1$, $\|y\|_0 = N$, $\|y\|_\infty \le \frac{\tau_0}{\sqrt{m}}$, it satisfies*

$$\forall i \in [n], \forall \ell \in [L], \forall k \in [m]: \quad |((\widetilde{W} + W')h'_{i,\ell})_k| \le O\Big(\frac{\rho^8 N^{2/3}\tau_0^{5/6}}{m^{2/3}}\Big) \ .$$

Proof. Without loss of generality we only prove the statement for fixed i, ℓ, k because one can take union bound at the end. We can rewrite $Wh'_{i,\ell}$ as follows

$$\begin{aligned}
(\widetilde{W} + W')h'_{i,\ell} &= W'h'_{i,\ell} + \widetilde{W}h'_{i,\ell} \\
&= W'h'_{i,\ell} + \widetilde{W}(h_{i,\ell} - \widetilde{h}_{i,\ell}) \\
&= W'h'_{i,\ell} + \widetilde{W}((\widetilde{D}_{i,\ell} + D'_{i,\ell})g_{i,\ell} - \widetilde{D}_{i,\ell}\widetilde{g}_{i,\ell}) \\
&= W'h'_{i,\ell} + \widetilde{W}\widetilde{D}_{i,\ell}g'_{i,\ell} + \widetilde{W}D'_{i,\ell}g_{i,\ell} \\
&= W'h'_{i,\ell} + \widetilde{W}\widetilde{D}_{i,\ell}((\widetilde{W} + W')h_{i,\ell-1} - \widetilde{W}\widetilde{h}_{i,\ell-1}) + \widetilde{W}D'_{i,\ell}g_{i,\ell} \\
&= W'h'_{i,\ell} + \widetilde{W}\widetilde{D}_{i,\ell}(\widetilde{W}h'_{i,\ell-1} + W'h_{i,\ell-1}) + \widetilde{W}D'_{i,\ell}g_{i,\ell} \\
&= W'h'_{i,\ell} + \widetilde{W}\widetilde{D}_{i,\ell}\underbrace{\widetilde{W}h'_{i,\ell-1}}_{\text{recurse}} + \widetilde{W}\widetilde{D}_{i,\ell}W'h_{i,\ell-1} + \widetilde{W}D'_{i,\ell}g_{i,\ell}
\end{aligned}$$

After recursively calculating as above, using $h'_{i,0} = 0$, and applying triangle inequality, we have

$$|((\widetilde{W} + W')h'_{i,\ell})_k| \le |(W'h'_{i,\ell})_k| + \sum_{a=0}^{\ell} |(\widetilde{W}\widetilde{D}_{i,\ell}\cdots\widetilde{W}\widetilde{D}_{i,a}W'h_{i,a})_k| + \sum_{a=0}^{\ell} |(\widetilde{W}\widetilde{D}_{i,\ell}\cdots\widetilde{W}\widetilde{D}_{i,a+1}\widetilde{W}D'_{i,a}g_{i,a})_k| \tag{6.45}$$

We bound the three types of terms on the RHS of (6.45) as follows.

- First, we can bound

$$|(W'h'_{i,\ell})_k| = |e_k^\top yz^\top h'_{i,\ell}| = |e_k^\top y| \cdot |z^\top h'_{i,\ell}| \le \|y\|_\infty \cdot \|h'_{i,\ell}\|_2 \le \frac{\tau_0}{\sqrt{m}} \cdot (\frac{O(L^6\tau_0\sqrt{N})}{\sqrt{m}})$$

  where the last step follows by $\|y\|_\infty \le \frac{\tau_0}{\sqrt{m}}$, $\|W'\|_2 \le \frac{\sqrt{N}\tau_0}{\sqrt{m}}$ and Lemma 6.12.1a.

- Second, we can bound

$$\begin{aligned}
|(\widetilde{W}\widetilde{D}_{i,\ell}\cdots\widetilde{W}\widetilde{D}_{i,a}W'h_{i,a})_k| &= |e_k^\top\widetilde{W}\widetilde{D}_{i,\ell}\cdots\widetilde{W}\widetilde{D}_{i,a}yz^\top h_{i,a}| \\
&= |e_k^\top\widetilde{W}\widetilde{D}_{i,\ell}\cdots\widetilde{W}\widetilde{D}_{i,a}y| \cdot |z^\top h_{i,a}| \\
&\overset{①}{\le} |e_k^\top\widetilde{W}\widetilde{D}_{i,\ell}\cdots\widetilde{W}\widetilde{D}_{i,a}y| \cdot \|h_{i,a}\|_2 \\
&\overset{②}{\le} |e_k^\top\widetilde{W}\widetilde{D}_{i,\ell}\cdots\widetilde{W}\widetilde{D}_{i,a}y| \cdot O(L) \\
&\le N \cdot \|y\|_\infty \max_j |e_k^\top\widetilde{W}\widetilde{D}_{i,\ell}\cdots\widetilde{W}\widetilde{D}_{i,a}e_j| \cdot O(L) \\
&\overset{③}{\le} N \cdot \|y\|_\infty \cdot \frac{\rho}{\sqrt{m}} \cdot O(L) \\
&\overset{④}{\le} N \cdot (\tau_0\frac{1}{\sqrt{m}}) \cdot \frac{\rho}{\sqrt{m}} \cdot O(L) \le O(\frac{N\tau_0\rho L}{m}).
\end{aligned}$$

  where ① follows by $\|z\|_2 \le 1$, ② follows by Lemma 6.11.1, ③ follows by Corollary 6.11.13, and ④ follows by $\|y\|_\infty \le \tau_0\frac{1}{\sqrt{m}}$.

- Third, we can bound,

$$\begin{aligned}
|(\widetilde{W}\widetilde{D}_{i,\ell}\cdots\widetilde{W}\widetilde{D}_{i,a+1}\widetilde{W}D'_{i,a}g_{i,a})_k| &\le \|e_k\widetilde{W}\widetilde{D}_{i,\ell}\cdots\widetilde{W}\widetilde{D}_{i,a+1}\widetilde{W}D'_{i,a}\|_2 \cdot \|D'_{i,a}g_{i,a}\|_2 \\
&\le O\left(\frac{L^{5/3}\tau_0^{1/3}N^{1/6}\log m}{m^{1/6}}\right) \cdot O\left(\frac{L^5\tau_0^{1/2}\sqrt{N}}{\sqrt{m}}\right)
\end{aligned}$$

  where the last step follows by Corollary 6.11.12 (which relies on Lemma 6.12.1b to give $s = O(L^{5/3}\tau_0^{1/3}N^{1/6})$) together with Lemma 6.12.1c.

Putting the three bounds into (6.45) (where the term one is the dominating term), we have

$$|((\widetilde{W}+W')h'_{i,\ell})_k| \le O\left(\frac{\rho^8 N^{2/3}\tau_0^{5/6}}{m^{2/3}}\right) \ . \qquad \square$$

The next one talks about backward propagation.

Lemma 6.12.10 (c.f. (6.12))**.** *Let $\rho = nLd\log m$, $\varrho = nLd\delta^{-1}\log(m/\epsilon)$, $\tau_0 \in [\varrho^{-100}, \varrho^{50}]$, $N \in [1, \varrho^{100}]$. If $\widetilde{W}, A, B$ are at random initialization, and given some perturbation $W' = yz^\top$ with $\|z\| = 1$, $\|y\|_0 = N$, $\|y\|_\infty \le \frac{\tau_0}{\sqrt{m}}$ where W' can only depend on the randomness of $\widetilde{W}$ and A (but not on B), then with probability at least $1-e^{-\Omega(\rho^2)}$, for all $i \in [n]$, all $1 \le \ell_1 \le \ell_2 \le L$, all $k \in [m]$:*

(a) $\left|a^\top B\left(\prod_{\ell=\ell_2}^{\ell_1} D_{i,\ell}\widetilde{W}\right)e_k - a^\top B\left(\prod_{\ell=\ell_2}^{\ell_1} \widetilde{D}_{i,\ell}\widetilde{W}\right)e_k\right| \le \|a\|_2 \cdot O\big(\frac{\rho^3\tau_0^{1/3}N^{1/6}}{m^{1/6}}\big)$,

(b) $\left|a^\top B\left(\prod_{\ell=\ell_2}^{\ell_1} D_{i,\ell}W\right)e_k - a^\top B\left(\prod_{\ell=\ell_2}^{\ell_1} D_{i,\ell}\widetilde{W}\right)e_k\right| \le \|a\|_2 \cdot O\big(\frac{\rho^{12}N^{5/6}\tau_0^{5/3}}{m^{1/3}}\big)$.

Proof. We prove for a fixed $i \in [n]$ and drop the subscript in i for notational simplicity. Without loss of generality we assume $\|a\| = 1$.

(a) We define set $\mathcal{C}$ to be

$$\mathcal{C} = \left\{ \prod_{\ell=\ell_2}^{\ell_1} (D'_\ell)^{c_\ell}(\widetilde{D}_\ell)^{1-c_\ell}\widetilde{W} \;\middle|\; c_\ell \in \{0,1\}, \forall \ell \in [\ell_1, \ell_2] \right\}.$$

For each $\ell \in [\ell_2 - \ell_1]$, we define set $\mathcal{C}_\ell$ to be

$$\mathcal{C}_\ell = \{C \in \mathcal{C} \mid D' \text{ appears } \ell \text{ times in } C\}.$$

Ignoring the subscripts for the ease of presentation, by Lemma 6.11.8, we know

$$\|\widetilde{D}\widetilde{W}\cdots\widetilde{D}\widetilde{W}\cdot D'\|_2 \le \|\widetilde{D}\widetilde{W}\cdots\widetilde{D}\widetilde{W}\|_2 \le O(L^3) \ .$$

By Corollary 6.11.12 (which relies on Lemma 6.12.1b to give $s = O(L^{5/3}\tau_0^{1/3}N^{1/6})$), we know

$$\left\|D'\widetilde{W}\widetilde{D}\cdots\widetilde{D}\widetilde{W}D'\right\|_2 \le O(\frac{L^{5/3}\tau_0^{1/3}N^{1/6}}{m^{1/6}}\log m) \ ,$$
$$\forall k\in[m]\colon \left\|D'\widetilde{W}\widetilde{D}\cdots\widetilde{D}\widetilde{W}e_k\right\|_2 \le O(\frac{L^{5/3}\tau_0^{1/3}N^{1/6}}{m^{1/6}}\log m) \ .$$

Thus, for each $k\in[m]$ and $C\in\mathcal{C}_\ell$, we can bound it

$$\|Ce_k\| \le L^3 \times \left(O(\frac{L^{5/3}\tau_0^{1/3}N^{1/6}}{m^{1/6}}\log m)\right)^\ell \ .$$

As a consequence, letting

$$v = \left(\prod_{\ell=\ell_2}^{\ell_1} D_{i,\ell}\widetilde{W}\right)e_k - \left(\prod_{\ell=\ell_2}^{\ell_1}\widetilde{D}_{i,\ell}\widetilde{W}\right)e_k$$

we have

$$\begin{aligned}\|v\| &= \left\|\sum_{\ell=1}^{\ell_2-\ell_1}\sum_{C\in\mathcal{C}_\ell} Ce_k\right\| \\ &\le \sum_{\ell=1}^{\ell_2-\ell_1}\sum_{C\in\mathcal{C}_\ell}\|Ce_k\| \le \sum_{\ell=1}^{\ell_2-\ell_1}\binom{L}{\ell}\cdot\left(O(\frac{L^{5/3}\tau_0^{1/3}N^{1/6}}{m^{1/6}}\log m)\right)^\ell \le O\left(\frac{\rho^3\tau_0^{1/3}N^{1/6}}{m^{1/6}}\right) \ .\end{aligned}$$

Finally, we use the randomness of B (recall that v does not depend on B), we conclude that with probability at least $1-e^{-\Omega(m)}$, it satisfies

$$\text{LHS} = \left\|a^\top Bv\right\| \le O\left(\frac{\rho^3\tau_0^{1/3}N^{1/6}}{m^{1/6}}\right) \ .$$

(b) This time, we define set $\mathcal{C}$ to be

$$\mathcal{C} = \left\{\prod_{\ell=\ell_2}^{\ell_1} D_\ell(W')^{c_\ell}\widetilde{W}^{1-c_\ell} \;\middle|\; c_\ell\in\{0,1\},\forall\ell\in[\ell_1,\ell_2]\right\}$$

For each $\ell \in [\ell_2 - \ell_1]$, we define set $\mathcal{C}_\ell$

$$\mathcal{C}_\ell = \{C \in \mathcal{C} \mid W' \text{ appears } \ell \text{ times in } C\}.$$

One can carefully derive that[19]

$$|a^\top B D\widetilde{W} \cdots \widetilde{W} D y| \le O\left(\frac{\rho^4 N^{5/6} \tau_0^{5/3}}{m^{1/3}}\right) .$$

By Lemma 6.12.6 we have

$$|z^\top D\widetilde{W} \cdots \widetilde{W} D y| \le \|z\|_2 \cdot O(L^7) \cdot \|y\|_2 \le O\Big(\frac{L^7 \sqrt{N}\tau_0}{\sqrt{m}}\Big) ,$$
$$|z^\top D\widetilde{W} \cdots \widetilde{W} D e_k| \le \|z\|_2 \cdot O(L^7) \cdot \|e_k\|_2 \le O(L^7) .$$

Therefore, for each $C \in \mathcal{C}_\ell$ we can upper bound $\|a^\top B C\|_2$ as follows

$$|a^\top B C e_k| \le O\left(\frac{\rho^4 N^{5/6} \tau_0^{5/3}}{m^{1/3}}\right) \cdot \left(O\Big(\frac{L^7 \sqrt{N}\tau_0}{\sqrt{m}}\Big)\right)^{\ell-1} \cdot O(L^7)$$

[19]Since we have done this too many times, let us quickly point out the calculation. By Corollary 6.11.16, we have with probability at least $1 - e^{-\Omega(\rho^2)}$

$$|a^\top B \widetilde{D}\widetilde{W} \cdots \widetilde{W}\widetilde{D} y| \le \|a\|_2 \cdot \sqrt{|N|} \log m \cdot \|y\|_2 \le \|y\|_\infty \|y\|_0 \cdot \rho \le \frac{\tau_0 |N|}{\sqrt{m}} .$$

Using binomial expansion again, we have

$$\begin{aligned}
|a^\top B \widetilde{D}\widetilde{W} \cdots \widetilde{W}\widetilde{D} y - a^\top B D\widetilde{W} \cdots \widetilde{W} D y| &\le \sum_{\ell=1}^{L} \binom{L}{\ell} \|a^\top B \widetilde{D}\widetilde{W} \cdots \widetilde{W} D'\| \cdot \|D'\widetilde{W} \cdots \widetilde{W} D'\|_2^{\ell-1} \cdot \|D'\widetilde{W} \cdots \widetilde{W}\widetilde{D} y\| \\
&\le \sum_{\ell=1}^{L} \binom{L}{\ell} (s m^{1/3} \log m) \cdot \left(\frac{s \log m}{m^{1/6}}\right)^{\ell-1} \cdot \left(\frac{s \log m}{m^{1/6}}\right) \cdot \|y\| \\
&\le O(L)(s m^{1/3} \log m) \left(\frac{s \log m}{m^{1/6}}\right) \cdot \frac{\sqrt{N}\tau_0}{\sqrt{m}} = O\left(\frac{\rho^4 N^{5/6} \tau_0^{5/3}}{m^{1/3}}\right)
\end{aligned}$$

Here, we have used Corollary 6.11.15 and Corollary 6.11.12 with parameter $s = O(L^{5/3} \tau_0^{1/3} N^{1/6})$ chosen from Lemma 6.12.1b, as well as $\|y\| \le \frac{\sqrt{N}\tau_0}{\sqrt{m}}$.

and therefore

$$\begin{aligned}\text{LHS} &= \left|\sum_{\ell=1}^{\ell_2-\ell_1}\sum_{C\in\mathcal{C}_\ell} a^\top BCe_k\right| \\ &\le \sum_{\ell=1}^{\ell_2-\ell_1}\binom{\ell_2-\ell_1}{\ell}\cdot O\left(\frac{\rho^4 N^{5/6}\tau_0^{5/3}}{m^{1/3}}\right)\cdot\left(O\Big(\frac{L^7\sqrt{N}\tau_0}{\sqrt{m}}\Big)\right)^{\ell-1}\cdot O(L^7) \le O\left(\frac{\rho^{12}N^{5/6}\tau_0^{5/3}}{m^{1/3}}\right)\ .\end{aligned}$$

□

6.13 Indicator and Backward Coordinate Bounds

In this section, let $W \in \mathbb{R}^{m \times m}$, $A \in \mathbb{R}^{m \times d_x}$ and $B \in \mathbb{R}^{d \times m}$ denote three random matrices where each entry of W and A is i.i.d. sampled from $\mathcal{N}(0, \frac{2}{m})$ and each entry of B is i.i.d. sampled from $\mathcal{N}(0, \frac{1}{d})$. We let $\{ \mathsf{loss}_{i,\ell} \in \mathbb{R}^d \colon i \in [n], \ell \in [L] \backslash \{1\} \}$ be arbitrary fixed vectors, and let $i^*, \ell^* = \arg\max_{i,\ell} \| \mathsf{loss}_{i,\ell} \|_2$.

- In Section 6.13.1, we prove that there are sufficiently many coordinates $k \in [m]$ such that the quantity $|(g_{i,\ell+1})_k| = |(Wh_{i,\ell} + Ax_{i,\ell+1})_k|$ is small for $(i, \ell) = (i^*, \ell^*)$ but large for $(i, \ell) \in [n] \times \{\ell^*, \ell^* + 1, L\} \backslash (i^*, \ell^*)$.
- In Section 6.13.2, we prove that there are sufficiently many coordinates $k \in [m]$ such that $|\sum_a (\mathsf{Back}_{i^*,\ell^* \to a}^\top \cdot \mathsf{loss}_{i^*,a})_k|$ is large.

6.13.1 Indicator Coordinate Bound

For this section, we fix some choice of $i^* \in [n]$ and $\ell^* \in [L]\backslash\{1\}$, and define two parameters

Definition 6.13.1.

$$\boxed{\beta_+ \stackrel{\text{def}}{=} \frac{\delta}{\rho^2} \quad \text{and} \quad \beta_- \stackrel{\text{def}}{=} \frac{\delta}{\rho^{10}}}$$

Lemma 6.13.1 (indicator coordinate bound, c.f. (6.15))**.** *Suppose W and A follow from random initialization. Given fixed set $N_1 \subseteq [m]$ and define*

$$N_4 \stackrel{\text{def}}{=} \left\{ k \in N_1 \;\middle|\; \begin{bmatrix} |\big(Wh_{i,\ell} + Ax_{i,\ell+1}\big)_k| \le \beta_-/\sqrt{m}, & \text{if } i = i^*, \ell = \ell^*; \\ |\big(Wh_{i,\ell} + Ax_{i,\ell+1}\big)_k| \ge \beta_+/\sqrt{m}, & \text{if } i \neq i^* \text{ and } \ell = \ell^*; \\ |\big(Wh_{i,\ell} + Ax_{i,\ell+1}\big)_k| \ge \beta_+/\sqrt{m}, & \text{if } i \in [n] \text{ and } \ell > \ell^*. \end{bmatrix} \right\}$$

Then, as long as $|N_1| \ge n^2L^2/\beta_-$, we have

$$\Pr_{W,A}\left[|N_4| \ge \frac{\beta_-|N_1|}{64L}\right] \ge 1 - e^{-\Omega(\beta_-|N_1|/L)}.$$

Lemma 6.13.2. *Suppose W and A follow from random initialization. Given fixed set $N_1 \subseteq [m]$ and define*

$$N_2 \stackrel{\text{def}}{=} \left\{ k \in N_1 \;\middle|\; |\langle W_k, h_{i^*,\ell^*}\rangle + \langle A_k, x_{i^*,\ell^*+1}\rangle| \le \frac{\beta_-}{\sqrt{m}} \right\}.$$

Then, we have

$$\Pr_{W,A}\left[|N_2| \ge \frac{\beta_-|N_1|}{16L}\right] \ge 1 - e^{-\Omega(\beta_-|N_1|/L)}.$$

Proof. Let $i = i^*$ and $\ell = \ell^*$. Similar to the proof of Lemma 6.11.1, we can write

$$y = Wh_{i,\ell} + Ax_{i,\ell+1} = WU_\ell U_\ell^\top h_{i,\ell} + Ax_{i,\ell+1} = M_1 z_1 + M_2 z_2$$

where $M_1 \in \mathbb{R}^{m \times n\ell}$, $M_2 = A$, $z_1 = U_\ell^\top h_{i,\ell}$ and $z_2 = x_{i,\ell+1}$. Again, the entries of M_1 and M_2 are i.i.d. from $\mathcal{N}(0, \frac{2}{m})$.

Now, suppose z_1 is fixed (instead of depending on the randomness of W and A), and it satisfies $\|z_1\| \le 6L$. We have each entry of y is is distributed as $\mathcal{N}\big(0, \frac{2\|z_1\|^2+2\|z_2\|^2}{m}\big)$. By property of Gaussian (see Fact 6.10.12), we have for each $y \in [m]$,

$$\Pr\left[|y_k| \le \frac{0.9\beta_-}{\sqrt{m}}\right] \ge \frac{2}{3}\frac{0.9\beta_-}{\sqrt{2\|z_1\|^2 + 2\|z_2\|^2}} \ge \frac{\beta_-}{15L} \ .$$

Since we have $|N_1|$ independent random variables, applying a Chernoff bound, we have

$$\Pr\left[\left|\left\{k \in N_1 \colon |y_k| \le \frac{0.9\beta_-}{\sqrt{m}}\right\}\right| \ge \frac{\beta_-}{16L}|N_1|\right] \ge 1 - \exp(-\Omega(\beta_-|N_1|/L)) \ .$$

Finally, by taking a union bound with respect to the ϵ-net over all possible choices of $z_1 \in \mathbb{R}^{n\ell}$, we have that

$$\Pr\left[\left|\left\{k \in N_1 \colon |y_k| \le \frac{\beta_-}{\sqrt{m}}\right\}\right| \ge \frac{\beta_-}{16L}|N_1|\right] \ge 1 - \exp(-\Omega(\beta_-|N_1|/L)) \ .$$

for all z_1 and a fixed z_2. Plugging in the random choice of $z_1 = U_\ell^\top h_{i,\ell}$ (and we have $\|z_1\| \le 6L$ by Lemma 6.11.1), we have the desired result. □

Observe that the set N_2 produced by Lemma 6.13.2 only depends on the randomness of A, WU_{ℓ^*-1} and Wh_{i^*,ℓ^*}. In other words, for any unit vector $z \in \mathbb{R}^m$ that is orthogonal to the columns of U_{ℓ^*-1} and orthogonal to h_{i^*,ℓ^*}, we have that Wz is independent of N_2.

We next proceed to refine N_2:

Lemma 6.13.3 ($i \ne i^*, \ell = \ell^*$)**.** *Suppose W and A follow from random initialization, and $N_2 \subseteq [m]$ is a given set (that may only depend on the randomness of A, WU_{ℓ^*-1} and Wh_{i^*,ℓ^*}).*

Define

$$N_3 = \left\{ k \in N_2 \;\middle|\; |\langle W_k, h_{i,\ell^*}\rangle + \langle A_k, x_{i,\ell^*+1}\rangle| \geq \frac{\beta_-}{\sqrt{m}}, \forall i \in [n]\backslash i^* \right\}.$$

Then

$$\Pr\left[|N_3| \geq \frac{1}{2}|N_2| \;\middle|\; A, WU_{\ell^*-1}, Wh_{i^*,\ell^*} \right] \geq 1 - e^{-\Omega(|N_2|/n)}.$$

Proof. First fix some $i \in [n]\backslash i^*$ and $\ell = \ell^*$. Define set $N_{3,i}$,

$$N_{3,i} \stackrel{\text{def}}{=} \left\{ k \in N_2 \;\middle|\; |\langle W_k, h_{i,\ell}\rangle + \langle A_k, x_{i,\ell+1}\rangle| \geq \frac{\beta_-}{\sqrt{m}} \right\} \ .$$

Let $v \stackrel{\text{def}}{=} \frac{(I - U_{\ell-1}U_{\ell-1}^\top)h_{i^*,\ell}}{\|(I - U_{\ell-1}U_{\ell-1}^\top)h_{i^*,\ell}\|}$, and let column orthonormal matrix

$$U \stackrel{\text{def}}{=} \mathsf{GS}(U_{\ell-1}, h_{i^*,\ell}) = [U_{\ell-1}, v] \ .$$

We have

$$\langle W_k, h_{i,\ell}\rangle + \langle A_k, x_{i,\ell+1}\rangle = \left(WUUh_{i,\ell} + Ax_{i,\ell+1} + W(I - UU^\top)h_{i,\ell} \right)_k \ .$$

The rest of the proof is focusing on having the WU and A being fixed (so the first two vectors $WUUh_{i,\ell} + Ax_{i,\ell+1}$ are fixed), and letting $W(I - UU^\top)h_{i,\ell}$ be the only random variable. We have

$$W(I - UU^\top)h_{i,\ell} \sim \mathcal{N}\left(0, \frac{2\|(I - UU^\top)h_{i,\ell}\|_2^2 \cdot I}{m}\right) \ .$$

and therefore for a fixed vector μ it satisfies

$$Wh_{i,\ell} + Ax_{i,\ell+1} = WUUh_{i,\ell} + Ax_{i,\ell+1} + W(I - UU^\top)h_{i,\ell} \sim \mathcal{N}\left(\mu, \frac{2\|(I - UU^\top)h_{i,\ell}\|_2^2 \cdot I}{m}\right) \ .$$

According to Lemma 6.11.6, with probability at least $1-\exp(-\Omega(\sqrt{m}))$, it satisfies $\|(I-UU^\top)h_{i,\ell}\|_2 \geq \frac{\delta}{2}$. By property of Gaussian distribution (see Fact 6.10.12), we have for each $k \in N_2$:

$$\Pr\left[|(Wh_{i,\ell}+Ax_{i,\ell+1})_k| \geq \frac{\beta_-}{\sqrt{m}} \,\middle|\, WU, A\right] \geq 1-\frac{\beta_-}{\delta} \geq 1-\frac{1}{4n} \ .$$

Applying Chernoff bound, with probability at least $1-e^{-\Omega(|N_2|/n)}$, we have $|N_{3,i}| \geq (1-\frac{1}{2n})|N_2|$. Applying union bound over all possible $i \in [n] \setminus \{i^*\}$, we have $N_3 = \bigcap_{i\neq i^*} N_{3,i}$ has cardinality at least $\frac{|N_2|}{2}$. □

Lemma 6.13.4 ($\ell > \ell^*$)**.** *Suppose W and A follow from random initialization, and $N_3 \subseteq [m]$ is a given set (that may only depend on the randomness of A, WU_{ℓ^*}). Define*

$$N_4 = \left\{ k \in N_3 \,\middle|\, |\langle W_k, h_{i,\ell}\rangle + \langle A_k, x_{i,\ell+1}\rangle| \geq \frac{\beta_-}{\sqrt{m}}, \forall i \in [n], \ell > \ell^* \right\} \ .$$

Then

$$\Pr\left[|N_4| \geq \frac{1}{2}|N_3| \,\middle|\, A, WU_{\ell^*}\right] \geq 1-e^{-\Omega(|N_3|/nL)} \ .$$

Proof. Letting $N_{4,\ell^*} \stackrel{\text{def}}{=} N_3$. For any $i \in [n]$ and $\ell = \ell^*+1, \ell^*+2, \ldots, L$, we define $N_{4,i,\ell}$ as

$$N_{4,i,\ell} \stackrel{\text{def}}{=} \left\{ k \in N_{4,\ell-1} \,\middle|\, |\langle W_k, h_{i,\ell}\rangle + \langle A_k, x_{i,\ell+1}\rangle| \geq \frac{\beta_-}{\sqrt{m}} \right\} \quad \text{and} \quad N_{4,\ell} \stackrel{\text{def}}{=} \bigcap_{i\in[n]} N_{4,i,\ell} \ .$$

We rewrite

$$\langle W_k, h_{i,\ell}\rangle + \langle A_k, x_{i,\ell+1}\rangle = (WU_{\ell-1}U_{\ell-1}^\top h_{i,\ell} + Ax_{i,\ell+1} + W(I-U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell})_k \ .$$

The rest of the proof is focusing on having the $WU_{\ell-1}$ and A being fixed (so the first two vectors $WUUh_{i,\ell}+Ax_{i,\ell+1}$ are fixed and $N_{4,\ell-1}$ is fixed), and letting $W(I-U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell}$ be

the only random variable. We have

$$W(I - U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell} \sim \mathcal{N}\left(0, \frac{2\|(I - U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell}\|_2^2 \cdot I}{m}\right) .$$

and therefore for a fixed vector μ it satisfies

$$Wh_{i,\ell}+Ax_{i,\ell+1} = WU_{\ell-1}U_{\ell-1}h_{i,\ell}+Ax_{i,\ell+1}+W(I-U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell} \sim \mathcal{N}\left(\mu, \frac{2\|(I - U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell}\|_2^2 \cdot I}{m}\right) .$$

According to Lemma 6.11.4, with probability at least $1 - \exp(-\Omega(\sqrt{m}))$, it satisfies $\|(I - UU^\top)h_{i,\ell}\|_2 \geq \frac{\delta}{2}$. By property of Gaussian distribution (see Fact 6.10.12), we have for each $k \in N_{4,\ell-1}$:

$$\Pr\left[|(\widetilde{W}h_{i,\ell} + Ax_{i,\ell+1})_k| \geq \frac{\beta_-}{\sqrt{m}} \,\middle|\, WU, A\right] \geq 1 - \frac{\beta_-}{\delta} \geq 1 - \frac{1}{4nL} .$$

Applying Chernoff bound, we have

$$\Pr\left[|N_{4,i,\ell}| \geq (1 - \frac{1}{3nL})|N_{4,\ell-1}| \,\middle|\, WU_{\ell-1}, A\right] \geq 1 - e^{-\Omega(|N_{4,\ell-1}|/nL)} .$$

Applying union bound over all possible $i \in [n]$, we have $N_{4,\ell} = \bigcap_{i\in[n]} N_{4,i,\ell}$ has cardinality at least $(1 - \frac{1}{3L})|N_{4,\ell-1}|$. After telescoping we have $|N_4| = |N_{4,L}| \geq \frac{1}{2}|N_3|$. □

6.13.2 Backward Coordinate Bound

Recall the following notions

Definition 6.13.2. Given matrices W, A, B. For each i, for each ℓ, we define

$$\mathsf{Back}_{i,\ell\to\ell} = B \in \mathbb{R}^{d\times m}.$$

For each i, for each $a \geq \ell + 1$, we define

$$\mathsf{Back}_{i,\ell\to a} = BD_{i,a}W \cdots D_{i,\ell+1}W \in \mathbb{R}^{d\times m}.$$

The goal of this section is to prove Lemma 6.13.5.

Lemma 6.13.5 (backward coordinate bound, c.f. (6.14))**.** *Let $\rho = ndL\log m$ and $\varrho = nLd\delta^{-1}\log(m/\epsilon)$. Let $\big\{\mathsf{loss}_{i,\ell} \in \mathbb{R}^d \colon i \in [n], \ell \in [L]\backslash\{1\}\big\}$ be fixed vectors and $i^*, \ell^* = \arg\max_{i,\ell} \|\mathsf{loss}_{i,\ell}\|_2$. If $W \in \mathbb{R}^{m\times m}, A \in \mathbb{R}^{m\times d_x}, B \in \mathbb{R}^{d\times m}$ are random, and $N_4 \subseteq [m]$ is a set with $|N_4| \in [\rho^4, \varrho^{100}]$ (N_4 can depend on the randomness of W and A, but not depend on B). Define*

$$N_5 \stackrel{\text{def}}{=} \left\{ k \in N_4 \;\middle|\; \left| \sum_{a=\ell^*}^{L} (\mathsf{Back}_{i^*,\ell^*\to a}^\top \cdot \mathsf{loss}_{i^*,a})_k \right| \geq \frac{\|\mathsf{loss}_{i^*,\ell^*}\|_2}{6\sqrt{d}nL} \right\}.$$

Then with probability at least $1 - e^{-\Omega(\rho^2)}$, we have

$$|N_5| \geq \left(1 - \frac{1}{2nL}\right)|N_4|.$$

Proof. For notational simplicity, in the proof we use ℓ to denote ℓ^*, use N to denote N_4, and drop the subscript i^*. We denote $B \in \mathbb{R}^{d\times m}$ as $[b_1, b_2, \cdots, b_m]$ where each $b_i \in \mathbb{R}^d$. We denote by $C_{a,\ell+1} = D_a W \cdots D_{\ell+1}W$.

We define a function $v_k(b_1, b_2, \cdots, b_m) \in \mathbb{R}$ as follows

$$v_k(b_1, b_2, \cdots, b_m) \stackrel{\text{def}}{=} \sum_{a=\ell}^{L} (\mathsf{Back}_{\ell \to a}^\top \cdot \mathsf{loss}_{i,a})_k.$$

We can rewrite

$$\begin{aligned}
v_k(b_1, b_2, \cdots, b_m) = & \left(B^\top \cdot \mathsf{loss}_{i,\ell} + \sum_{a=\ell+1}^{L} \mathsf{Back}_{\ell \to a}^\top \cdot \mathsf{loss}_{i,a} \right)_k \\
= & \left(B^\top \cdot \mathsf{loss}_{i,\ell} + \sum_{a=\ell+1}^{L} (C_{a,\ell+1})^\top B^\top \cdot \mathsf{loss}_{i,a} \right)_k \\
= & \langle b_k, \mathsf{loss}_{i,\ell} \rangle + \sum_{a=\ell+1}^{L} \left\langle \sum_{j=1}^{m} (C_{a,\ell+1})_{k,j} \cdot b_j, \mathsf{loss}_{i,a} \right\rangle \\
= & \left\langle b_k, \mathsf{loss}_{i,\ell} + \sum_{a=\ell+1}^{L} (C_{a,\ell+1})_{k,j} \cdot \mathsf{loss}_{i,a} \right\rangle + \sum_{j \in [m] \setminus k} \left\langle b_j, \sum_{a=\ell+1}^{L} (C_{a,\ell+1})_{k,j} \cdot \mathsf{loss}_{i,a} \right\rangle
\end{aligned}$$

where we have used $(C_{a,\ell+1})_{k,j}$ to denote the (k,j) entry of matrix $C_{a,\ell+1}$.

Choose parameter $\mathfrak{L}_h = \frac{3\sqrt{d}nL}{\| \mathsf{loss}_{i,\ell} \|_2}$ and we can define function $h \colon \mathbb{R} \to [0,1]$ by

$$h(t) \stackrel{\text{def}}{=} \begin{cases} |t| \cdot \mathfrak{L}_h, & \text{if } |t| \leq 1/\mathfrak{L}_h; \\ 1, & \text{otherwise.} \end{cases}$$

We have $h(t)$ is $\mathfrak{L}_h$-Lipschitz continuous.

We define two probabilistic events E_1, E_2.

- Event E_1 depends on the randomness of W and A:

$$E_1 \stackrel{\text{def}}{=} \left\{ |z^\top C_{a,\ell+1} y| \leq \frac{\rho}{\sqrt{m}} \|z\| \|y\| \text{ for all } a, \ell \text{ and for all 1-sparse vectors } y, z \right\}$$

Corollary 6.11.13 says $\Pr[E_1] \geq 1 - e^{-\Omega(\rho^2)}$.

- Event E_2 depends on the randomness of B:

$$E_2 \stackrel{\text{def}}{=} \left\{ |B_{i,j}| \leq \frac{\rho}{\sqrt{d}} \text{ for all } i,j \right\}$$

  By Gaussian tail bound, we have $\Pr[E_2] \geq 1 - e^{-\Omega(\rho^2)}$.

In the rest of the proof, we assume W and A are fixed and satisfy E_1. We let B be the only source of randomness but we condition on B satisfies E_2.

For simplicity we use subscript $-j$ to denote $[m] \setminus j$, and subscript $-N$ to denote $[m] \setminus N$. For instance, we shall write $b = (b_{-k}, b_k) = (b_N, b_{-N})$.

Step 1 Fixing b_{-N} and letting b_N be the only randomness, we claim for each $k \in N$:

$$\mathop{\mathbb{E}}_{b_N}[h(v_k)] \geq \Pr_{b_N}\left[|v_k| \geq \frac{1}{\mathfrak{L}_h}\right] \geq 1 - \frac{1}{4nL} \ .$$

We prove this inequality as follows. We can rewrite

$$\begin{aligned} v_k = & \left\langle b_k, \mathsf{loss}_{i,\ell} + \sum_{a=\ell+1}^{L} (C_{a,\ell+1})_{k,k} \cdot \mathsf{loss}_{i,a} \right\rangle + \sum_{j \in N \setminus \{k\}} \left\langle b_j, \sum_{a=\ell+1}^{L} (C_{a,\ell+1})_{k,j} \cdot \mathsf{loss}_{i,a} \right\rangle \\ & + \sum_{j \in [m] \setminus N} \left\langle b_j, \sum_{a=\ell+1}^{L} (C_{a,\ell+1})_{k,j} \cdot \mathsf{loss}_{i,a} \right\rangle \end{aligned}$$

and v_k is distributed as Gaussian random variable $\mathcal{N}(\mu, \sigma^2)$, and μ and σ^2 are defined as follows

$$\begin{aligned} \mu &= \sum_{j \in [m] \setminus N} \left\langle b_j, \sum_{a=\ell+1}^{L} (C_{a,\ell+1})_{k,j} \cdot \mathsf{loss}_{i,a} \right\rangle \\ \sigma^2 &= \frac{1}{d} \left\| \mathsf{loss}_{i,\ell} + \sum_{a=\ell+1}^{L} (C_{a,\ell+1})_{k,k} \cdot \mathsf{loss}_{i,a} \right\|_2^2 + \frac{1}{d} \sum_{j \in N \setminus \{k\}} \left\| \sum_{a=\ell+1}^{L} (C_{a,\ell+1})_{k,j} \cdot \mathsf{loss}_{i,a} \right\|_2^2 \end{aligned}$$

Meanwhile, we calculate that

$$\left\| \sum_{a=\ell+1}^{L} (C_{a,\ell+1})_{k,j} \cdot \mathsf{loss}_{i,a} \right\|_2 \overset{①}{\leq} \sum_{a=\ell+1}^{L} |(C_{a,\ell+1})_{k,j}| \cdot \| \mathsf{loss}_{i,a} \|_2$$
$$\overset{②}{\leq} \sum_{a=\ell+1}^{L} |(C_{a,\ell+1})_{k,j}| \cdot \| \mathsf{loss}_{i,\ell} \|_2 \overset{③}{\leq} \frac{L\rho}{\sqrt{m}} \cdot \| \mathsf{loss}_{i,\ell} \|_2 \tag{6.46}$$

where ① follows by triangle inequality, ② follows by $i, \ell = \arg\max_{i',\ell'} \| \mathsf{loss}_{i',\ell'} \|$, and ③ follows from event E_1. Therefore,

$$\sigma^2 \geq \frac{1}{d} \left(\| \mathsf{loss}_{i,\ell} \|_2 - \left\| \sum_{a=\ell+1}^{L} (C_{a,\ell+1})_{k,j} \cdot \mathsf{loss}_{i,a} \right\|_2 \right)^2$$
$$\geq \frac{1}{d} \left(1 - \frac{L\rho}{\sqrt{m}} \right)^2 \| \mathsf{loss}_{i,\ell} \|_2^2 \geq \frac{1}{2d} \| \mathsf{loss}_{i,\ell} \|_2^2$$

where the first step follows by $\|a+b\|_2 \geq \|a\|_2 - \|b\|_2$, the second step follows by (6.46). In sum, we have that v_k is a random Gaussian with $\sigma^2 \geq \frac{1}{2d} \| \mathsf{loss}_{i,\ell} \|_2^2$. This means,

$$\Pr_{b_N} \left[|v_k| \geq \frac{1}{\mathfrak{L}_h} \right] \geq \Pr_{b_N} \left[|v_k| \geq \frac{\| \mathsf{loss}_{i,\ell} \|_2}{3\sqrt{d} n L} \right] \geq 1 - \frac{1}{4nL} \ .$$

according to Fact 6.10.12.

Step 2 For every $b_1, b_2, \cdots, b_m$ and $b'_k \in \mathbb{R}^d$ satisfying event E_2, for every $j \neq k$, we have

$$|v_j(b_{-k}, b_k) - v_j(b_{-k}, b'_k)| = \left| \left\langle b_k - b'_k, \sum_{a=\ell+1}^{L} (C_{a,\ell+1})_{k,k} \cdot \mathsf{loss}_{i,a} \right\rangle \right|$$
$$\leq \|b_k - b'_k\|_2 \cdot \left\| \sum_{a=\ell+1}^{L} (C_{a,\ell+1})_{k,k} \cdot \mathsf{loss}_{i,a} \right\|_2$$
$$\leq \rho \cdot \frac{L\rho}{\sqrt{m}} \| \mathsf{loss}_{i,\ell} \|_2 \leq \frac{\rho^3}{\sqrt{m}} \| \mathsf{loss}_{i,\ell} \|_2 \tag{6.47}$$

where the second step follows by $|\langle a, b \rangle| \leq \|a\|_2 \cdot \|b\|_2$, the third step follows by (6.46).

Step 3 Fixing b_{-N} and letting function $g(b_1, b_2, \cdots, b_m) \stackrel{\text{def}}{=} \sum_{k\in N} h(v_k(b_1, b_2, \cdots, b_m))$. We have

$$\begin{aligned}
|g(b_j, b_{-j}) - g(b'_j, b_{-j})| &= \left|\sum_{k\in N} h(v_k(b_j, b_{-j})) - \sum_{k\in N} h(v_k(b'_j, b_{-j}))\right| \\
&\le \sum_{k\in N} \left|h(v_k(b_j, b_{-j})) - h(v_k(b'_j, b_{-j}))\right| \\
&= \left|h(v_j(b_j, b_{-j})) - h(v_j(b'_j, b_{-j}))\right| + \sum_{k\in N\setminus\{j\}} \left|h(v_k(b_j, b_{-j})) - h(v_k(b'_j, b_{-j}))\right| \\
&\overset{①}{\le} 1 + \sum_{k\in N\setminus\{j\}} \left|h(v_k(b_j, b_{-j})) - h(v_k(b'_j, b_{-j}))\right| \\
&\le 1 + \sum_{k\in N\setminus\{j\}} \mathfrak{L}_h \cdot |v_k(b_j, b_{-j}) - v_k(b'_j, b_{-j})| \\
&\overset{②}{\le} 1 + |N| \cdot \frac{3\sqrt{d}nL}{\|\,\mathsf{loss}_{i,\ell}\,\|_2} \cdot \left((nLd\log m)^3 \frac{\|\,\mathsf{loss}_{i,\ell}\,\|_2}{\sqrt{m}}\right) \\
&\le 1 + \frac{|N| \cdot 3(nLd\log m)^4}{\sqrt{m}} \le 2 \ .
\end{aligned}$$

Above, inequality ① follows by $h(t) \in [0, 1]$, inequality ② follows from (6.47). Using McDiarmid inequality (see Lemma 6.10.17), we have

$$\begin{aligned}
&\Pr_{b_N}\left[\left|g(b_1, \cdots, b_m) - \mathop{\mathbb{E}}_{b_N}[g]\right| \ge \epsilon\right] \le \exp\left(-\frac{\epsilon^2}{8|N|}\right) \\
\implies &\Pr_{b_N}\left[\left|g(b_1, \cdots, b_m) - \mathop{\mathbb{E}}_{b_N}[g]\right| \ge \frac{|N|}{4nL}\right] < \exp\left(-\frac{|N|}{128(nL)^2}\right)
\end{aligned}$$

where we choose $\epsilon = \frac{|N|}{4nL}$.

Finally, combining this with Step 1 —which gives $\mathbb{E}_{b_N}[g(b_1, \cdots, b_m)] \ge |N|(1 - \frac{1}{4nL})$— we have with probability at least $1 - e^{-\Omega(|N|/(nL)^2)}$ over randomness of b_N,

$$g(b_1, \cdots, b_m) \ge |N|\left(1 - \frac{1}{2nL}\right) \ .$$

This implies at least $(1 - \frac{1}{2nL})$-fraction of $k \in N$ will have $|v_k| \ge \frac{1}{2\mathfrak{L}_h} = \frac{\|\,\mathsf{loss}_{i,\ell}\,\|_2}{6nL\sqrt{d}}$. □

6.14 Gradient Bound at Random Initialization (Theorem 6.14.2)

The goal of this section is to understand the lower and upper bounds of gradients. Instead of analyzing the true gradient directly —where the forward and backward propagation have correlated randomness— we assume that the loss vectors $\{\mathsf{loss}_{i,a}\}_{i\in[n],a\in\{2,\dots,L\}}$ are fixed (no randomness) in this section, as opposed to being defined as $\mathsf{loss}_{i,a} = Bh_{i,a} - y^*_{i,a}$ which is random. We call this the "fake loss." We define a corresponding "fake gradient" with respect to this fixed loss.

Definition 6.14.1 (fake gradient, c.f. (6.13))**.** Given fixed vectors $\{\mathsf{loss}_{i,a}\}_{i\in[n],a\in\{2,\dots,L\}}$, we define

$$\widehat{\nabla}_k f(W) \stackrel{\text{def}}{=} \sum_{i=1}^n \sum_{a=2}^L \sum_{\ell=1}^{a-1} (\mathsf{Back}_{i,\ell+1\to a}^\top \cdot \mathsf{loss}_{i,a})_k \cdot h_{i,\ell} \cdot \mathbf{1}_{\langle W_k, h_{i,\ell}\rangle + \langle A_k, x_{i,\ell+1}\rangle \geq 0}$$

$$\widehat{\nabla} f(W) \stackrel{\text{def}}{=} \sum_{i=1}^n \sum_{a=2}^L \sum_{\ell=1}^{a-1} D_{i,\ell+1}(\mathsf{Back}_{i,\ell+1\to a}^\top \cdot \mathsf{loss}_{i,a}) \cdot h_{i,\ell}^\top$$

$$\widehat{\nabla} f_i(W) \stackrel{\text{def}}{=} \sum_{a=2}^L \sum_{\ell=1}^{a-1} D_{i,\ell+1}(\mathsf{Back}_{i,\ell+1\to a}^\top \cdot \mathsf{loss}_{i,a}) \cdot h_{i,\ell}^\top$$

In our analysis, we also write it as

$$\widehat{\nabla}_k f(W) = \sum_{i=1}^n \sum_{\ell=1}^{L-1} (u_{i,\ell})_k \cdot h_{i,\ell} \cdot \mathbf{1}_{(g_{i,\ell+1})_k \geq 0}$$

$$\widehat{\nabla} f(W) = \sum_{i=1}^n \sum_{\ell=1}^{L-1} D_{i,\ell+1} u_{i,\ell} \cdot h_{i,\ell}^\top$$

$$\widehat{\nabla} f_i(W) = \sum_{\ell=1}^{L-1} D_{i,\ell+1} u_{i,\ell} \cdot h_{i,\ell}^\top$$

where vectors $u_{i,\ell}, g_{i,\ell+1} \in \mathbb{R}^m$ are defined as

$$u_{i,\ell} \stackrel{\text{def}}{=} \sum_{a=\ell+1}^L \mathsf{Back}_{i,\ell+1\to a}^\top \cdot \mathsf{loss}_{i,a} \qquad\qquad g_{i,\ell+1} \stackrel{\text{def}}{=} Wh_{i,\ell} + Ax_{i,\ell+1} \ .$$

We first state a simple upper bound on the gradients.

Lemma 6.14.1. *Letting $\rho = nLd\log m$, given fixed vectors $\{\mathsf{loss}_{i,\ell} \in \mathbb{R}^d\}_{i\in[n],\ell\in[L]\setminus\{1\}}$, with probability at least $1 - e^{-\Omega(m/L^2)}$ over W, A, B, we have*

$$\|\widehat{\nabla} f(W)\|_F \le O(nL^6\sqrt{m}) \cdot \max_{i,\ell}\{\|\,\mathsf{loss}_{i,\ell}\,\|\} \quad \text{and}$$
$$\forall i \in [n]\colon \|\widehat{\nabla} f_i(W)\|_F \le O(L^6\sqrt{m}) \cdot \max_{i,\ell}\{\|\,\mathsf{loss}_{i,\ell}\,\|\}\ .$$

With probability at least $1 - e^{-\Omega(\rho^2)}$, we have for every $k \in [m]$:

$$\|\widehat{\nabla}_k f(W)\|_2 \le O(n\rho L^3) \cdot \max_{i,\ell}\{\|\,\mathsf{loss}_{i,\ell}\,\|\}\ .$$

Proof of Lemma 6.14.1. For each i, a, ℓ, we can calculate that

$$\begin{aligned}\left\|D_{i,\ell+1}(\mathsf{Back}_{i,\ell+1\to a}^\top \cdot \mathsf{loss}_{i,a}) \cdot h_{i,\ell}^\top\right\|_F &= \left\|D_{i,\ell+1}(\mathsf{Back}_{i,\ell+1\to a}^\top \cdot \mathsf{loss}_{i,a})\right\|_2 \cdot \|h_{i,\ell}^\top\|_2 \\ &\le \|\mathsf{Back}_{i,\ell+1\to a}\|_2 \cdot \|\,\mathsf{loss}_{i,a}\,\|_2 \cdot \|h_{i,\ell}^\top\|_2 \\ &\overset{①}{\le} O(\sqrt{m}) \cdot O(L^3) \cdot O(L) \cdot \|\,\mathsf{loss}_{i,a}\,\|_2\ .\end{aligned}$$

where inequality ① uses Lemma 6.11.8, Lemma 6.11.1, and $\|B\|_2 \le O(\sqrt{m})$ with high probability. Applying triangle inequality and using the definition of fake gradient (see Definition 6.14.1), we finish the proof of the first statement.

As for the second statement, we replace the use of Lemma 6.11.8 with Corollary 6.11.16.

□

The rest of this section is devoted to proving a (much more involved) lower bound on this fake gradient.

Theorem 6.14.2 (gradient lower bound at random init, restated)**.** *Letting* $\rho = nLd\log m$*, given fixed vectors* $\{\mathsf{loss}_{i,\ell} \in \mathbb{R}^d\}_{i\in[n],\ell\in[L]\setminus\{1\}}$*, with probability at least* $1-e^{-\Omega(\rho^2)}$ *over* W, A, B*, we have*

$$\|\widehat{\nabla} f(W)\|_F^2 \geq \Omega\left(\frac{\delta}{\rho^{14}}\right) \times m \times \max_{i,\ell}\{\|\,\mathsf{loss}_{i,\ell}\,\|^2\} \ .$$

In the rest of this section, we first present a elegant way to decompose the randomness in Section 6.14.1 (motivated by smooth analysis [ST04]). We give a lower bound on the *expected* fake gradient in Section 6.14.2. We then calculate the stability of fake gradient against rank-one perturbations in Section 6.14.3. Finally, in Section 6.14.4, we apply our extended McDiarmid's inequality to prove Theorem 6.14.2.

6.14.1 Randomness Decomposition

We introduce a parameter θ as follows:

Definition 6.14.2. Choose any

$$\boxed{\theta \in \left[\rho^4 \cdot \beta_-, \rho^{-3} \cdot \beta_+\right]}$$

where the notions β_- and β_+ come from Definition 6.13.1. We have $\theta \le \frac{\delta}{\rho}$.

In the next lemma, we introduce a way to decompose the randomness of W into $W = W_2 + W'$ for two corollated random matrices W_2 and W'. We will make sure that the entries of W_2 are also i.i.d. from $N(0, \frac{2}{m})$. This definition requires us to choose a specific pair $(i^*, \ell^*) \in [n] \times [L]$.

Lemma 6.14.3. *Suppose W and A follow from random initialization. Given any fixed $i^* \in [n]$, $\ell^* \in [L]$, and parameter $\theta \in \left(0, \frac{1}{2\rho}\right]$, letting random vector $v_{i^*,\ell^*} \in \mathbb{R}^m$ be defined as*

$$v_{i^*,\ell^*} \stackrel{\text{def}}{=} \frac{(I - U_{\ell^*-1}U_{\ell^*-1}^\top)h_{i^*,\ell^*}}{\|(I - U_{\ell^*-1}U_{\ell^*-1}^\top)h_{i^*,\ell^*}\|_2} \ ,$$

then we can write $W = W_2 + W'$ for two random matrices $W_2 \in \mathbb{R}^{m\times m}$ and $W' \in \mathbb{R}^{m\times m}$ where

(a) entries of W_2 are i.i.d. drawn from $\mathcal{N}(0, \frac{2}{m})$ (so W_2 is in the same distribution as W);

(b) W' is correlated with W_2 and can be written as $W' = uv_{i^*,\ell^*}^\top$ for some $u \in \mathbb{R}^m$;

(c) With probability at least $1 - e^{-\Omega(\rho^2)}$ over the randomness of W_2:

$$\forall k\colon \quad \Pr_{W'}\left[u_k = (W'v_{i^*,\ell^*})_k \ge \frac{\theta}{2\sqrt{m}} \;\middle|\; W_2\right] \ge \frac{1}{4} \quad \text{and}$$
$$\Pr_{W'}\left[u_k = (W'v_{i^*,\ell^*})_k \le -\frac{\theta}{2\sqrt{m}} \;\middle|\; W_2\right] \ge \frac{1}{4}$$

(d) With probability at least $1 - e^{-\Omega(\rho^2)}$ over the randomness of W_2:

$$\Pr_{W'}\left[\|u\|_\infty = \|W' v_{i^*,\ell^*}\|_\infty \le \frac{3\theta\rho}{2\sqrt{m}} \;\middle|\; W_2\right] \ge 1 - e^{-\Omega(\rho^2)} \ .$$

Proof. Since v_{i^*,ℓ^*} only depends on the randomness of WU_{ℓ^*-1}, we have $Wv_{i^*,\ell^*} \sim \mathcal{N}(0, \frac{2I}{m})$. As a result, letting $g_1, g_2 \in \mathbb{R}^m$ be two independent random Gaussian vectors sampled from $\mathcal{N}(0, \frac{2I}{m})$, we can couple them to make sure

$$Wv_{i^*,\ell^*} = \sqrt{1-\theta^2} g_1 + \theta g_2 \ .$$

We define $W_2, W' \in \mathbb{R}^{n\times n}$ as follows

$$\begin{aligned} W_2 &\stackrel{\text{def}}{=} WU_{\ell^*-1}U_{\ell^*-1}^\top + g_1 v_{i^*,\ell^*}^\top + W(I - U_{\ell^*-1}U_{\ell^*-1}^\top)(I - v_{i^*,\ell^*}v_{i^*,\ell^*}^\top) \\ W' &\stackrel{\text{def}}{=} uv_{i^*,\ell^*}^\top \quad \text{where} \quad u \stackrel{\text{def}}{=} \theta g_2 - (1-\sqrt{1-\theta^2})g_1 \end{aligned}$$

- It is easy to verify that

$$\begin{aligned} W_2 + W' &= W(I - v_{i^*,\ell^*}v_{i^*,\ell^*}^\top) + g_1 v_{i^*,\ell^*}^\top + (\theta g_2 - (1-\sqrt{1-\theta^2})g_1)v_{i^*,\ell^*}^\top \\ &= W(I - v_{i^*,\ell^*}v_{i^*,\ell^*}^\top) + (\theta g_2 + \sqrt{1-\theta^2} g_1)v_{i^*,\ell^*}^\top \\ &= W(I - v_{i^*,\ell^*}v_{i^*,\ell^*}^\top) + Wv_{i^*,\ell^*}v_{i^*,\ell^*}^\top \\ &= W. \end{aligned}$$

- We verify that the entries of W_2 are i.i.d. Gaussian in two steps.

  On one hand, let $U = [\widehat{h}_1, \ldots, \widehat{h}_m] \in \mathbb{R}^{m\times m}$ be an arbitrary orthonormal matrix where its first nL columns are identical to $U_L \in \mathbb{R}^{m\times nL}$. For each $k \in [nL]$, although $\widehat{h}_k$ may depend on the randomness of $W = W_2 + W'$, it can only depend on $W[\widehat{h}_1, \ldots, \widehat{h}_{k-1}]$.

Therefore, conditioning on the randomness of $W_2[\widehat{h}_1, \ldots, \widehat{h}_{k-1}]$, we have that $W_2\widehat{h}_k$ is still $\mathcal{N}(0, \frac{2I}{m})$. This shows that all entries of W_2U still follow from $N(0, \frac{2}{m})$.

On the other hand, let $V = W_2U = [v_1, \ldots, v_m] \in \mathbb{R}^{m\times m}$, then we have $v_k = W_2\widehat{h}_k$ is independent of $\widehat{h}_k$ as argued above. Since each $v_k \sim N(0, \frac{2I}{m})$, we have that all entries of $VU^\top = \sum_k v_k\widehat{k}_k^\top$ are i.i.d. from $N(0, \frac{2}{m})$. Since $W_2 = VU^\top$ this concludes the proof.

- By standard Gaussian tail bound, we have with probability at least $1 - e^{-\Omega(\rho^2)}$, it satisfies $\|g_1\|_\infty \le \frac{\rho}{\sqrt{m}}$ and therefore $\|(1-\sqrt{1-\theta^2})g_1\|_\infty \le \frac{\theta^2\rho}{\sqrt{m}}$. If this happens, for every $k \in [m]$, we have (see for instance Fact 6.10.12) that $\Pr_{g_2}[(\theta g_2)_k > \frac{\theta}{\sqrt{m}}] \ge \frac{1}{4}$ and $\Pr_{g_2}[(\theta g_2)_k < -\frac{\theta}{\sqrt{m}}] \ge \frac{1}{4}$. Recalling

$$u = (\theta g_2 - (1-\sqrt{1-\theta^2})g_1 \ .$$

and using the fact that $\theta \le \frac{1}{2\rho}$, we conclude that

$$\Pr_{W'}\left[u_k > \frac{\theta}{2\sqrt{m}} \,\middle|\, W_2, A\right] \ge \frac{1}{4} \quad \text{and} \quad \Pr_{W'}\left[u_k < -\frac{\theta}{2\sqrt{m}} \,\middle|\, W_2, A\right] \ge \frac{1}{4} \ .$$

- Again by Gaussian tail bound, we have with probability at least $1 - e^{-\Omega(\rho^2)}$, it satisfies $\|g_1\|_\infty, \|g_2\|_\infty \le \frac{\rho}{\sqrt{m}}$. Therefore, $\|(1-\sqrt{1-\theta^2})g_1\|_\infty \le \frac{\theta^2\rho}{\sqrt{m}}$ and using our assumption on θ, we have

$$\|u\|_\infty = \left\|(\theta g_2 - (1-\sqrt{1-\theta^2})g_1\right\|_\infty \le \frac{3\theta\rho}{2\sqrt{m}} \ .$$

□

Lemma 6.14.4. *Given any fixed $i^* \in [n]$, $\ell^* \in [L]$, and parameter $\theta \in \left(0, \frac{1}{2\rho}\right]$, and suppose suppose W and A are at random initialization and $W = W_2 + W'$ where $W' = uv_{i^*,\ell^*}^\top$ (following Lemma 6.14.3).*

Now, we introduce another two ways of decomposing randomness based on this definition.

(a) Given fixed $k \in [m]$, we can write $W = W_0 + W'_k$ where $W'_k = u_k v_{i^*,\ell^*}^\top$ for $u_k = (0, \ldots, 0, u_k, 0, \ldots, 0)$ that is non-zero only at the k-th coordinate. We again have the entries of W_0 are i.i.d. from $N(0, \frac{2}{m})$.

(b) Given fixed $N \subseteq [m]$, we can write $W = W_1 + W'_N$ where $W'_N = u_N v_{i^*,\ell^*}^\top$ for u_N being the projection of u onto coordinates in N (so $\|u\|_0 = |N|$). We again have the entries of W_0 are i.i.d. from $N(0, \frac{2}{m})$.

(c) Given fixed $N \subseteq [m]$, we can write $W = W_2 + W'_N + W'_{-N}$ where $W'_N = u_N v_{i^*,\ell^*}^\top$ and $W'_{-N} = u_{-N} v_{i^*,\ell^*}^\top$. Here, u_{-N} is the projection of u onto coordinates in $[m] \setminus N$.

Proof. The proofs are analogous to Lemma 6.14.3. □

6.14.2 Gradient Lower Bound in Expectation

The goal of this subsection is to prove Lemma 6.14.5 and then translate it into our Core Lemma A (see Lemma 6.14.6).

Lemma 6.14.5 (c.f. (6.18)). *Let $\rho = nLd\log m$ and $\varrho = nLd\delta^{-1}\log(m/\epsilon)$. Fix integer $N \in [\rho^6/\beta_-, \varrho^{100}]$, θ from Definition 6.14.2, fix vectors $\{\mathsf{loss}_{i,\ell} \in \mathbb{R}^d\}_{i\in[n],\ell\in[L]\setminus\{1\}}$, let $(i^*,\ell^*) = \mathrm{argmin}_{i,\ell}\ \{\|\,\mathsf{loss}_{i,\ell}\,\|\}$. Suppose W_1, A, B are at random initialization, and suppose W'_N is defined according to Lemma 6.14.4b so that $W = W_1 + W'_N$ is also at random initialization. With probability at least $1 - e^{-\Omega(\rho^2)}$ over the randomness of W_1, A, B, we have*

$$\left|\left\{k \in N \;\middle|\; \mathop{\mathbb{E}}_{W'_N}\Big[\|\widehat{\nabla}_k f(W_1+W'_N)\|_2\Big] \ge \Omega\Big(\frac{\|\,\mathsf{loss}_{i^*,\ell^*}\,\|_2}{nL\sqrt{d}}\Big)\right\}\right| \ge \frac{\beta_-|N|}{100L}$$

6.14.2.1 Proof of Lemma 6.14.5

Throughout this proof we denote by $\widetilde{W} = W_1$. We introduce some (old and new) notations:

$$\widetilde{\mathsf{Back}}_{i,\ell\to\ell} = B, \qquad \mathsf{Back}_{i,\ell\to\ell} = B$$
$$\widetilde{\mathsf{Back}}_{i,\ell\to a} = B\widetilde{D}_{i,a}\widetilde{W}\cdots\widetilde{D}_{i,\ell+1}\widetilde{W}, \qquad \mathsf{Back}_{i,\ell\to a} = BD_{i,a}W\cdots D_{i,\ell+1}W,$$

and we let $\mathsf{Back}'_{i,\ell\to a} = \mathsf{Back}_{i,\ell\to a} - \widetilde{\mathsf{Back}}_{i,\ell\to a}$. For each $i\in[n]$, $\ell\in[L]$, we define

$$\widetilde{g}_{i,\ell} = Ax_{i,\ell} + \widetilde{W}\widetilde{D}_{i,\ell-1}\widetilde{g}_{i,\ell-1} \qquad g_{i,\ell} = Ax_{i,\ell} + WD_{i,\ell-1}g_{i,\ell-1} \qquad g'_{i,\ell} = g_{i,\ell} - \widetilde{g}_{i,\ell}$$
$$\widetilde{h}_{i,\ell} = \widetilde{D}_{i,\ell}(Ax_{i,\ell} + \widetilde{W}\widetilde{h}_{i,\ell-1}) \qquad h_{i,\ell} = D_{i,\ell}(Ax_{i,\ell} + Wh_{i,\ell-1}) \qquad h'_{i,\ell} = h_{i,\ell} - \widetilde{h}_{i,\ell}$$
$$\widetilde{u}_{i,\ell} = \sum_{a=\ell}^{L} \widetilde{\mathsf{Back}}_{\ell\to a}^\top \mathsf{loss}_{i,a} \qquad u_{i,\ell} = \sum_{a=\ell}^{L} \mathsf{Back}_{\ell\to a}^\top \mathsf{loss}_{i,a} \qquad u'_{i,\ell} = u_{i,\ell} - \widetilde{u}_{i,\ell}$$

We also let

$$v_{i^*,\ell^*} = \frac{(I - U_{\ell^*-1}U_{\ell^*-1}^\top)\widetilde{h}_{i^*,\ell^*}}{\|(I - U_{\ell^*-1}U_{\ell^*-1}^\top)\widetilde{h}_{i^*,\ell^*}\|_2}$$

and recall from Lemma 6.14.3d, we have

$$W'_N = yv_{i^*,\ell^*}^\top \text{ for some } y \in \mathbb{R}^m \text{ with } \|y\|_0 = |N| \text{ and } \|y\|_\infty \le \frac{\tau_0}{\sqrt{m}} \stackrel{\text{def}}{=} \frac{3\theta\rho}{2\sqrt{m}} \in \left[\frac{\varrho^{-20}}{\sqrt{m}}, \frac{\varrho^{20}}{\sqrt{m}}\right]$$

Proof of Lemma 6.14.5. We let $N_1 = N$, apply Lemma 6.13.1 to obtain $N_4 \subseteq N_1$ with $|N_4| \ge \frac{\beta_-|N_1|}{64L}$, and apply Lemma 6.13.5 to obtain $N_5 \subseteq N_4$. According to the statements of these lemmas, we know that with probability at least $1 - e^{-\Omega(\rho^2)}$, the random choice of W_1, A, B will satisfy $|N_5| \ge \frac{\beta_-|N_1|}{100L}$.

Fixing such $k \in N_5$, we use $u_{i,\ell}$ to denote $(u_{i,\ell})_k$ and $g_{i,\ell}$ to denote $(g_{i,\ell})_k$ for notational simplicity. We can rewrite $\widehat{\nabla}_k f(W)$ as follows and apply triangle inequality:

$$\begin{aligned}
\|\widehat{\nabla}_k f(W)\| &= \left\|u_{i^*,\ell^*} \cdot h_{i^*,\ell^*} \cdot \mathbf{1}_{g_{i^*,\ell^*+1}\ge 0} + \textstyle\sum_{(i,\ell)\neq(i^*,\ell^*)} u_{i,\ell} \cdot h_{i,\ell} \cdot \mathbf{1}_{g_{i,\ell+1}\ge 0}\right\| \\
&\ge \underbrace{\left\|\widetilde{u}_{i^*,\ell^*} \cdot \widetilde{h}_{i^*,\ell^*} \cdot \mathbf{1}_{g_{i^*,\ell^*+1}\ge 0} + \textstyle\sum_{(i,\ell)\neq(i^*,\ell^*)} \widetilde{u}_{i,\ell} \cdot \widetilde{h}_{i,\ell} \cdot \mathbf{1}_{g_{i,\ell+1}\ge 0}\right\|_2}_{\clubsuit} \\
&\quad - \underbrace{\textstyle\sum_{i,\ell} \left\|u'_{i,\ell} \cdot \widetilde{h}_{i,\ell} + \widetilde{u}_{i,\ell} \cdot h'_{i,\ell} + u'_{i,\ell} \cdot h'_{i,\ell}\right\|_2}_{\spadesuit}
\end{aligned} \tag{6.48}$$

where recall $g_{i,\ell+1} = \langle W_k, h_{i,\ell}\rangle + \langle A_k, x_{i,\ell+1}\rangle$.

Step 1 To bound the ♠ term on the RHS of (6.48), we consider the following bounds:

1. Using Lemma 6.12.10, we have with probability at least $1 - e^{-\Omega(\rho^2)}$, for all i, ℓ, a

$$|(\widetilde{\mathsf{Back}}_{i,\ell\to a} \cdot \mathsf{loss}_{i,a})_k - (\mathsf{Back}_{i,\ell\to a} \cdot \mathsf{loss}_{i,a})_k| \le O\Big(\frac{\rho^3\tau_0^{1/3}N^{1/6}}{m^{1/6}}\Big) \cdot \|\,\mathsf{loss}_{i,a}\,\| \ .$$

This implies, by triangle inequality and the fact that $\| \mathsf{loss}_{i,a} \| \le \| \mathsf{loss}_{i^*,a^*} \|$,

$$\left|u'_{i,\ell}\right| = |u_{i,\ell} - \widetilde{u}_{i,\ell}| \le O\big(\frac{\rho^4 \tau_0^{1/3} N^{1/6}}{m^{1/6}}\big) \cdot \| \mathsf{loss}_{i^*,a^*} \| \ .$$

2. Using Corollary 6.11.16, we have with probability at least $1 - e^{-\Omega(\rho^2)}$, for all i, ℓ, a

$$|(\widetilde{\mathsf{Back}}_{i,\ell\to a} \cdot \mathsf{loss}_{i,a})_k| \le \rho \| \mathsf{loss}_{i,a} \| \ .$$

This implies, by triangle inequality and the fact that $\| \mathsf{loss}_{i,a} \| \le \| \mathsf{loss}_{i^*,a^*} \|$,

$$|\widetilde{u}_{i,\ell}| \le \rho^2 \| \mathsf{loss}_{i^*,a^*} \| \ .$$

3. Using Lemma 6.11.1 and Lemma 6.12.1a we have

$$\|\widetilde{h}_{i,\ell}\|_2 \le O(L) \quad \text{and} \quad \|h'_{i,\ell}\|_2 \le O(L^6 \tau_0 \sqrt{N})/m^{1/2}$$

All together, they imply

$$\sum_{i,\ell} \left\| u'_{i,\ell} \cdot \widetilde{h}_{i,\ell} + \widetilde{u}_{i,\ell} \cdot h'_{i,\ell} + u'_{i,\ell} \cdot h'_{i,\ell} \right\|_2 \le O\big(\tfrac{\rho^6 \tau_0^{1/3} N^{1/6}}{m^{1/6}}\big) \cdot \| \mathsf{loss}_{i^*,a^*} \| \ . \tag{6.49}$$

Step 2 We next turn to the ♣ term on the RHS of (6.48). We divide into three cases to analyze the sign change of $g_{i,\ell+1}$ for all possible i and ℓ in the above formula (under the randomness of W'_N). Before we do so, first note that Lemma 6.12.9 implies

$$|(W h'_{i,\ell})_k| = |(W_1 + W'_N) h'_{i,\ell}| \le O\Big(\frac{\rho^8 N^{2/3} \tau_0^{5/6}}{m^{2/3}}\Big) \tag{6.50}$$

1. Consider $g_{i,\ell+1}$ for the case of $i = i^*, \ell = \ell^*$. We want to show that the sign of $g_{i,\ell+1}$ changes (at least with constant probability) with respect to the randomness of W'_N.

One can easily check that:[20]

$$g_{i,\ell+1} = \langle A_k, x_{i,\ell+1}\rangle + (W_1\widetilde{h}_{i,\ell})_k + (Wh'_{i,\ell})_k + (W'_N v_{i,\ell})_k \cdot \|(I - U_{\ell-1}U_{\ell-1}^\top)h_{i,\ell}\|_2. \quad (6.51)$$

By Lemma 6.13.1, we have $|\langle A_k, x_{i,\ell}\rangle + (W_1\widetilde{h}_{i,\ell})_k| \le \frac{\beta_-}{\sqrt{m}}$ Thus, putting this and (6.50) into (6.51), we can write

$$g_{i,\ell+1} = \Xi + (W'_N v_{i,\ell})_k \cdot \|(I - U_{\ell-1}U_{\ell-1}^\top)\widetilde{h}_{i,\ell}\|_2$$

for some value Ξ with $|\Xi| \le \frac{2\beta_-}{\sqrt{m}}$. By Lemma 6.11.4, we have $\|(I - U_{\ell-1}U_{\ell-1}^\top)\widetilde{h}_{i,\ell}\|_2 \ge \Omega\big(\frac{1}{L^2\log^3 m}\big)$. By Lemma 6.14.3c, we have $(W'_N v_{i,\ell})_k$ shall be larger than $\frac{\theta}{2\sqrt{m}}$ and smaller than $-\frac{\theta}{2\sqrt{m}}$ each with probability at least $1/4$. Since by our choice of θ (see Definition 6.14.2),

$$\frac{\theta}{2\sqrt{m}} \cdot \Omega\big(\frac{1}{L^2\log^3 m}\big) \gg \frac{2\beta_-}{\sqrt{m}} \ge |\Xi|$$

This concludes that, with probability at least $1 - e^{-\Omega(\rho^2)}$ over W_1 and A, it satisfies

$$\Pr_{W'_N}[g_{i,\ell+1} > 0 \mid W_1, A] \ge \frac{1}{5} \quad \text{and} \quad \Pr_{W'_N}[g_{i,\ell+1} < 0 \mid W_1, A] \ge \frac{1}{5}$$

[20] We can write $(g_{i,\ell+1})_k = \langle A_k, x_{i,\ell+1}\rangle + (W(\widetilde{h}_{i,\ell} + h'_{i,\ell}))_k = \langle A_k, x_{i,\ell+1}\rangle + (W\widetilde{h}_{i,\ell})_k + (Wh'_{i,\ell})_k$. For the second term in the above equation, we have

$$\begin{aligned}
(W\widetilde{h}_{i,\ell})_k &= \left(WU_{\ell-1}U_{\ell-1}^\top\widetilde{h}_{i,\ell} + \frac{W(I - U_{\ell-1}U_{\ell-1}^\top)\widetilde{h}_{i,\ell}}{\|(I - U_{\ell-1}U_{\ell-1}^\top)\widetilde{h}_{i,\ell}\|_2}\|(I - U_{\ell-1}U_{\ell-1}^\top)\widetilde{h}_{i,\ell}\|_2\right)_k \\
&\overset{①}{=} \left(WU_{\ell-1}U_{\ell-1}^\top\widetilde{h}_{i,\ell} + Wv_{i,\ell}\|(I - U_{\ell-1}U_{\ell-1}^\top\widetilde{h}_{i,\ell})\|_2\right)_k \\
&\overset{②}{=} \left(W_1U_{\ell-1}U_{\ell-1}^\top\widetilde{h}_{i,\ell} + Wv_{i,\ell}\|(I - U_{\ell-1}U_{\ell-1}^\top\widetilde{h}_{i,\ell})\|_2\right)_k \\
&\overset{③}{=} \left(W_1U_{\ell-1}U_{\ell-1}^\top\widetilde{h}_{i,\ell} + W_1v_{i,\ell}\|(I - U_{\ell-1}U_{\ell-1}^\top\widetilde{h}_{i,\ell})\|_2\right)_k + \left(W'_N v_{i,\ell} \cdot \|(I - U_{\ell-1}U_{\ell-1}^\top\widetilde{h}_{i,\ell})\|_2\right)_k \\
&= (W_1\widetilde{h}_{i,\ell})_k + (W'_N v_{i,\ell})_k \cdot \|(I - U_{\ell-1}U_{\ell-1}^\top\widetilde{h}_{i,\ell})\|_2
\end{aligned}$$

where ① follows by definition of $v_{i,\ell}$, ② follows by definition of W_1, ③ follows by $W = W_1 + W'_N$.

2. Consider $g_{i,\ell+1}$ for the case of $i \in [n] \backslash \{i^*\}, \ell = \ell^*$ or $i \in [n], \ell > \ell^*$. We want to show the sign of $g_{i,\ell+1}$ is fixed, meaning with high probability independent of the choice of W'_N. One can easily check that:

$$g_{i,\ell+1} = \langle A_k, x_{i,\ell+1} \rangle + (W_1 \widetilde{h}_{i,\ell})_k + (W h'_{i,\ell})_k + (W'_N \widetilde{h}_{i,\ell})_k \ . \tag{6.52}$$

By Lemma 6.13.1, we have $|\langle A_k, x_{i,\ell} \rangle + (W_1 \widetilde{h}_{i,\ell})_k| \geq \frac{\beta_+}{\sqrt{m}}$. Thus, putting this and (6.50) into (6.53), we can write

$$g_{i,\ell+1} = \Xi + (W'_N \widetilde{h}_{i,\ell})_k = \Xi + (W'_N v_{i^*,\ell^*})_k \cdot \langle v_{i^*,\ell^*}, \widetilde{h}_{i,\ell} \rangle$$

for some value Ξ with $|\Xi| \geq \frac{\beta_+}{2\sqrt{m}}$. By Lemma 6.11.1, we have $|\langle v_{i^*,\ell^*}, \widetilde{h}_{i,\ell} \rangle| \leq \|\widetilde{h}_{i,\ell}\|_2 \leq O(L)$. By Lemma 6.14.3d, we have $|(W'_N v_{i^*,\ell^*})_k| \leq \frac{2\theta\rho}{\sqrt{m}}$ and by our choice of θ (see Definition 6.14.2),

$$\frac{2\theta\rho}{\sqrt{m}} \cdot O(L) \ll \frac{2\beta_+}{\sqrt{m}} \leq |\Xi|$$

This concludes that, with probability at least $1 - e^{-\Omega(\rho^2)}$ over W_1 and A, it satisfies

$$\exists s \in \{-1, 1\} \colon \quad \Pr_{W'_N} [\operatorname{sgn}(g_{i,\ell+1}) = s \mid W_1, A] \geq 1 - e^{-\Omega(\rho^2)} \ .$$

3. Consider $g_{i,\ell+1}$ for the case of $i \in [n]$ and $\ell < \ell^*$. We want to show such $g_{i,\ell+1}$ is fixed, meaning independent of W'_N. One can easily check that:

$$g_{i,\ell+1} = \langle A_k, x_{i,\ell+1} \rangle + (W_1 \widetilde{h}_{i,\ell})_k + (W h'_{i,\ell})_k + (W'_N \widetilde{h}_{i,\ell})_k \ . \tag{6.53}$$

Now, since $\ell < \ell^*$, we know $h_{i,\ell} = \widetilde{h}_{i,\ell}$ because both of which only depend on the randomness of $W U_{\ell^*-1} = W_1 U_{\ell^*-1}$ and A; this implies $h'_{i,\ell} = 0$. Also, since $W'_N = (W'_N v_{i^*,\ell^*}) v_{i^*,\ell^*}^\top$ but $\langle v_{i^*,\ell^*}, \widetilde{h}_{i,\ell} \rangle = 0$, we know that

$$g_{i,\ell+1} = \langle A_k, x_{i,\ell+1} \rangle + (W_1 \widetilde{h}_{i,\ell})_k \ .$$

This is a fixed value, independent of W'_N.

Therefore, combining the three cases above, we conclude that with at least constant probability, the sign of g_{i^*,ℓ^*+1} can possibly change, but the sign of $g_{i,\ell+1}$ will not change for any other $(i,\ell) \neq (i^*,\ell^*)$. This means,

$$\begin{aligned}\mathbb{E}[\clubsuit] &= \mathbb{E}\left[\left\|\widetilde{u}_{i^*,\ell^*} \cdot \widetilde{h}_{i^*,\ell^*} \cdot \mathbf{1}_{g_{i^*,\ell^*+1}\geq 0} + \textstyle\sum_{(i,\ell)\neq(i^*,\ell^*)} \widetilde{u}_{i,\ell} \cdot \widetilde{h}_{i,\ell} \cdot \mathbf{1}_{g_{i,\ell+1}\geq 0}\right\|_2\right] \\ &\geq \Omega(\|\widetilde{u}_{i^*,\ell^*}\widetilde{h}_{i^*,\ell^*}\|_2) = \Omega\big(|\widetilde{u}_{i^*,\ell^*}| \cdot \|\widetilde{h}_{i^*,\ell^*}\|_2\big)\end{aligned}$$

Finally, for each $k \in N_5$, owing to Lemma 6.13.5 and Lemma 6.11.1, we have

$$|\widetilde{u}_{i^*,\ell^*}|_2 = \left|\sum_{a=\ell^*}^{L} (\widetilde{\mathsf{Back}}_{i^*,\ell^*\to a}^{\top} \mathsf{loss}_{i^*,a})_k\right| \geq \frac{\|\,\mathsf{loss}_{i^*,\ell^*}\,\|_2}{6\sqrt{d}nL} \quad \text{and} \quad \|\widetilde{h}_{i^*,\ell^*}\|_2 \geq \frac{1}{2}\ .$$

This means,

$$\mathbb{E}[\clubsuit] \geq \Omega\left(\frac{\|\,\mathsf{loss}_{i^*,\ell^*}\,\|_2}{\sqrt{d}nL}\right)\ . \tag{6.54}$$

Putting (6.49) and (6.54) back to (6.48), we conclude that

$$\forall k \in N_5 \colon \quad \mathbb{E}[\|\widehat{\nabla}_k f(W)\|] \geq \Omega\left(\frac{\|\,\mathsf{loss}_{i^*,\ell^*}\,\|_2}{\sqrt{d}nL}\right)\ .$$

□

6.14.2.2 Core Lemma A

In Lemma 6.14.5, we split W into $W = W_1 + W'_N$ for a fixed $N \subseteq [m]$. In this subsection, we split W into three parts $W = W_2 + W'_N + W'_{-N}$ following Lemma 6.14.4c. Our purpose is to rewrite Lemma 6.14.5 into the following variant:

Lemma 6.14.6 (Core Lemma A). *Let $\rho = nLd\log m$ and $\varrho = nLd\delta^{-1}\log(m/\epsilon)$. Fix vectors $\{\mathsf{loss}_{i,\ell} \in \mathbb{R}^d\}_{i\in[n],\ell\in[L]\setminus\{1\}}$, integer $|N| \in [\rho^6/\beta_-, \varrho^{100}]$, and parameter $t = m/|N|$. Let $N_1, \ldots, N_t$ be i.i.d. random subsets of $[m]$ with cardinality $|N_i| = |N|$. Then,*

- *with probability $\geq 1 - e^{-\Omega(\rho^2)}$ over the randomness of W_2, A, B and $N_1, \cdots N_t$, the following holds:*
  - *for every $N \in \{N_1, N_2, \cdots, N_t\}$, the following holds:*
    - *with probability at $1 - e^{-\Omega(\rho^2)}$ over the randomness of W'_{-N}, the following holds:*

$$\sum_{k\in N} \mathop{\mathbb{E}}_{W'_N}\left[\|\widehat{\nabla}_k f(W_2 + W'_N + W'_{-N})\|_2^2\right] \geq \Omega\left(\frac{\beta_-|N|}{\rho^2}\right) \cdot \max_{i,\ell} \|\,\mathsf{loss}_{i,\ell}\,\|_2^2.$$

Proof of Lemma 6.14.6. We denote by $(i^*, \ell^*) = \mathrm{argmax}_{i,\ell} \|\,\mathsf{loss}_{i,\ell}\,\|_2$. We first note that Lemma 6.14.5 directly implies

- with probability $\geq 1 - e^{-\Omega(\rho^2)}$ over the randomness of W_2, W'_{-N}, A, B, N, the following holds:

$$\left|\left\{k \in N \;\middle|\; \mathop{\mathbb{E}}_{W'_N}\left[\|\widehat{\nabla}_k f(W_2 + W'_{-N} + W'_N)\|_2\right] \geq \Omega\Big(\frac{\|\,\mathsf{loss}_{i^*,\ell^*}\,\|_2}{nL\sqrt{d}}\Big)\right\}\right| \geq \frac{\beta_-}{100L}|N|$$

or putting it in another way, using our choice of q,

- with probability $\geq 1 - e^{-\Omega(\rho^2)}$ over the randomness of W_2, W'_{-N}, A, B, N, the following holds ($q = \frac{\beta_-|N|}{c\rho^2}$ for some sufficiently large constant):

$$\sum_{k\in N} \mathop{\mathbb{E}}_{W'_N}\left[\|\widehat{\nabla}_k f(W_2 + W'_{-N} + W_N)\|_2^2\right] \geq q \cdot \|\,\mathsf{loss}_{i^*,\ell^*}\,\|_2^2.$$

Applying simple tricks to switch the ordering of randomness (see Fact 6.10.2), we have

- with probability $\geq 1 - e^{-\Omega(\rho^2)}$ over the randomness of W_2, A, B, the following holds:

- with probability $\geq 1 - e^{-\Omega(\rho^2)}$ over the randomness of N, the following holds:
  - $*$ with probability $\geq 1 - e^{-\Omega(\rho^2)}$ over randomness of W'_{-N}, the following holds:

$$\sum_{k \in N} \mathop{\mathbb{E}}_{W'_N} [\|\widehat{\nabla}_k f(W_2 + W'_N + W'_{-N})\|_2^2] \geq q \cdot \| \mathsf{loss}_{i^*,\ell^*} \|_2^2.$$

Repeating the choice of N for t times, and using union bound, we have

- with probability $\geq 1 - e^{-\Omega(\rho^2)}$ over the randomness of W_2, A, B, the following holds:
  - with probability $\geq 1 - e^{-\Omega(\rho^2)}$ over the randomness of $N_1, N_2, \cdots, N_t$, the following holds:
    - $*$ for all $N \in \{N_1, N_2, \cdots, N_t\}$, the following holds:
      - $\cdot$ with probability $\geq 1 - e^{-\Omega(\rho^2)}$ over randomness of W'_{-N}, the following holds:

$$\sum_{k \in N} \mathop{\mathbb{E}}_{W'_N} [\|\widehat{\nabla}_k f(W_2 + W'_N + W'_{-N})\|_2^2] \geq q \cdot \| \mathsf{loss}_{i^*,\ell^*} \|_2^2.$$

Combining the above statement with Fact 6.10.1 (to merge randomness), we conclude the proof. □

6.14.3 Gradient Stability

The goal of this subsection is to prove Lemma 6.14.7 and then translate it into our Core Lemma B (see Lemma 6.14.9).

Lemma 6.14.7 (c.f. (6.19))**.** *Fix parameter* $\rho = nLd\log m$*, vectors* $\{\mathsf{loss}_{i,\ell} \in \mathbb{R}^d\}_{i\in[n],\ell\in[L]\setminus\{1\}}$*,* $(i^*,\ell^*) = \mathrm{argmin}_{i,\ell}\{\|\mathsf{loss}_{i,\ell}\|\}$*, index* $j \in [m]$*. Let* $N \subseteq [m]$ *be a random subset containing* j *of fixed cardinality* $|N|$*, let* W, A, B *be at random initialization, and* W_j'' *be defined as Definition 6.14.4a so that* $W + W_j''$ *is also at random initialization. Then, with probability at least* $1 - e^{-\Omega(\rho^2)}$

$$\sum_{k\in[N]} \left| \|\widehat{\nabla}_k(W)\|_2^2 - \|\widehat{\nabla}_k(W + W_j'')\|_2^2 \right| \le O\left(\rho^8 + \frac{\rho^{11}\theta^{1/3}}{m^{1/6}}|N|\right) \quad . \tag{6.55}$$

6.14.3.1 Proof of Lemma 6.14.7

Throughout this proof we denote by $\widetilde{W} = W$ to emphasize that W is at random initialization. We first show some properties before proving Lemma 6.14.7.

Claim 6.14.8. *Fix parameter* $\rho = nLd\log m$*, vectors* $\{\mathsf{loss}_{i,\ell} \in \mathbb{R}^d\}_{i\in[n],\ell\in[L]\setminus\{1\}}$*,* $(i^*,\ell^*) = \mathrm{argmin}_{i,\ell}\{\|\mathsf{loss}_{i,\ell}\|\}$*, index* $j \in [m]$*. Let* $\widetilde{W}, A, B$ *be at random initialization, and* W_j'' *be defined as Lemma 6.14.4a so that* $W = \widetilde{W} + W_j''$ *is also at random initialization. Then, then with probability* $\ge 1 - e^{-\Omega(\rho^2)}$ *over* $\widetilde{W}, A, B, W_j''$*,*

- $\left|\left\{k \in [m] \;\middle|\; \left|\|\widehat{\nabla}_k f(\widetilde{W} + W_j'')\|_2^2 - \|\widehat{\nabla}_k f(\widetilde{W})\|_2^2\right| \le O\left(\frac{\rho^{11}\theta^{1/3}}{m^{1/6}}\right)\right\}\right| \ge \left(1 - \frac{\rho^5\theta^{2/3}}{m^{1/3}}\right)m$.
- $\left|\|\widehat{\nabla}_k f(\widetilde{W} + W_j'')\|_2^2 - \|\widehat{\nabla}_k f(\widetilde{W})\|_2^2\right| \le O(\rho^6)$ *for every* $k \in [m]$*.*

Proof of Claim 6.14.8. As before, let $\widetilde{D}_{i,\ell}$ denote the diagonal matrix consisting of the indicator function $\mathbb{1}_{(\widetilde{g}_{i,\ell+1})_k \geq 0}$ for its k-th diagonal entry. Let $D_{i,\ell}$ be the same thing but with respect to weight matrix $\widetilde{W} + W_j''$. Let $D''_{i,\ell} = D_{i,\ell} - \widetilde{D}_{i,\ell}$ be the diagonal matrix of sign change.

- By Lemma 6.12.1 (with $\tau_0 = \frac{3\theta\rho}{2}$ owing to Lemma 6.14.3d), we have $\|D''_\ell\|_0 \leq \rho^4\theta^{2/3}m^{2/3}$. Therefore, letting $J \stackrel{\text{def}}{=} [m] \setminus \cup_{i,\ell} \operatorname{supp}(D_{i,\ell})$ be the set of all indices of sign changes, we have

$$|J| \geq m - nL\rho^4\theta^{2/3}m^{2/3} \geq \left(1 - \frac{\rho^5\theta^{2/3}}{m^{1/3}}\right) \cdot m.$$

  Next, for every index $k \in J$, we have

$$\begin{aligned}
&\|\widehat{\nabla}_k f(\widetilde{W} + W_j'') - \widehat{\nabla}_k f(\widetilde{W})\|_2 \\
\stackrel{①}{=}& \left\| \sum_{i=1}^n \sum_{\ell=1}^L (\widetilde{u}_{i,\ell})_k \cdot \widetilde{h}_{i,\ell} \cdot \mathbf{1}_{(\widetilde{g}_{i,\ell+1})_k \geq 0} - \sum_{i=1}^n \sum_{\ell=1}^L (u_{i,\ell})_k \cdot h_{i,\ell} \cdot \mathbf{1}_{(g_{i,\ell+1})_k \geq 0} \right\|_2 \\
\stackrel{②}{=}& \left\| \sum_{i=1}^n \sum_{\ell=1}^L (\widetilde{u}_{i,\ell})_k \cdot \widetilde{h}_{i,\ell} \cdot \mathbf{1}_{(g_{i,\ell+1})_k \geq 0} - \sum_{i=1}^n \sum_{\ell=1}^L (u_{i,\ell})_k \cdot h_{i,\ell} \cdot \mathbf{1}_{(g_{i,\ell+1})_k \geq 0} \right\|_2 \\
\stackrel{③}{\leq}& \sum_{i=1}^n \sum_{\ell=1}^L \|((\widetilde{u}_{i,\ell})_k \cdot \widetilde{h}_{i,\ell} - (u_{i,\ell})_k \cdot h_{i,\ell}) \cdot \mathbf{1}_{(g_{i,\ell+1})_k \geq 0}\|_2 \ .
\end{aligned}$$

  where ① follows by definition, ② follows by our choice of $k \in J$, and ③ follows by triangle inequality. For each i, ℓ, using the same proof as (6.49) (so invoking Lemma 6.12.10, Corollary 6.11.16, Lemma 6.11.1 and Lemma 6.12.1a), we have with probability at least $1 - e^{-\Omega(\rho^2)}$:

$$\|(\widetilde{u}_{i,\ell})_k \cdot \widetilde{h}_{i,\ell} - (u_{i,\ell})_k \cdot h_{i,\ell}\|_2 \leq O\Big(\frac{\rho^6 \tau_0^{1/3}}{m^{1/6}}\Big) \cdot \|\, \mathsf{loss}_{i^*,a^*} \,\| \ . \tag{6.56}$$

which implies

$$\|\widehat{\nabla}_k f(\widetilde{W}+W_j'')-\widehat{\nabla}_k f(\widetilde{W})\|_2 \le O\big(\frac{\rho^6\tau_0^{1/3}}{m^{1/6}}\big)\cdot\|\,\mathsf{loss}_{i^*,a^*}\,\|\ .$$

Combining this with $\|\widehat{\nabla}_k f(\widetilde{W})\|_2 \le O(\rho^4)$ from Lemma 6.14.1, we finish the proof of the first item.

- For every index $k\in[m]$, we have

$$\begin{aligned}
&\|\widehat{\nabla}_k f(\widetilde{W}+W_j'')-\widehat{\nabla}_k f(\widetilde{W})\|_2 \\
=\ &\left\|\sum_{i=1}^n\sum_{\ell=1}^L(\widetilde{u}_{i,\ell})_k\cdot\widetilde{h}_{i,\ell}\cdot\mathbf{1}_{(\widetilde{g}_{i,\ell+1})_k\ge0}-\sum_{i=1}^n\sum_{\ell=1}^L(u_{i,\ell})_k\cdot h_{i,\ell}\cdot\mathbf{1}_{(g_{i,\ell+1})_k\ge0}\right\|_2 \\
\le\ &\sum_{i=1}^n\sum_{\ell=1}^L\|(\widetilde{u}_{i,\ell})_k\cdot\widetilde{h}_{i,\ell}\|_2+\|(u_{i,\ell})_k\cdot h_{i,\ell})\|_2\ .
\end{aligned}$$

Using (6.56) and $\|(\widetilde{u}_{i,\ell})_k\cdot\widetilde{h}_{i,\ell}\|_2\le O(\rho^2 L)$ (see the proof of Lemma 6.14.1), we immediately have the desired bound.

□

Proof of Lemma 6.14.7. Letting $J\stackrel{\text{def}}{=}\left\{k\in[m]\ \middle|\ \left|\|\widehat{\nabla}_k f(\widetilde{W}+W_j'')\|_2^2-\|\widehat{\nabla}_k f(\widetilde{W})\|_2^2\right|\le O\left(\frac{\rho^{11}\theta^{1/3}}{m^{1/6}}\right)\right\}$, we have $|J|\ge\left(1-\frac{\rho^5\theta^{2/3}}{m^{1/3}}\right)m$ according to Claim 6.14.8.

Now, for the indices in N that are randomly sampled from $[m]$, if $|N\cap J|\ge|N|-S$ for a parameter $S=\rho^2$, then we have

$$\sum_{k\in N}\left|\|\widehat{\nabla}_k f(\widetilde{W})\|_2^2-\|\widehat{\nabla}_k f(\widetilde{W}+W_j'')\|_2^2\right|\le|S|\cdot O(\rho^6)+|N|\cdot O\left(\frac{\rho^{11}\theta^{1/3}}{m^{1/6}}\right)\le O\left(\rho^8+\frac{\rho^{11}\theta^{1/3}}{m^{1/6}}|N|\right)\ .$$

Otherwise, if $|N\cap J|\le|N|-S$, this means at least S indices that are chosen from N are outside $J\subseteq[m]$. This happens with probability at most $\left(\frac{\rho^5\theta^{2/3}}{m^{1/3}}\right)^S\le e^{-\Omega(\rho^2)}$. □

6.14.3.2 Core Lemma B

In this subsection, we split W into three parts $W = W_2 + W'_N + W'_{-N}$ following def:random-decomp:N-N. Our purpose is to rewrite Lemma 6.14.7 into the following variant:

Lemma 6.14.9 (Core Lemma B)**.** *Let $\rho = nLd\log m$ and $\varrho = nLd\delta^{-1}\log(m/\epsilon)$. Fix parameter θ from Definition 6.14.2, vectors $\{\mathsf{loss}_{i,\ell} \in \mathbb{R}^d\}_{i\in[n],\ell\in[L]\setminus\{1\}}$, integer $|N| \in [1, \varrho^{100}]$, parameter $t = m/|N|$. Let $N_1, \ldots, N_t$ be i.i.d. random subsets of $[m]$ with cardinality $|N_i| = |N|$. Then, with probability $\geq 1 - e^{-\Omega(\rho^2)}$ over the randomness of W_2, A, B and $N_1, \cdots N_t$, the following holds:*

- *for every $N \in \{N_1, N_2, \cdots, N_t\}$, the following holds:*
  - *with probability at $1 - e^{-\Omega(\rho^2)}$ over the randomness of W'_{-N}, the following holds:*
    - *with probability at least $1 - e^{-\Omega(\rho^2)}$ over the randomness of W'_N,we have :*
      - *for all $j \in N$, and for all $W''_j = u_j v_{i^*,\ell^*}^\top$ satisfying*

$$\|u_j\|_0 = 1, \quad \|u_j\|_\infty \leq \tfrac{3\theta\rho}{\sqrt{m}}, \quad v_{i^*,\ell^*} = \tfrac{(I - U_{\ell^*-1}U_{\ell-1}^\top)h_{i^*,\ell}h_{i^*,\ell^*}}{\|(I - U_{\ell^*-1}U_{\ell^*-1}^\top)h_{i^*,\ell^*}\|_2} \ , \tag{6.57}$$

we have

$$\begin{aligned}&\textstyle\sum_{k\in N}\Big|\|\widehat{\nabla}_k f(W_2 + W'_N + W'_{-N})\|_2^2 - \|\widehat{\nabla}_k f(W_2 + W'_N + W'_{-N} + W''_j)\|_2^2\Big| \\ &\leq O(\rho^8)\cdot \max_{i,\ell}\|\,\mathsf{loss}_{i,\ell}\,\|_2^2 \ .\end{aligned}$$

Proof of Lemma 6.14.9. Without loss of generality we assume $\max_{i,\ell}\|\,\mathsf{loss}_{i,\ell}\,\|_2^2 = 1$ in the proof. We now first rewrite Lemma 6.14.7 as follows (recalling m is sufficiently large so we only need to keep the $O(\rho^8)$ term):

- with probability $\geq 1 - e^{-\Omega(\rho^2)}$ over random $N \subset [m]$, random $j \in N$, random W, A, B, and random W'_j, the following holds:

$$\sum_{k \in [N]} \left| \|\widehat{\nabla}_k(W)\|_2^2 - \|\widehat{\nabla}_k(W + W''_j)\|_2^2 \right| \leq O\left(\rho^8 + \frac{\rho^{11}\theta^{1/3}}{m^{1/6}}|N|\right) \leq O(\rho^8) \ . \tag{6.58}$$

We can split the randomness (see Fact 6.10.1) and derive that

- With probability $\geq 1 - e^{-\Omega(\rho^2)}$ over $N \subseteq [m]$, W, A, B, the following holds:
  - With probability $\geq 1 - e^{-\Omega(\rho^2)}$ over $j \in N$ and W''_j, Eq. (6.58) holds.

Applying standard ϵ-net argument, we derive that

- With probability $\geq 1 - e^{-\Omega(\rho^2)}$ over $N \subseteq [m]$, W, A, B, the following holds:
  - for all $j \in N$, and for all $W''_j = u_j v_{i^*,\ell^*}^\top$ satisfying (6.57), we have Eq. (6.58) holds.

Finally, letting $W = W_2 + W'_N + W'_{-N}$, we have

- With probability $\geq 1 - e^{-\Omega(\rho^2)}$ over the randomness of $N \subseteq [m], W_2, W_N, W'_{-N}, A, B$, the following holds:
  - for all $j \in N$, and for all $W''_j = u_j v_{i^*,\ell^*}^\top$ satisfying (6.57), we have

$$\sum_{k \in N} \left| \|\widehat{\nabla}_k f(W_2 + W'_N + W'_{-N})\|_2^2 - \|\widehat{\nabla}_k f(W_2 + W'_N + W_{-N'} + W''_j)\|_2^2 \right| \leq O\left(\rho^8\right) \ .$$

Finally, splitting the randomness (using Fact 6.10.1), and applying a union bound over multiple samples $N_1, \ldots, N_t$, we finish the proof. □

6.14.4 Main Theorem: Proof of Theorem 6.14.2

Proof of Theorem 6.14.2. Without loss of generality, we assume that $\max_{i,\ell} \| \mathsf{loss}_{i,\ell} \|_2^2 = 1$.

Combining Core Lemma A and B (i.e., Lemma 6.14.6 and Lemma 6.14.9), we know that if $|N|$ is appropriately chosen, with probability $\geq 1 - e^{-\Omega(\rho^2)}$ over the randomness of W_2, A, B and $N_1, \cdots N_t$, the following holds:

- for every $N \in \{N_1, N_2, \cdots, N_t\}$, the following holds:
  - with probability at $1 - e^{-\Omega(\rho^2)}$ over the randomness of W'_{-N}, the following boxed statement holds:
- (core A)

$$\mathbb{E}_{W'_N} \left[\textstyle\sum_{k \in N} \| \widehat{\nabla}_k f(W_2 + W'_N + W'_{-N}) \|_2^2 \right] \geq q \stackrel{\text{def}}{=} \Omega\left(\tfrac{\beta_- |N|}{\rho^2} \right)$$

- (core B) with probability at least $1 - e^{-\Omega(\rho^2)}$ over the randomness of W'_N, the following holds:
  - for all $j \in N$, and for all $W''_j = u_j v_{i^*,\ell^*}^\top$ satisfying

$$\|u_j\|_0 = 1, \quad \|u_j\|_\infty \leq \tfrac{3\theta\rho}{\sqrt{m}}, \quad v_{i^*,\ell^*} = \tfrac{(I - U_{\ell^*-1} U_{\ell-1}^\top) h_{i^*,\ell} h_{i^*,\ell^*}}{\|(I - U_{\ell^*-1} U_{\ell^*-1}^\top) h_{i^*,\ell^*}\|_2} \ ,$$

    we have

$$\textstyle\sum_{k \in N} \left| \| \widehat{\nabla}_k f(W_2 + W'_N + W'_{-N}) \|_2^2 - \| \widehat{\nabla}_k f(W_2 + W'_N + W'_{-N} + W''_j) \|_2^2 \right| \leq p \stackrel{\text{def}}{=} O(\rho^8) \ .$$

We now wish to apply our extended McDiarmid's inequality (see Lemma 6.10.18) to the boxed statement. For this goal, recalling that $W'_N = u_N v_{i^*,\ell^*}^\top$ for a vector $u_N \in \mathbb{R}^m$ that is only supported on indices in N. That is, $(u_N)_k = 0$ for all $k \notin N$. Therefore, we can define function $F(u_N) \stackrel{\text{def}}{=} \sum_{k \in N} \| \widehat{\nabla}_k f(W_2 + W'_{-N} + W'_N) \|^2$ where $W'_N = u_N v_{i^*,\ell^*}^\top$. We emphasize

here that, inside the boxed statement, W_2, W'_{-N} and v_{i^*,ℓ^*} are already fixed, and u_N is the only source of randomness.

Below, we condition on the high probability event (see Lemma 6.14.3d) that $\|u_N\|_\infty \leq \frac{3\theta\rho}{2\sqrt{m}}$. The boxed statement tells us:

- $\mathbb{E}_{u_N}\left[\digamma(u_N)\right] \geq q$, and
- With probability $\geq 1 - e^{-\Omega(\rho^2)}$ over u_N, it satisfies

$$\forall j \in [N], \forall u''_j \colon \left|\digamma(u_{-j}, u_j) - \digamma(u_{-j}, u''_j)\right| \leq p \ .$$

At the same time, we have $0 \leq \digamma(u_N) \leq O(N\rho^8)$ owing to Lemma 6.14.1. Therefore, scaling down $\digamma(u_N)$ by $\Theta(N\rho^8)$ (to make sure the function value stays in $[0,1]$), we can applying extended McDiarmid's inequality (see Lemma 6.10.18), we have

$$\Pr_{u_N}\left[\digamma(u_N) \geq \frac{q}{2}\right] \geq 1 - N^2 \cdot e^{-\Omega(\rho^2)} - \exp\left(-\Omega\left(\frac{(q/\rho^8)^2}{N(p/\rho^8)^2 + Ne^{-\Omega(\rho^2)}}\right)\right) \ . \tag{6.59}$$

As long as $N \geq \frac{\rho^{22}}{\beta_-^2}$, we have that the above probability is at least $1 - e^{-\Omega(\rho^2)}$.

Finally, we choose

$$\boxed{N = \frac{\rho^{22}}{\beta_-^2}} \tag{6.60}$$

in order to satisfy Lemma 6.14.6. We replace the boxed statement with (6.59). This tells us

- with probability $\geq 1 - e^{-\Omega(\rho^2)}$ over the randomness of W_2, A, B and $N_1, \cdots N_t$, the following holds:
  - for every $N \in \{N_1, N_2, \cdots, N_t\}$, the following holds:

* with probability at $1 - e^{-\Omega(\rho^2)}$ over the randomness of W'_{-N} and W'_N, the following holds:

$$\sum_{k \in N} \|\widehat{\nabla}_k f(W_2 + W'_N + W'_{-N})\|_2^2 \geq \Omega\left(\frac{\beta_- |N|}{\rho^2}\right)$$

After rearranging randomness, and using $W = W_2 + W'_N + W'_{-N}$, we have

- with probability $\geq 1 - e^{-\Omega(\rho^2)}$ over the randomness of W, A, B, the following holds:
  - with probability $\geq 1 - e^{-\Omega(\rho^2)}$ over the randomness of $N_1, \cdots N_t$, the following holds:
    * for every $N \in \{N_1, N_2, \cdots, N_t\}$, the following holds:

$$\sum_{k \in N} \|\widehat{\nabla}_k f(W)\|_2^2 \geq \Omega\left(\frac{\beta_- |N|}{\rho^2}\right)$$

Finally, since $N_1, \ldots, N_t$ are t random subsets of $[m]$, we know that with probability at least $1 - e^{-\Omega(\rho^2)}$, for each index $k \in [m]$, it is covered by at most ρ^2 random subsets. Therefore,

$$\sum_{k \in N} \|\widehat{\nabla}_k f(W)\|_2^2 \geq \frac{1}{\rho^2} \times t \times \Omega\left(\frac{\beta_- |N|}{\rho^2}\right) = \Omega\left(\frac{\delta}{\rho^{14}}\right) \times m \ .$$

□

6.15 Gradient Bound After Perturbation (Theorem 6.15.2)

We use the same fake gradient notion (see Definition 6.14.1) and first derive the following result based on Lemma 6.14.1 and Theorem 6.14.2.

Lemma 6.15.1. *Let* $\rho = nLd\log m$ *and* $\varrho = nLd\delta^{-1}\log(m/\epsilon)$. *Given fixed vectors* $\{\mathsf{loss}_{i,\ell} \in \mathbb{R}^d\}_{i\in[n],\ell\in[L]\setminus\{1\}}$, *with probability at least* $1 - e^{-\Omega(\rho^2)}$ *over* $\widetilde{W}, A, B$, *it satisfies for* all $W' \in \mathbb{R}^{m\times m}$ *with* $\|W'\|_2 \le \frac{\tau_0}{\sqrt{m}}$ *with* $\tau_0 \le \varrho^{100}$,

$$\|\widehat{\nabla} f(\widetilde{W}+W')\|_F^2 \ge \Omega\left(\frac{\delta}{\rho^{14}}\right) \times m \times \max_{i,\ell}\{\|\mathsf{loss}_{i,\ell}\|^2\}$$
$$\|\widehat{\nabla} f(\widetilde{W}+W')\|_F^2 \le O(\rho^{12}m) \times \max_{i,\ell}\{\|\mathsf{loss}_{i,\ell}\|^2\}$$
$$\|\widehat{\nabla} f_i(\widetilde{W}+W')\|_F^2 \le \frac{1}{n^2}O(\rho^{12}m) \times \max_{i,\ell}\{\|\mathsf{loss}_{i,\ell}\|^2\} \ .$$

Proof of Lemma 6.15.1. Like before, we denote by $\widetilde{D}_{i,\ell}, \widetilde{u}_{i,\ell}, \widetilde{h}_{i,\ell}$ the corresponding matrices or vectors when the weight matrix is $\widetilde{W}$, and by $D_{i,\ell}, u_{i,\ell}, h_{i,\ell}$ the corresponding terms when when the weight matrix is $W = \widetilde{W} + W'$.

Lower bound on $\|\widehat{\nabla} f(\widetilde{W}+W')\|_F$ Recall

$$\widehat{\nabla} f(\widetilde{W}+W') = \sum_{i=1}^{n}\sum_{\ell=1}^{L} D_{i,\ell+1}\left(\sum_{a=\ell}^{L}\mathsf{Back}_{i,\ell\to a}^\top \mathsf{loss}_{i,a}\right) h_{i,\ell}^\top = \sum_{i=1}^{n}\sum_{\ell=1}^{L} D_{i,\ell+1}u_{i,\ell}h_{i,\ell}^\top$$

In Theorem 6.14.2 of the previous section, we already have a lower bound on $\|\widehat{\nabla} f(\widetilde{W})\|_F$.

We just need to upper bound $\|\widehat{\nabla} f(\widetilde{W}+W') - \widehat{\nabla} f(\widetilde{W})\|_F$.

$$\begin{aligned}
\|\widehat{\nabla} f(\widetilde{W}+W') - \widehat{\nabla} f(\widetilde{W})\|_F &\overset{①}{=} \left\| \sum_{i=1}^{n}\sum_{\ell=1}^{L} D_{i,\ell+1} u_{i,\ell} h_{i,\ell}^\top - \widetilde{D}_{i,\ell+1}\widetilde{u}_{i,\ell}\widetilde{h}_{i,\ell}^\top \right\|_F \\
&\overset{②}{\le} \sum_{i=1}^{n}\sum_{\ell=1}^{L} \left\| D_{i,\ell+1} u_{i,\ell} h_{i,\ell}^\top - \widetilde{D}_{i,\ell+1}\widetilde{u}_{i,\ell}\widetilde{h}_{i,\ell}^\top \right\|_F \\
&\overset{③}{\le} \sum_{i=1}^{n}\sum_{\ell=1}^{L} \|D'_{i,\ell+1}\widehat{u}_{i,\ell}\widehat{h}_{i,\ell}^\top\|_F + \|\widetilde{D}_{i,\ell+1}u'_{i,\ell}\widehat{h}_{i,\ell}^\top\|_F + \|\widetilde{D}_{i,\ell+1}\widetilde{u}_{i,\ell}{h'_{i,\ell}}^\top\|_F + o(m^{1/3}).
\end{aligned}$$

where ① follows by definition and ② and ③ follow by the triangle inequality. Note that in inequality ③ we have hidden four more higher order terms in $o(m^{1/3})$. We ignore the details for how to bound them, for the ease of presentation. We bound the three terms separately:

- Using Corollary 6.11.15 (with $s^2 = O(L^{10/3}\tau_0^{2/3})$ from Lemma 6.12.1b) and Lemma 6.11.1 we have

$$\begin{aligned}
\|D'_{i,\ell+1}\widehat{u}_{i,\ell}\widehat{h}_{i,\ell}^\top\|_F &\le \|D'_{i,\ell+1}\widehat{u}_{i,\ell}\|_2 \cdot \|\widehat{h}_{i,\ell}\|_2 \\
&\le O(L \cdot L^4\tau_0^{1/3}m^{1/3}\log m \cdot \|\,\mathsf{loss}_{i^*,\ell^*}\,\|_2)\cdot L
\end{aligned}$$

- Using $\|\widetilde{D}_{i,\ell+1}\|_2 \le 1$, Lemma 6.12.8 and Lemma 6.11.1 we have

$$\begin{aligned}
\|\widetilde{D}_{i,\ell+1}u'_{i,\ell}\widehat{h}_{i,\ell}^\top\|_F &\le \|\widetilde{D}_{i,\ell+1}\| \cdot \|u'_{i,\ell}\|_2 \cdot \|\widehat{h}_{i,\ell}\|_2 \\
&\le O(L \cdot L^6\tau_0^{1/3}m^{1/3}\log m \cdot \|\,\mathsf{loss}_{i^*,\ell^*}\,\|_2)\cdot L
\end{aligned}$$

- Using $\|\widetilde{D}_{i,\ell+1}\|_2 \le 1$, $\|\widetilde{u}_{i,\ell}\|_2 \le O(L^4)\sqrt{m}\|\,\mathsf{loss}_{i^*,\ell^*}\,\|_2$ (implied by Lemma 6.11.8) and Lemma 6.12.1a, we have

$$\begin{aligned}
\|\widetilde{D}_{i,\ell+1}\widetilde{u}_{i,\ell}{h'_{i,\ell}}^\top\|_F &\le \|\widetilde{D}_{i,\ell+1}\| \cdot \|\widetilde{u}_{i,\ell}\|_2 \cdot \|h'_{i,\ell}\|_2 \\
&\le O(L^4\sqrt{m} \cdot \|\,\mathsf{loss}_{i^*,\ell^*}\,\|_2)\cdot (L^6\tau_0^{1/2}\frac{1}{\sqrt{m}})
\end{aligned}$$

Putting it all together, we have

$$\|\widehat{\nabla} f(\widetilde{W}+W') - \widehat{\nabla} f(\widetilde{W})\|_F \le O(\rho^8 \tau_0^{1/3} m^{1/3}) \cdot \|\,\mathsf{loss}_{i^*,\ell^*}\,\|_F \ . \tag{6.61}$$

Finally, using $(a-b)^2 \ge \frac{1}{2}a^2 - b^2$, we have

$$\begin{aligned}
\|\widehat{\nabla} f(\widetilde{W}+W')\|_F^2 &\ge (\|\widehat{\nabla} f(\widetilde{W})\|_F - \|\widehat{\nabla} f(\widetilde{W}+W') - \widehat{\nabla} f(\widetilde{W})\|_F)^2 \\
&\ge \frac{1}{2}\|\widehat{\nabla} f(\widetilde{W})\|_F^2 - \|\widehat{\nabla} f(\widetilde{W}+W') - \widehat{\nabla} f(\widetilde{W})\|_F^2 \\
&\ge \Omega\left(\frac{\delta}{\rho^{14}}\right) \times m \times \|\,\mathsf{loss}_{i^*,\ell^*}\,\|^2 \ .
\end{aligned}$$

where the last step follows by (6.61) (with our sufficiently large choice of m) and Theorem 6.14.2.

Upper bound on $\|\widehat{\nabla} f(\widetilde{W}+W')\|_F$ Using $(a+b)^2 \le 2a^2 + 2b^2$, we have

$$\begin{aligned}
\|\widehat{\nabla} f(\widetilde{W}+W')\|_F^2 &\le 2\|\widehat{\nabla} f(\widetilde{W})\|_F^2 + 2\|\widehat{\nabla} f(\widetilde{W}+W') - \widehat{\nabla} f(\widetilde{W})\|_F^2 \\
&\overset{①}{\le} O(\rho^{12} m) \cdot \|\,\mathsf{loss}_{i^*,\ell^*}\,\|_F^2 + 2\|\widehat{\nabla} f(\widetilde{W}+W') - \widehat{\nabla} f(\widetilde{W})\|_F^2 \overset{②}{\le} O(\rho^{12} m) \cdot \|\,\mathsf{loss}_{i^*,\ell^*}\,\|_F^2
\end{aligned}$$

where ① follows by Lemma 6.14.1 and ② follows by (6.61).

Upper bound on $\|\widehat{\nabla} f_i(\widetilde{W}+W')\|_F$ This is completely analogous so we do not replicate the proofs here. □

By applying an ϵ-net argument over all possible $\mathsf{loss}_{i,\ell} \in \mathbb{R}^d$, we can modify Lemma 6.15.1 from "for fixed loss" to "for all loss." This allows us to plug in the true loss $\mathsf{loss}_{i,\ell} = Bh_{i,\ell} - y^*_{i,\ell}$ and derive that:

Theorem 6.15.2 (restated)**.** *Let* $\rho = nLd \log m$ *and* $\varrho = nLd\delta^{-1} \log(m/\epsilon)$*. With probability at least* $1 - e^{-\Omega(\rho^2)}$ *over* W, A, B*, it satisfies for* all $W' \in \mathbb{R}^{m \times m}$ *with* $\|W'\|_2 \leq \frac{\varrho^{100}}{\sqrt{m}}$*,*

$$\|\nabla f(\widetilde{W} + W')\|_F^2 \geq \Omega\left(\frac{\delta}{\rho^{14}}\right) \times m \times \max_{i,\ell}\{\| \mathsf{loss}_{i,\ell} \|^2\}$$
$$\|\nabla f(\widetilde{W} + W')\|_F^2 \leq O(\rho^{12} m) \times \max_{i,\ell}\{\| \mathsf{loss}_{i,\ell} \|^2\}$$
$$\|\nabla f_i(\widetilde{W} + W')\|_F^2 \leq \frac{1}{n^2} O(\rho^{12} m) \times \max_{i,\ell}\{\| \mathsf{loss}_{i,\ell} \|^2\} \ .$$

6.16 Objective Semi-Smoothness (Theorem 6.16.1)

The purpose of this section is to prove

Theorem 6.16.1 (objective semi-smoothness, restated)**.** *Let $\rho = nLd\log m$, $\varrho = nLd\delta^{-1}\log(m/\epsilon)$, $\tau_0 \in [\varrho^{-100}, \varrho^{100}]$, and $\widetilde{W}, A, B$ be at random initialization. With probability at least $1-e^{-\Omega(\rho^2)}$ over the randomness of $\widetilde{W}, A, B$, we have for every $\breve{W} \in \mathbb{R}^{m\times m}$ with $\|\breve{W}-\widetilde{W}\| \le \frac{\tau_0}{\sqrt{m}}$, and for every $W' \in \mathbb{R}^{m\times m}$ with $\|W'\| \le \frac{\tau_0}{\sqrt{m}}$, and letting $(i^*,\ell^*) = \mathrm{argmax}_{i,\ell}\{\|\breve{\mathsf{loss}}_{i,\ell}\|_2\}$,*

$$f(\breve{W}+W') \le f(\breve{W}) + \langle \nabla f(\breve{W}), W'\rangle + O(\rho^{11}\tau_0^{1/3}m^{1/3})\cdot\|\breve{\mathsf{loss}}_{i^*,\ell^*}\|_2\cdot\|W'\|_2 + O(L^{18}nm)\|W'\|_2^2$$

We introduce the following notations before we go to proofs.

Definition 6.16.1. For $i\in[n]$ and $\ell\in[L]$:

$$\begin{array}{lll}
\widetilde{g}_{i,0} = \widetilde{h}_{i,0} = 0 & \breve{g}_{i,0} = \hbar_{i,0} = 0 & g_{i,0} = h_{i,0} = 0 \\
\widetilde{g}_{i,\ell} = \widetilde{W}\widetilde{h}_{i,\ell-1} + Ax_{i,\ell} & \breve{g}_{i,\ell} = \breve{W}\hbar_{i,\ell-1} + Ax_{i,\ell} & g_{i,\ell} = (\breve{W}+W')h_{i,\ell-1} + Ax_{i,\ell} \\
\widetilde{h}_{i,\ell} = \phi(\widetilde{W}\widetilde{h}_{i,\ell-1} + Ax_{i,\ell}) & \hbar_{i,\ell} = \phi(\breve{W}\hbar_{i,\ell-1} + Ax_{i,\ell}) & h_{i,\ell} = \phi((\breve{W}+W')h_{i,\ell-1} + Ax_{i,\ell}) \\
 & \breve{\mathsf{loss}}_{i,\ell} = B\hbar_{i,\ell} - y^*_{i,\ell} &
\end{array}$$

Define diagonal matrices $\widetilde{D}_{i,\ell}$ and $\breve{D}_{i,\ell}$ respectively by letting

$$(\widetilde{D}_{i,\ell})_{k,k} = \mathbb{1}_{(\widetilde{g}_{i,\ell})_k\ge 0} \text{ and } (\breve{D}_{i,\ell})_{k,k} = \mathbb{1}_{(\breve{g}_{i,\ell})_k\ge 0}.$$

The following claim gives rise to a new recursive formula to calculate $h_{i,\ell} - \hbar_{i,\ell}$.

Claim 6.16.2 (c.f. (6.21))**.** *There exist diagonal matrices $D''_{i,\ell}\in\mathbb{R}^{m\times m}$ with entries in $[-1,1]$ such that,*

$$\forall i\in[n], \forall \ell\in[L]\colon \quad h_{i,\ell} - \hbar_{i,\ell} = \sum_{a=1}^{\ell-1}(\breve{D}_{i,\ell} + D''_{i,\ell})\breve{W}\cdots\breve{W}(\breve{D}_{i,a+1} + D''_{i,a+1})W'h_{i,a} \tag{6.62}$$

Furthermore, we have $\|h_{i,\ell} - \hbar_{i,\ell}\| \le O(L^9)\|W'\|_2$ *and* $\|D''_{i,\ell}\|_0 \le O(L^{10/3}\tau_0^{2/3}m^{2/3})$.

Proof of Claim 6.16.2. We ignore the subscript in i for cleanness, and calculate that

$$\begin{aligned} h_\ell - \hbar_\ell &\overset{①}{=} \phi((\breve{W} + W')h_{\ell-1} + Ax_\ell) - \phi(\breve{W}\hbar_{\ell-1} + Ax_\ell) \\ &\overset{②}{=} (\breve{D}_\ell + D''_\ell)\left((\breve{W} + W')h_{\ell-1} - \breve{W}\hbar_{\ell-1}\right) \\ &= (\breve{D}_\ell + D''_\ell)\breve{W}(h_{\ell-1} - \hbar_{\ell-1}) + (\breve{D}_\ell + D''_\ell)W'h_{\ell-1} \\ &\overset{③}{=} \sum_{a=1}^{\ell-1}(\breve{D}_\ell + D''_\ell)\breve{W}\cdots\breve{W}(\breve{D}_{a+1} + D''_{a+1})W'h_a \end{aligned}$$

Above, ① is by the recursive definition of h_ℓ and $\hbar_\ell$; ② is by Proposition 6.16.3 and D''_ℓ is defined according to Proposition 6.16.3; and inequality ③ is by recursively computing $h_{\ell-1} - \hbar_{\ell-1}$. As for the two properties:

- We have $\|h_\ell - \hbar_\ell\| \le O(L^9)\|W'\|_2$. This is because we have
  - $\left\|(\breve{D}_\ell + D''_\ell)\breve{W}\cdots\breve{W}(\breve{D}_{a+1} + D''_{a+1})\right\|_2 \le O(L^7)$ by Lemma 6.12.6;
  - $\|h_a\| \le O(L)$ (by $\|\widetilde{h}_a\| \le O(L)$ from Lemma 6.11.1 and $\|\widetilde{h}_a - h_a\| \le o(1)$ from Lemma 6.12.1a); and
  - $\|W'h_a\| \le \|W'\|_2\|h_a\|$.
- We have $\|D''_\ell\|_0 \le O(L^{10/3}\tau_0^{2/3}m^{2/3})$.

  This is because, $(D''_\ell)_{k,k}$ is non-zero only at the coordinates $k \in [m]$ where the signs of $\breve{g}_\ell$ and g_ℓ are opposite (by Proposition 6.16.3). Such a coordinate k must satisfy either $(\widetilde{D}_\ell)_{k,k} \ne (\breve{D}_\ell)_{k,k}$ or $(\widetilde{D}_\ell)_{k,k} \ne (D_\ell)_{k,k}$, and therefore by Lemma 6.12.1 — with probability $\ge 1 - e^{-\Omega(L^6\tau_0^{4/3}m^{1/3})}$ — there are at most $O(L^{10/3}\tau_0^{2/3}m^{2/3})$ such coordinates k.

□

Proof of Theorem 6.16.1. First of all, since

$$\frac{1}{2}\|Bh_{i,\ell}-y^*_{i,\ell}\|^2=\frac{1}{2}\|\breve{\mathsf{loss}}_{i,\ell}+B(h_{i,\ell}-\hbar_{i,\ell})\|^2=\frac{1}{2}\|\breve{\mathsf{loss}}_{i,\ell}\|^2+\breve{\mathsf{loss}}_{i,\ell}^\top B(h_{i,\ell}-\hbar_{i,\ell})+\frac{1}{2}\|B(h_{i,\ell}-\hbar_{i,\ell})\|^2 \tag{6.63}$$

we can write

$$\begin{aligned}
&f(\breve{W}+W')-f(W)-\langle\nabla f(W),W'\rangle\\
\overset{①}{=}&-\langle\nabla f(\breve{W}),W'\rangle+\frac{1}{2}\sum_{i=1}^n\sum_{\ell=2}^L\|Bh_{i,\ell}-y^*_{i,\ell}\|^2-\|B\hbar_{i,\ell}-y^*_{i,\ell}\|^2\\
\overset{②}{=}&-\langle\nabla f(\breve{W}),W'\rangle+\sum_{i=1}^n\sum_{\ell=2}^L\breve{\mathsf{loss}}_{i,\ell}^\top B(h_{i,\ell}-\hbar_{i,\ell})+\frac{1}{2}\|B(h_{i,\ell}-\hbar_{i,\ell})\|^2\\
\overset{③}{=}&\sum_{i=1}^n\sum_{\ell=2}^L\breve{\mathsf{loss}}_{i,\ell}^\top B\left((h_{i,\ell}-\hbar_{i,\ell})-\sum_{a=1}^{\ell-1}\breve{D}_{i,\ell}\breve{W}\cdots\breve{W}\breve{D}_{i,a+1}W'\hbar_{i,a}\right)+\frac{1}{2}\|B(h_{i,\ell}-\hbar_{i,\ell})\|^2\\
\overset{④}{=}&\sum_{i=1}^n\sum_{\ell=2}^L\breve{\mathsf{loss}}_{i,\ell}^\top B\left(\sum_{a=1}^{\ell-1}(\breve{D}_{i,\ell}+D''_{i,\ell})\breve{W}\cdots\breve{W}(\breve{D}_{i,a+1}+D''_{i,a+1})W'h_{i,a}-\breve{D}_{i,\ell}\breve{W}\cdots\breve{W}\breve{D}_{i,a+1}W'\hbar_{i,a}\right)\\
&+\frac{1}{2}\|B(h_{i,\ell}-\hbar_{i,\ell})\|^2
\end{aligned} \tag{6.64}$$

Above, ① is by the definition of $f(\cdot)$; ② is by (6.63); ③ is by the definition of $\nabla f(\cdot)$ (see Fact 6.2.3 for an explicit form of the gradient); ④ is by Claim 6.16.2.

We next bound the RHS of (6.64). We drop subscripts in i for notational simplicity.

We first use (6.62) in Claim 6.16.2 to calculate

$$\begin{aligned}\|B(h_\ell-\hbar_\ell)\| &\le \sum_{a=1}^{\ell-1}\|B(\breve{D}_\ell+D''_\ell)\breve{W}\cdots\breve{W}(\breve{D}_{a+1}+D''_{a+1})W'h_a\| \\ &\le \sum_{a=1}^{\ell-1}\|B\|_2\|(\breve{D}_\ell+D''_\ell)\breve{W}\cdots\breve{W}(\breve{D}_{a+1}+D''_{a+1})\|_2\|W'\|_2\|h_a\| \\ &\overset{①}{\le} \sum_{a=1}^{\ell-1} O(\sqrt{m})\cdot O(L^7)\cdot O(L)\cdot\|W'\|_2 \le O(L^9\sqrt{m})\cdot\|W'\|_2\ . \end{aligned} \tag{6.65}$$

In the last inequality ① above, we have used $\left\|(\breve{D}_\ell+D''_\ell)\breve{W}\cdots\breve{W}(\breve{D}_{a+1}+D''_{a+1})\right\|_2\le O(L^7)$ from Lemma 6.12.6; we have used $\|B\|_2\le O(\sqrt{m})$ with high probability; and we have used $\|h_a\|\le O(L)$ (by $\|\widetilde{h}_a\|\le O(L)$ from Lemma 6.11.1 and $\|\widetilde{h}_a-h_a\|\le o(1)$ from Lemma 6.12.1a).

Since for each D''_ℓ, we can write it as $D''_\ell=D_\ell^{0/1}D''_\ell D_\ell^{0/1}$, where each $D_\ell^{0/1}$ is a diagonal matrix satisfying

$$(D_\ell^{0/1})_{k,k}=\begin{cases}1, & (D''_\ell)_{k,k}\neq 0;\\ 0, & (D''_\ell)_{k,k}=0.\end{cases}\qquad\text{and}\quad \|D_\ell^{0/1}\|_0\le O(L^{10/3}\tau_0^{2/3}m^{2/3})$$

Therefore,

$$\begin{aligned}&\left|\breve{\mathsf{loss}}_\ell^\top B(\breve{D}_\ell+D''_\ell)\breve{W}\cdots\breve{W}(\breve{D}_{a+1}+D''_{a+1})W'h_a-\breve{\mathsf{loss}}_\ell^\top B\breve{D}_\ell\breve{W}\cdots\breve{D}_{a+1}W'h_a\right| \\ &\overset{①}{\le}\|\breve{\mathsf{loss}}_\ell\|_2\cdot\sum_{b=1}^{\ell-a}\binom{\ell-a}{b}\|B\breve{D}\breve{W}\cdots\breve{D}\breve{W}D^{0/1}\|_2\cdot\|D^{0/1}\breve{W}\breve{D}\cdots\breve{D}\breve{W}D^{0/1}\|_2^{b-1}\cdot\|D^{0/1}\breve{W}\cdots\breve{W}\breve{D}W'h_a\|_2 \\ &\overset{②}{\le}\|\breve{\mathsf{loss}}_\ell\|_2\cdot\sum_{b=1}^{\ell-a}\binom{\ell-a}{b}\cdot O(\rho^2\tau_0^{1/3}m^{1/3})\cdot\left(O(\frac{\rho^2}{m^{1/6}})\right)^{b-1}\cdot O(L^7)\cdot\|W'\|_2\cdot O(L) \\ &\overset{②}{\le}\|\breve{\mathsf{loss}}_\ell\|_2\cdot O(\rho^{11}\tau_0^{1/3}m^{1/3})\cdot\|W'\|_2\end{aligned} \tag{6.66}$$

Above, ① is an abbreviation and we have dropped the subscripts for the easy of presentation; ② uses Corollary 6.11.15, Corollary 6.11.12, Lemma 6.12.6 and Lemma 6.11.1.

Finally, we also have

$$\begin{aligned}\left|\breve{\mathsf{loss}}_\ell^\top B\breve{D}_\ell\breve{W}\cdots\breve{D}_{a+1}W'(h_a-\hbar_a)\right| &\overset{①}{\le} \|\breve{\mathsf{loss}}_\ell\|_2\cdot O(\sqrt{m})\cdot O(L^7)\cdot\|W'\|_2\cdot\|h_a-\hbar_a\|_2\\ &\overset{②}{\le} O(\rho^{16}\sqrt{m})\cdot\|\breve{\mathsf{loss}}_\ell\|_2\cdot\|W'\|_2^2 \qquad (6.67)\end{aligned}$$

where ① uses Lemma 6.12.6 and ② uses Claim 6.16.2 to bound $\|h_a-\hbar_a\|_2$.

Putting (6.65), (6.66) and (6.67) back to (6.64), and using triangle inequality, we have the desired result. □

6.16.1 Tool

Proposition 6.16.3. *Given vectors $a, b \in \mathbb{R}^m$ and $D \in \mathbb{R}^{m \times m}$ the diagonal matrix where $D_{k,k} = \mathbb{1}_{a_k \geq 0}$. Then, then there exists a diagonal matrix $D'' \in \mathbb{R}^{m \times m}$ with*

- $|D''_{k,k}| \leq 1$ *for every* $k \in [m]$,
- $D''_{k,k} \neq 0$ *only when* $\mathbb{1}_{a_k \geq 0} \neq \mathbb{1}_{b_k \geq 0}$, *and*
- $\phi(a) - \phi(b) = D(a-b) + D''(a-b)$

Proof. We verify coordinate by coordinate for each $k \in [m]$.

- If $a_k \geq 0$ and $b_k \geq 0$, then $(\phi(a) - \phi(b))_k = a_k - b_k = \big(D(a-b)\big)_k$.
- If $a_k < 0$ and $b_k < 0$, then $(\phi(a) - \phi(b))_k = 0 - 0 = \big(D(a-b)\big)_k$.
- If $a_k \geq 0$ and $b_k < 0$, then $(\phi(a) - \phi(b))_k = a_k = (a_k - b_k) + \frac{b_k}{a_k - b_k}(a_k - b_k) = \big(D(a-b) + D''(a-b)\big)_k$, if we define $(D'')_{k,k} = \frac{b_k}{a_k - b_k} \in [-1, 0]$.
- If $a_k < 0$ and $b_k \geq 0$, then $(\phi(a) - \phi(b))_k = -b_k = 0 \cdot (a_k - b_k) - \frac{b_k}{b_k - a_k}(a_k - b_k) = \big(D(a-b) + D''(a-b)\big)_k$, if we define $(D'')_{k,k} = \frac{b_k}{b_k - b_a} \in [0, 1]$. □

6.17 Convergence Rate of Gradient Descent (Theorem 6.17.1)

Theorem 6.17.1 (gradient descent, restated)**.** *There exists some absolute constant $C > 1$ such that the following holds. Let $\rho = nLd \log m$, $\epsilon \in (0, 1]$, $\varrho = nLd\delta^{-1} \log(m/\epsilon)$, and $\eta \stackrel{\text{def}}{=} \frac{\delta}{\rho^{44} m}$. Suppose $m \geq C\varrho^C$, and $W^{(0)}, A, B$ be at random initialization. Then, with probability at least $1 - e^{-\Omega(\rho^2)}$ over the randomness of $W^{(0)}, A, B$, suppose we start at $W^{(0)}$ and for each $t = 0, 1, \ldots, T-1$,*

$$W^{(t+1)} = W^{(t)} - \eta \nabla f(W^{(t)}) \ .$$

Then, it satisfies

$$f(W^{(T)}) \leq \epsilon \quad \text{for all} \quad T \in \left[\frac{\rho^{59}}{\delta^2} \log \frac{1}{\epsilon}, \frac{\rho^{59}\varrho^{28}}{\delta^2} \log \frac{1}{\epsilon} \right] \ .$$

In other words, the training loss of the recurrent neural network drops to ϵ in a linear convergence speed.

To present the simplest possible result, we have not tried to tighten the polynomial dependency with respect to n, d and L. We only tightened the dependency with respect to δ and ϵ. In fact, a more involved analysis can also get ride of the $\log(1/\epsilon)$ dependency in m [AZLS19].

Proof of Theorem 6.17.1. Using Lemma 6.11.1 and the randomness of B, it is easy to show that $\|Bh_{i,\ell} - y^*_{i,\ell}\|^2 \leq O(\rho^2 L^2)$ with at least $1 - e^{-\Omega(\rho^2)}$ (where $h_{i,\ell}$ is defined with respect to $W^{(0)}$), and therefore

$$f(W^{(0)}) \leq O(n\rho^2 L^3) \ .$$

In the rest of the proof, we first assume that for every $t = 0, 1, \ldots, T-1$, the following holds

$$\|W^{(t)} - W^{(0)}\|_F \leq \frac{\tau_0}{\sqrt{m}} \stackrel{\text{def}}{=} \frac{\varrho^{50}}{\sqrt{m}} \ . \tag{6.68}$$

We shall prove the convergence of gradient descent assuming (6.68), so that previous statements such as Theorem 6.16.1 and Theorem 6.15.2 can be applied. At the end of the proof, we shall verify that (6.68) is satisfied throughout the gradient descent process.

For each $t = 0, 1, \dots, T-1$, we let $\{\mathsf{loss}_{i,\ell}^{(t)}\}_{i,\ell}$ denote the loss vectors with respect to the current point $W^{(t)}$. We denote by $(i^*, \ell^*) = \mathrm{argmax}_{i,\ell}\{\| \mathsf{loss}_{i,\ell}^{(t)} \|_2\}$ and $\nabla_t = \nabla f(W^{(t)})$.

We calculate that

$$\begin{aligned}
f(W^{(t+1)}) &\overset{①}{\le} f(W^{(t)}) - \eta\|\nabla_t\|_F^2 + O(\rho^{11}\tau_0^{1/3}m^{1/3}) \cdot \| \mathsf{loss}_{i^*,\ell^*}^{(t)} \|_2 \cdot \eta\|\nabla_t\|_2 + O(L^{18}nm\eta^2)\|\nabla_t\|_2^2 \\
&\overset{②}{\le} f(W^{(t)}) - \eta\|\nabla_t\|_F^2 + O\left(\rho^{30}\eta^2m^2\right) \cdot \| \mathsf{loss}_{i^*,\ell^*}^{(t)} \|_2^2 \\
&\overset{③}{\le} f(W^{(t)}) - \left(\Omega\Big(\frac{\eta\delta}{\rho^{14}}m\Big) - O(\rho^{30}\eta^2m^2)\right) \cdot \| \mathsf{loss}_{i^*,\ell^*}^{(t)} \|_2^2 \\
&\overset{④}{\le} f(W^{(t)}) - \Omega\Big(\frac{\eta\delta}{\rho^{14}}m\Big) \cdot \| \mathsf{loss}_{i^*,\ell^*}^{(t)} \|_2^2 \\
&\overset{⑤}{\le} \left(1 - \Omega\Big(\frac{\eta\delta}{\rho^{15}}m\Big)\right) f(W^{(t)})
\end{aligned}$$

Above, ① uses Theorem 6.16.1; ② uses Theorem 6.15.2 (which gives $\|\nabla_t\|_2 \le \|\nabla_t\|_F \le O(\rho^6\sqrt{m}) \times \| \mathsf{loss}_{i^*,\ell^*}^{(t)} \|$), and our choices of τ_0 and m; ③ uses Theorem 6.15.2; ④ uses our choice of η; and ⑤ uses $f(W^{(t)}) \le nL\| \mathsf{loss}_{i^*,\ell^*}^{(t)} \|^2$. In other words, after $T = \Omega(\frac{\rho^{15}}{\eta\delta m}) \log \frac{nL^2}{\epsilon}$ iterations we have $f(W^{(T)}) \le \epsilon$.

We need to verify for each t, $\|W^{(t)} - W^{(0)}\|_F$ is small so that (6.68) holds. By Theorem 6.15.2,

$$\begin{aligned}
\|W^{(t)} - W^{(0)}\|_F \le \sum_{i=0}^{t-1} \|\eta\nabla f(W^{(i)})\|_F \le O(\eta\rho^6\sqrt{m}) \cdot \sum_{i=0}^{t-1} \sqrt{f(W^{(i)})} &\le O(\eta\rho^6\sqrt{m}) \cdot O(T \cdot \sqrt{n\rho^2L^3}) \\
&\le \eta T \cdot O(\rho^{8.5}\sqrt{m}) \le \frac{\rho^{50}}{\sqrt{m}} \ .
\end{aligned}$$

where the last step follows by our choice of T. □

6.18 Convergence Rate of Stochastic Gradient Descent (Theorem 6.18.1)

Theorem 6.18.1 (stochastic gradient descent, stated)**.** *There exists some absolute constant $C > 1$ such that the following holds. Let $\rho = nLd \log m$, $\epsilon \in (0,1]$, $\varrho = nLd\delta^{-1}\log(m/\epsilon)$, and $\eta \stackrel{\text{def}}{=} \frac{\delta}{\rho^{42} m}$. Suppose $m \geq C\varrho^C$, and $W^{(0)}, A, B$ be at random initialization. Then, with probability at least $1 - e^{-\Omega(\rho^2)}$ over the randomness of $W^{(0)}, A, B$, suppose we start at $W^{(0)}$ and for each $t = 0, 1, \ldots, T-1$,*

$$W^{(t+1)} = W^{(t)} - \eta \cdot \frac{n}{|S_t|} \sum_{i \in S_t} \nabla f(W^{(t)}) \quad \text{(for a random subset } S_t \subseteq [n] \text{ of fixed cardinality.)}$$

Then, it satisfies with probability at least $1 - e^{-\Omega(\rho^2)}$ over the randomness of $S_1, \ldots, S_T$:

$$f(W^{(T)}) \leq \epsilon \quad \textit{for all} \quad T \in \left[\frac{\rho^{57}}{\delta^2} \log \frac{1}{\epsilon}, \frac{\rho^{57}\varrho^{28}}{\delta^2} \log \frac{1}{\epsilon} \right] .$$

(To present the simplest possible result, we have not tried to tighten the polynomial dependency with respect to n, d and L. We only tightened the dependency with respect to δ and ϵ. In fact, a more involved analysis can also get ride of the $\log(1/\epsilon)$ dependency in m.)

Proof of Theorem 6.18.1. The proof is almost identical to that of Theorem 6.17.1. We again have with probability at least $1 - e^{-\Omega(\rho^2)}$

$$f(W^{(0)}) \leq O(n\rho^2 L^3) .$$

Again, we first assume for every $t = 0, 1, \ldots, T-1$, the following holds

$$\|W^{(t)} - W^{(0)}\|_F \leq \frac{\tau_0}{\sqrt{m}} \stackrel{\text{def}}{=} \frac{\varrho^{50}}{\sqrt{m}} . \tag{6.69}$$

We shall prove the convergence of SGD assuming (6.69), so that previous statements such as Theorem 6.16.1 and Theorem 6.15.2 can be applied. At the end of the proof, we shall verify that (6.69) is satisfied throughout the SGD with high probability.

For each $t = 0, 1, \ldots, T-1$, using the same notation as Theorem 6.17.1, except that we choose $\nabla_t = \frac{n}{|S_t|} \sum_{i \in S_t} \nabla f_i(W^{(t)})$. We have $\mathbb{E}_{S_t}[\nabla_t] = \nabla f(W^{(t)})$ and therefore

$$
\begin{aligned}
&\mathop{\mathbb{E}}_{S_t}[f(W^{(t+1)})] \\
&\overset{①}{\le} f(W^{(t)}) - \eta \|\nabla f(W^{(t)})\|_F^2 + O(\rho^{11}\tau_0^{1/3} m^{1/3}) \cdot \| \mathsf{loss}_{i^*,\ell^*}^{(t)} \|_2 \cdot \eta \mathop{\mathbb{E}}_{S_t}[\|\nabla_t\|_2] + O(L^{18} n m \eta^2) \mathop{\mathbb{E}}_{S_t}[\|\nabla_t\|_2^2] \\
&\overset{②}{\le} f(W^{(t)}) - \eta \|\nabla_t\|_F^2 + O\left(\rho^{30}\eta^2 m^2\right) \cdot \| \mathsf{loss}_{i^*,\ell^*}^{(t)} \|_2^2 \\
&\overset{③}{\le} \left(1 - \Omega\Big(\frac{\eta\delta}{\rho^{15}} m\Big)\right) f(W^{(t)}) \ . \qquad (6.70)
\end{aligned}
$$

Above, ① uses Theorem 6.16.1 and $\mathbb{E}_{S_t}[\nabla_t] = \nabla f(W^{(t)})$; ② uses Theorem 6.15.2 (which gives $\|\nabla_t\|_2^2 \le \frac{n^2}{|S_t|^2} \sum_{i \in S_t} \|\nabla f_i(W^{(t)})\|_F^2 \le O(\rho^{12} m) \times \| \mathsf{loss}_{i^*,\ell^*}^{(t)} \|^2$); ③ is identical to the proof of Theorem 6.17.1.

At the same time, we also have the following absolute value bound:

$$
\begin{aligned}
&f(W^{(t+1)}) \\
&\overset{①}{\le} f(W^{(t)}) + \eta \|\nabla f(W^{(t)})\|_F \cdot \|\nabla_t\|_F + O(\rho^{11}\tau_0^{1/3} m^{1/3}) \cdot \| \mathsf{loss}_{i^*,\ell^*}^{(t)} \|_2 \cdot \eta \|\nabla_t\|_2 + O(L^{18} n m \eta^2) \|\nabla_t\|_2^2 \\
&\overset{②}{\le} f(W^{(t)}) + O\left(\rho^{12}\eta m + \rho^{30}\eta^2 m^2\right) \cdot \| \mathsf{loss}_{i^*,\ell^*}^{(t)} \|_2^2 \\
&\overset{③}{\le} \big(1 + O\big(\rho^{12}\eta m\big)\big) f(W^{(t)}) \ . \qquad (6.71)
\end{aligned}
$$

Above, ① uses Theorem 6.16.1 and Cauchy-Shwartz $\langle A, B \rangle \le \|A\|_F \|B\|_F$, and ② uses Theorem 6.15.2 and the derivation from (6.70).

Next, taking logarithm on both sides of (6.70) and (6.71), and using Jensen's inequality $\mathbb{E}[\log X] \le \log \mathbb{E}[X]$, we have

$$
\mathbb{E}[\log f(W^{(t+1)})] \le \log f(W^{(t)}) - \Omega\Big(\frac{\eta\delta}{\rho^{15}} m\Big) \quad \text{and} \quad \log f(W^{(t+1)}) \le \log f(W^{(t)}) + O\big(\rho^{12}\eta m\big)
$$

By one-sided Azuma's inequality (a.k.a. martingale concentration), we have with probability at least $1 - e^{-\Omega(\rho^2)}$, for every $t = 1, 2, \ldots, T$:

$$\log f(W^{(t)}) - \mathbb{E}[\log f(W^{(t)})] \le \sqrt{t} \cdot O\big(\rho^{12}\eta m\big) \cdot \rho \ .$$

This implies two things.

- On one hand, after $T = \Omega(\frac{\rho^{15}\log(nL^2/\epsilon)}{\eta\delta m})$ iterations we have

$$\begin{aligned}\log f(W^{(T)}) &\le \sqrt{T} \cdot O\big(\rho^{12}\eta m\big) \cdot \rho + \log f(W^{(0)}) - \Omega\Big(\frac{\eta\delta}{\rho^{15}} m\Big) T \\ &\le \log f(W^{(0)}) - \Omega\Big(\frac{\eta\delta}{\rho^{15}} m\Big) T \le \log O(n\rho^2 L^3) - \Omega(\log \frac{\rho^5}{\epsilon}) \le \log \epsilon \ .\end{aligned}$$

  Therefore, we have $f(W^{(T)}) \le \epsilon$.

- On the other hand, for every $t = 1, 2, \ldots, T$, we have

$$\begin{aligned}\log f(W^{(t)}) &\le \sqrt{t} \cdot O\big(\rho^{12}\eta m\big) \cdot \rho + \log f(W^{(0)}) - \Omega\Big(\frac{\eta\delta}{\rho^{15}} m\Big) t \\ &\overset{①}{=} \log f(W^{(0)}) - \left(\sqrt{\frac{\eta\delta m}{\rho^{15}}} \cdot \Omega(\sqrt{t}) - \sqrt{\frac{\rho^{15}}{\eta\delta m}} \cdot O(\rho^{13}\eta m)\right)^2 + O\Big(\frac{\rho^{41}\eta m}{\delta}\Big) \\ &\overset{②}{\le} \log f(W^{(0)}) + 1\end{aligned}$$

  where in ① we have used $2a\sqrt{t} - b^2 t = -(b\sqrt{t} - a/b)^2 + a^2/b^2$, and in ② we have used $\eta \le O\big(\frac{\delta}{\rho^{42} m}\big)$. This implies $f(W^{(t)}) \le O(n\rho^2 L^3)$. We can now verify for each t, $\|W^{(t)} - W^{(0)}\|_F$ is small so that (6.69) holds. By Theorem 6.15.2,

$$\begin{aligned}\|W^{(t)} - W^{(0)}\|_F \le \sum_{i=0}^{t-1} \|\eta\nabla_t\|_F &\le O(\eta\rho^6\sqrt{m}) \cdot \sum_{i=0}^{t-1} \sqrt{f(W^{(i)})} \le O(\eta\rho^6\sqrt{m}) \cdot O(T\sqrt{n\rho^2 L^3}) \\ &\le \eta T \cdot O(\rho^{8.5}\sqrt{m}) \le \frac{\varrho^{50}}{\sqrt{m}} \ .\end{aligned}$$

  where the last step follows by our choice of T. □

Part II

Matrix Concentrations

Chapter 7

Matrix Chernoff Bound on Expander

We prove a Chernoff-type bound for sums of matrix-valued random variables sampled via a random walk on an expander, confirming a conjecture due to Wigderson and Xiao [WX06]. Our proof is based on a new multi-matrix extension of the Golden-Thompson inequality which improves in some ways the inequality in [SBT17] and may be of independent interest, as well as an adaptation of an argument for the scalar case due to Healy [Hea08]. Secondarily, we also provide a generic reduction showing that any concentration inequality for vector-valued martingales implies a concentration inequality for the corresponding expander walk, with a weakening of parameters proportional to the squared mixing time.

7.1 Introduction

The Chernoff Bound [Che52] is one of the most widely used probabilistic results in computer science. It states that a sum of independent bounded random variables exhibits subgaussian concentration around its mean. In particular, when the random variables are i.i.d. samples from a fixed distribution, it implies that the empirical mean of k samples is ϵ-close to the true mean with exponentially small deviation probability proportional to $e^{-\Omega(k\epsilon^2)}$.

An important generalization of this bound was achieved by Gillman [Gil98] (with refinements later by [Lez98, Kah97, LP04, WX05, Hea08, Wag08, CLLM12, RR17]), who significantly relaxed the independence assumption to Markov dependence. In particular, suppose G is a regular graph with vertex set $V = [n]$, $X : V \to \mathbb{C}$ is a bounded function, and $v_1, \ldots, v_k$ is a stationary random walk[1] of length k on G. Then, even though the random variables $X(v_i)$ are in not independent (except when G is the complete graph with self loops), it is shown that:

$$\Pr\left[\left|\frac{1}{k}\sum_{i=1}^{k} X(v_i) - \mathbb{E}[X]\right| > \epsilon\right] \leq 2 \cdot \exp(-\Omega((1-\lambda)k\epsilon^2)), \tag{7.1}$$

where $1 - \lambda$ is the spectral gap of the transition matrix of the random walk. The gain here is that sampling a stationary random walk of length k on a constant degree graph with constant spectral gap requires $\log(n) + O(k)$ random bits, which is much less than the $k \log(n)$ bits required to produce k independent samples. Since such graphs can be explicitly constructed, this leads to a generic "derandomization" of the Chernoff bound, which has

[1] That is the first vertex v_1 is chosen uniformly at random – which is the stationary distribution of the graph G.

had several important applications (see [WX05] for a detailed discussion). In particular, it leads to the following randomness efficient sampler for scalar-valued functions ([Gil98]) using known strongly explicit constructions of expander graphs [RVW00, LPS88]:

Theorem 7.1.1 ([Gil98])**.** *For any $\epsilon > 0$ and $k \geq 1$, there is a* poly(r)*-time computable sampler $\sigma : \{0,1\}^r \to [n]^k$, where $r = \log(n) + O(k)$ s.t. for all functions $f : [n] \to [-1,1]$ satisfying $\mathbb{E}\, f = 0$, we have that*

$$\Pr_{w \in_R \{0,1\}^r}\left[\left|\frac{1}{k}\sum_{i=1}^{k} f(\sigma(w)_i)\right| \geq \epsilon\right] \leq 2\exp\left(-\Omega\left(\epsilon^2 k\right)\right).$$

In many applications of interest k is about $\log(n)$, and going from $O(\log^2(n))$ to $O(\log(n))$ random bits leads to a complete derandomization by cycling over all seeds $w \in \{0,1\}^r$.

A different generalization of the Chernoff bound appeared in the works of Rudelson [Rud99], Ahlswede-Winter [AW02], and Tropp [Tro12], who showed that a similar concentration phenomenon is true for *matrix-valued* random variables. In particular, if $X_1, \ldots, X_k$ are independent $d \times d$ complex Hermitian random matrices with $\|X_i\| \leq 1$, then the following is true:

$$\Pr\left[\left\|\frac{1}{k}\sum_{i=1}^{k} X_i - \mathbb{E}[X]\right\| > \epsilon\right] \leq 2d \cdot \exp(-\Omega(k\epsilon^2)). \tag{7.2}$$

The only difference between this and the usual Chernoff bound is the factor of d in front of the deviation probability; to see that it is necessary, notice that the diagonal case simply corresponds to a direct sum of d arbitrarily correlated instances of the scalar Chernoff bound, so by the union bound the probability should be d times as large in the worst case. This so called "Matrix Chernoff Bound" has seen several applications as well, notably in quantum

information theory, numerical linear algebra, and spectral graph theory; the reader may consult e.g. the book [Tro15] for many examples.

We present two different extensions of the above results in this chapter.

7.1.1 A Matrix Expander Chernoff Bound

It is natural to wonder whether there is a common generalization of (7.1) and (7.2), i.e., a "Matrix Expander Chernoff Bound". Such a result was conjectured by Wigderson and Xiao in [WX06] — in fact, [WX05] contained a proof of it, but the authors later discovered a gap in the proof. In this chapter, we prove the Wigderson and Xiao conjecture, namely:

Theorem 7.1.2. *Let $G = (V, E)$ be a regular undirected graph whose transition matrix has second eigenvalue λ, and let $f : V \to \mathbb{C}^{d \times d}$ be a function such that:*

1. *For each $v \in V$, $f(v)$ is Hermitian and $\|f(v)\| \leq 1$.*
2. *$\sum_{v \in V} f(v) = 0$.*

Then, for a stationary random walk $v_1, \ldots, v_k$ with $\epsilon \in (0, 1)$ we have:

$$\Pr\left[\lambda_{\max}\left(\frac{1}{k}\sum_{j=1}^{k} f(v_j)\right) \geq \quad \epsilon\right] \leq d \cdot \exp\left(-\Omega\left(\epsilon^2(1-\lambda)k\right)\right),$$

$$\Pr\left[\lambda_{\min}\left(\frac{1}{k}\sum_{j=1}^{k} f(v_j)\right) \leq -\epsilon\right] \leq d \cdot \exp\left(-\Omega\left(\epsilon^2(1-\lambda)k\right)\right).$$

This theorem adds to the amazingly long list of pseudorandom properties of expander graphs. By applying the theorem with a strongly explicit bounded degree expander, one obtains the following randomness-efficient sampler for matrix-calued functions conjectured in [WX06].

Theorem 7.1.3. *For any $\epsilon > 0$, $k \geq 1$ and $d \geq 1$, there is a $\mathrm{poly}(r)$-time computable sampler $\sigma : \{0,1\}^r \to [n]^k$, where $r = \log(n) + O(k)$ s.t. for all functions $f : [n] \to \mathbb{C}^{d \times d}$ satisfying $\mathbb{E}\, f = 0$ and for each $v \in [n]$, $f(v)$ is Hermitian and $\|f(v)\| \leq 1$, we have that*

$$\Pr_{w \in_R \{0,1\}^r} \left[\left\| \frac{1}{k} \sum_{i=1}^{k} f(\sigma(w)_i) \right\| \geq \epsilon \right] \leq 2d \exp\left(-\Omega\left(-\epsilon^2 k\right)\right).$$

We remark that while the derandomization applications studied in [WX05] were later recovered in [WX08] using the method of pessimistic estimators, that method requires additional assumptions to be efficiently implementable (specifically, computability of the matrix moment generating function, which is problem-dependent) and therefore does not constitute a truly black box derandomization of the matrix Chernoff bound, whereas Theorem 7.1.3 does. Given the increasing ubiquity of applications of this bound, we therefore suspect that it will find further applications in the study of derandomization and expander graphs, beyond the ones mentioned in [WX05].

Techniques

To describe the ideas that go into the proof of Theorem 7.1.2, let us begin by recalling how the usual scalar Chernoff bound is proved, in the case when the random variables have mean zero. The key observation is that if $X_1, \ldots, X_k$ are independent random variables, then the moment generating function of the sum is equal to the product of the moment generating functions:

$$\mathbb{E}\left[\exp\left(t \sum_{i=1}^{k} X_i\right)\right] = \prod_{i=1}^{k} \mathbb{E}[\exp(tX_i)].$$

This is no longer true in case where the X_i come from a random walk, but we still have the algebraic fact that

$$\exp\left(t\sum_{i=1}^{k} X_i\right) = \prod_{i=1}^{k} \exp(tX_i), \tag{7.3}$$

which allows one to decompose the sum as a product. The latter allows one to consider the steps of the random walk separately and analyze the change in the expectation inductively.

The analogue of the moment generating function in the matrix setting is

$$\mathbb{E}\left[\operatorname{tr}\left[\exp\left(t\sum_{i=1}^{k} X_i\right)\right]\right],$$

and the main difficulty is that (7.3) no longer holds if the matrices X_i do not commute. A substitute for this fact is given by the Golden-Thompson inequality [Gol65, Tho65], which states that for any Hermitian A, B:

$$\operatorname{tr}[\exp(A+B)] \leq \operatorname{tr}[\exp(A)\exp(B)]. \tag{7.4}$$

The latter expression may further be bounded by
$\|\exp(A)\|\operatorname{tr}[\exp(B)]$, and this is sufficient to prove (7.2) in the independent case as is done in [AW02], where an inductive application of it yields

$$\mathbb{E}\left[\operatorname{tr}\left[\exp\left(t\sum_{i=1}^{k} X_i\right)\right]\right] \leq \operatorname{tr}[I]\cdot\prod_{i=1}^{k}\left\|\mathbb{E}[\exp(tX_i)]\right\|.$$

However, this approach is too crude to handle the Markov case, roughly because in the absence of inependence, passing to the norm makes it difficult to utilize the fact that the expectation of each X_i is zero.

The original proof of Wigderson-Xiao was based on the following plausible multi-matrix generalization of (7.4):

$$\operatorname{tr}\left[\exp\left(\sum_{i=1}^{k} A_i\right)\right] \leq \operatorname{tr}\left[\prod_{i=1}^{k} \exp(A_i)\right],$$

which turns out to be false for $k > 2$. To see why, observe that the left hand side is always nonnegative, whereas the right hand side can be the trace of a product of any three positive semidefinite matrices, which can be negative (and this is not the case for two matrices). This led to a fatal gap in their proof.

The main ingredient in our proof is a new multi-matrix generalization of (7.4), which is inspired by the following statement that was recently proven in [SBT17] (see also [HKT16]).

Theorem 7.1.4 (Corollary 3.3 in [SBT17])**.** *Let $H_1, \ldots, H_k \in \mathbb{C}^{d\times d}$ be Hermitian matrices. Then*

$$\log\left[\operatorname{tr}\left(\exp\left(\sum_{j=1}^{k} H_j\right)\right)\right] \leq \int_{-\infty}^{\infty} \log\left[\operatorname{tr}\left(\prod_{j=1}^{k} \exp\left(\frac{H_j(1+\mathbf{i}b)}{2}\right) \prod_{j=k}^{1} \exp\left(\frac{H_j(1-\mathbf{i}b)}{2}\right)\right)\right] \mathrm{d}\mu(b)$$

where μ is some probability distribution on $(-\infty, \infty)$.

The above inequality successfully relates the matrix exponential of a sum to a product of matrix exponential, but is not adequate for proving an optimal Chernoff bound. The reason is that all known arguments require a Taylor expansion, and Theorem 7.1.4 involves integration over an unbounded region (this region can be truncated, but this introduces a loss which leads to a suboptimal bound). To remedy this, we prove a new multi-matrix Golden-Thompson inequality, which only involves integration over a bounded region instead of a line.

Theorem 7.1.5 (Bounded Multi-matrix Golden-Thompson inequality)**.** *Let* $H_1, \ldots, H_k \in \mathbb{C}^{d\times d}$ *be Hermitian matrices. Then*

$$\log\left(\operatorname{tr}\left[\exp\left(\sum_{j=1}^{k} H_j\right)\right]\right) \leq \frac{4}{\pi}\int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} \log\left(\operatorname{tr}\left[\prod_{j=1}^{k}\exp\left(\frac{e^{\mathbf{i}\phi}}{2}H_j\right)\prod_{j=k}^{1}\exp\left(\frac{e^{-\mathbf{i}\phi}}{2}H_j\right)\right]\right)\mathrm{d}\mu(\phi)$$

where μ *is some probability distribution on* $[-\frac{\pi}{2}, \frac{\pi}{2}]$.

We present the proof in Section 7.3. Theorem 7.1.5 is likely to be of independent interest and could have further applications, e.g. in quantum information theory. We draw attention to the following notable features of the above two theorems:

(a) Since $\exp(H(1+\mathbf{i}b)) = \exp(H(1-\mathbf{i}b))^*$ and $\exp\left(\frac{e^{\mathbf{i}\phi}}{2}H_j\right) = \exp\left(\frac{e^{-\mathbf{i}\phi}}{2}H_j\right)^*$ for Hermitian H, the right hand always considers the trace of a matrix times its adjoint, which is always positive semidefinite, ruling out the bad example described above.

(b) They are *average case* inequalities, where the averaging is done over specific distributions. We remark that the first inequality is known to be false in the worst case (i.e., with $b = 0$ and with other small values of b; see [SBT17] for a discussion).

The main point is that Theorem 7.1.5 allows one to relate the exponential of a sum of matrices to a (two-sided) product of bounded $d \times d$ matrices and their adjoints. In order to prove Theorem 7.1.2, we rewrite this as a one-sided matrix product of $d^2 \times d^2$ matrices acting on $\mathbb{C}^{d\times d}$, by encoding left and right multiplication on this space via a tensor product. However, these matrices are no longer Hermitian (or even normal), so it is difficult to analyze the moment generating function of their product over the random walk using the perturbation-theoretic approach of [WX05]. We surmount this difficulty by employing a

variant of the more robust linear algebraic proof technique of Healy [Hea08]. The proof of Theorem 7.1.2 is presented in Section 7.4.

7.1.2 Martingale Approximation of Expander Walks

While Theorem 7.1.2 provides a satisfactory generalization of the expander Chernoff bound to the case when one is interested in the spectral norm of a matrix-valued function on V, one could ask what happens for other matrix norms (such as Schatten norms), or even more generally, for functions taking values in an arbitrary Banach space. Our second contribution is a generic reduction from this problem, of proving concentration for random variables sampled using a Markov chain, to the much more well-studied problem (see e.g. [CL06]) of concentration for sums of *martingale* random variables. We remark that the technique used in the proof of Theorem 7.1.6 is not new, and was introduced in a slightly different context in the paper [NPSS06].

Theorem 7.1.6. *Suppose $G = (V, E)$ is a regular graph whose transition matrix has second eigenvalue λ and $f : V \to \mathbb{R}^N$ is a vector-valued function satisfying $\sum_{v \in V} f(v) = 0$ with $F := \sqrt{\sum_{v \in V} \|f(v)\|_2^2}$, where $\|\cdot\|_2$ denotes the Frobenius norm. If $v_1, \ldots, v_k$ is a stationary random walk on G, then for every $\epsilon > 0$, there is a martingale difference sequence $Z_1, \ldots, Z_k$ with respect to the filtration generated by initial segments of $v_1, \ldots, v_k$ such that*

$$\frac{1}{k} \sum_{i=1}^{k} f(v_i) = W + \frac{1}{k} \sum_{i=1}^{k} Z_i,$$

where

1. *W is a random vector satisfying $\|W\|_2 \leq \epsilon$.*

2. Each term Z_i satisfies

$$\|Z_i\|_* \leq \frac{2\log(F/\epsilon)}{1-\lambda} \cdot \max_{v \in V} \|f(v)\|_*$$

for every norm $\|\cdot\|_*$.

Thus, the empirical sums of any bounded (in any norm) function on a graph are well-approximated by a martingale whose increments are also bounded, with a loss in the bound depending on the ℓ_2 norm F of the function and the spectral gap of the graph. Since F will typically scale with the number of vertices, the ratio above is typically comparable to the mixing time.

To see the theorem in action, consider the case when $f(v)$ is matrix-valued in $d \times d$ Hermitian matrices and $\|\cdot\|_*$ is the operator norm. If $\|f(v)\| \leq 1$ then we have the bound

$$F^2 = \sum_{v \in V} \|f(v)\|_F^2 \leq dn.$$

Suppose we are interested in obtaining an estimate on the probability:

$$\Pr\left[\left\|\frac{1}{k}\sum_{v \in V} f(v)\right\| > \epsilon\right]. \tag{7.5}$$

Applying Theorem 7.1.6 with parameter $\epsilon/2$ and noting that $\|W\| \leq \|W\|_F$, we have that (7.5) is at most

$$\Pr\left[\left\|\frac{1}{k}\sum_{i=1}^{k} Z_i\right\| > \epsilon/2\right],$$

where Z_i is a martingale with bound

$$\|Z_i\| \leq \frac{\log(nd/\epsilon)}{1-\lambda}.$$

We now appeal to the existing martingale generalization of (7.2) (see e.g. [Tro12]) and find that this probability is at most

$$2d \cdot \exp\left(-\Omega\left(\frac{k\epsilon^2(1-\lambda)^2}{\log^2(nd)}\right)\right).$$

While this theorem is much weaker than the previous one in terms of parameters (depending on the square of the mixing time rather than on the spectral gap), it shows qualitatively that concentration for Markov chains is a generic phenomenon rather than something specific to matrices. It also allows one to instantly import the wealth of results regarding concentration for martingales in various Banach spaces (see e.g., [LT13]) to the random walk setting, albeit with suboptimal parameters. The simple proof of Theorem 7.1.6 is presented in Section 7.5.

7.2 Preliminaries

For an $n \in \mathbb{N}_+$, let $[n]$ denote the set $\{1, 2, \cdots, n\}$. Let $\mathbf{i}$ denote $\sqrt{-1}$. For $z = a + \mathbf{i}b$, where $a, b \in \mathbb{R}$, we define the complex conjugate of z to be $\overline{z} = a - \mathbf{i}b$ and $|z| = \sqrt{a^2 + b^2}$. Then $|z|^2 = z\overline{z}$. We define real part $\mathrm{Re}(z) = a$ and imaginary part $\mathrm{Im(z)} = b$. Then $\mathrm{Re}(z) = \frac{z+\overline{z}}{2}$ and $\mathrm{Im}(z) = \frac{z-\overline{z}}{2\mathbf{i}}$.

We will be working with D-regular undirected graphs $G = (V, E)$. The number of vertices of the graph, V will be denoted by n. A will denote the adjacency matrix of the graph and $P = A/D$ will denote its normalized adjacency matrix. A regular graph G will be called a λ-expander ($0 < \lambda < 1$) if $\|Px\| \leq \lambda \cdot \|x\|$ for all vectors $x \in \mathbb{C}^n$ s.t. $\sum_{i=1}^{n} x_i = 0$.

We will use $e_i \in \mathbb{C}^d$ to denote the standard basis vector with 1 in i^{th} position and 0 everywhere else.

7.2.1 Linear Algebra

Matrices and Norms. For matrix A, we use $A^\top$ to denote the transpose of A, we use $\overline{A}$ to denote the entry-wise complex conjugate of A. For square matrix $A \in \mathbb{C}^{n\times n}$, we use A^* to denote the conjugate transpose of matrix A. It is obvious that $A^* = \overline{A}^\top = \overline{A^\top}$. We say a complex square matrix A is Hermitian, if $A = A^*$, unitary if $AA^* = A^*A = I$, and positive-semidefinite (psd) if $A = A^*$ and $x^*Ax \geq 0$ for all $x \in \mathbb{C}^n$. We use $\succeq, \preceq$ to denote the semidefinite ordering, e.g. $A \succeq 0$ means that A is psd.

For $p \in [1, \infty)$, define the Schatten p-norm of A as

$$\|A\|_p = \left(\sum_{n \geq 1} s_n^p(A) \right)^{1/p}$$

for $s_1(A) \geq s_2(A) \geq \cdots \geq s_n(A) \geq \cdots \geq 0$ the singular values of A, i.e., the eigenvalues of the Hermitian matrix $|A| = \sqrt{(A^*A)}$. Then $\|A\|_p^p = \mathrm{tr}[|T|^p]$.

For matrix $A \in \mathbb{C}^{n\times n}$, we define $\|A\|$ to be the spectral norm of A, i.e.,

$$\|A\| = \max_{\|x\|_2=1, x\in\mathbb{C}^n} x^*Ax.$$

Tensor Products. Given two vectors $v \in \mathbb{C}^{d_1}$ and $w \in \mathbb{C}^{d_2}$, their tensor product $v \otimes w \in \mathbb{C}^{d_1 d_2}$ is the vector whose $(i,j)^{\text{th}}$ entry is $v(i)w(j)$ (for concreteness, assume the entries are in lexicographic order). Given two matrices $A_1 \in \mathbb{C}^{d_1\times d_1}$ and $A_2 \in \mathbb{C}^{d_2\times d_2}$, their tensor product $A_1 \otimes A_2 \in \mathbb{C}^{d_1 d_2 \times d_1 d_2}$ is the matrix whose $((i,k),(j,l))^{\text{th}}$ entry is $A_1(i,j)A_2(k,l)$. It is easy to see that

$$(A \otimes B)(v \otimes w) = Av \otimes Bw$$

and

$$(A \otimes B)(C \otimes D) = AB \otimes CD.$$

For a matrix $X \in \mathbb{C}^{d\times d}$, $\mathrm{vec}(X) \in \mathbb{C}^{d^2}$ will denote the vectorized version of the matrix X. That is

$$\mathrm{vec}(X) = \sum_{i,j=1}^{d} X(i,j) e_i \otimes e_j.$$

We have the following relationship between matrix multiplication and the tensor product:

$$\mathrm{vec}(AXB) = (A \otimes B^\top)\mathrm{vec}(X).$$

Exponential and Logarithm. All logarithms will be taken with the base e, and $\exp(x)$ will denote e^x. The matrix exponential of a complex matrix $A \in \mathbb{C}^{d\times d}$ is defined by the

Taylor expansion:

$$\exp(A) = \sum_{j=0}^{\infty} \frac{A^j}{j!},$$

which converges for all matrices A. We will use the fact that

$$\exp(A) \otimes \exp(B) = \exp(A \otimes I + I \otimes B),$$

which may be checked by expanding both sides and comparing terms.

The matrix logarithm of a positive definite matrix $A = UDU^*$ with D diagonal and positive is defined by

$$\log(A) := U \log(D) U^*,$$

where the logarithm of D is taken entrywise. For such matrices we have

$$\log(\exp(A)) = \exp(\log(A)) = A.$$

For positive definite A and complex z, we define
$A^z := \exp(z \log(A))$.

Polar Decomposition. The polar decomposition of a square complex matrix A is a matrix decomposition of the form

$$A = UV$$

where U is a unitary matrix and V is a psd matrix. The polar decomposition separates matrix A into a component that stretches the space along a set of orthogonal axes, represented by V, and a rotation (with possible reflection) represented by U. The decomposition of the complex conjugate of matrix A can written as

$$\overline{A} = \overline{UV}.$$

The decomposition of the conjugate transpose of matrix A can be written as

$$A^* = V^* U^*.$$

The following simple proposition will be useful in our proofs.

Proposition 7.2.1. *Let A and B be Hermitian psd matrices. Then*

$$\mathrm{tr}[AB] \leq \|A\| \cdot \mathrm{tr}[B]$$

Proof. Let $B = \sum_{j=1}^{n} \sigma_j v_j v_j^\dagger$ be the eigenvalue decomposition of B. Then

$$\begin{aligned}
\mathrm{tr}[AB] &= \sum_{j=1}^{n} \sigma_j \,\mathrm{tr}\left[A v_j v_j^\dagger\right] \\
&= \sum_{j=1}^{n} \sigma_j v_j^\dagger A v_j \\
&\leq \sum_{j=1}^{n} \sigma_j \cdot \|A\| \\
&= \|A\| \cdot \mathrm{tr}[B].
\end{aligned}$$

□

7.2.2 Complex analysis

A function $f : U \to \mathbb{C}$ on a domain $U \subseteq \mathbb{C}$ is *holomorphic* if it has a complex derivative in a neighborhood of every point $z \in U$. The existence of a complex derivative in a neighborhood is a very strong condition, for it implies that any holomorphic function is actually infinitely differentiable and equal to its own Taylor series (i.e., *analytic*) at every point in U. A *biholomorphic* function is a bijective holomorphic function whose inverse is

also holomorphic. It follows from the definition that sums, products, and compositions of holomorphic functions are holomorphic. We will also talk about matrix-valued holomorphic functions $f : U \to \mathbb{C}^{d\times d}$, which just means that every entry is holomorphic.

The main property that we will use is that the value of a holomorphic function at a point $z \in U$ can be related to values that it takes on the boundary of U, in the following way. A function $f : U \to \mathbb{R} \cup \{-\infty\}$ is called *subharmonic* if it is upper semicontinuous and

$$f(z) \leq \frac{1}{2\pi} \int_0^{2\pi} f(z + re^{i\theta}) d\theta$$

for all $z \in U$ and $r > 0$ such that the closed disk $D(z, r)$ is contained in U, and all of the above integrals converge.

We will make frequent use of the following standard fact.

Proposition 7.2.2. *If f is analytic on a domain $U \subset \mathbb{C}$ then $\log |f(z)|$ is subharmonic on U.*

Our main tool will be the Poisson Integral Formula for subharmonic functions.

Lemma 7.2.3 (Poisson integral formula on unit disk [Gao08, Eq 1.3.35])**.** *For any subharmonic function U defined on the unit disk $\{z \in \mathbb{C} : |z| \leq 1\}$, we have that*

$$U(z) \leq \frac{1}{2\pi} \int_{-\pi}^{\pi} U(e^{\mathbf{i}\varphi}) \frac{1 - |z|^2}{|e^{\mathbf{i}\varphi} - z|^2} \mathrm{d}\varphi, \qquad \forall\ |z| < 1.$$

7.3 New Golden-Thompson inequality

We begin by giving an outline of the proof of Theorem 7.1.5. The proof of Theorem 7.1.4 in [SBT17] relies on the multivariate Lie-Trotter product formula (e.g. see [Bha97]), which states that:

$$\exp\left(\sum_{j=1}^{k} L_j\right) = \lim_{\theta \to 0^+} \left(\prod_{j=1}^{k} \exp(\theta L_j)\right)^{\frac{1}{\theta}}.$$

For Hermitian L_j, a judicious application of the above allows one to rewrite the trace of the exponential as a limit of Schatten norms:

$$\log\left(\operatorname{tr}\left[\exp\left(\sum_{j=1}^{k} L_j\right)\right]\right) = \lim_{\theta \to 0^+} \frac{2}{\theta} \log \left\| \prod_{j=1}^{k} \exp\left(\frac{\theta}{2} L_j\right) \right\|_{2/\theta}.$$

Thus, understanding the matrix exponential of a sum is the same as understanding the behavior of a certain norm of the product as $\theta \to 0$. The idea of [SBT17] is to use *complex interpolation*, along the lines of the Stein-Hirschman theorem in complex analysis: for every fixed real θ near zero, find a complex function $F_\theta(z)$ that agrees with the right hand side at $z = \theta$ and is holomorphic on the strip $\{0 \leq \Re(z) \leq 1\}$. Since the value of a holomorphic function at any point can be related to an integral of its values on the boundary, this allows one to relate $F_\theta(\theta)$ to its integrals on $\{\Re(z) = 0\}$ and $\{\Re(z) = 1\}$, which are easy to understand. Taking the limit in θ yields Theorem 7.1.4.

To avoid integration on the whole vertical line $\{1 + \mathbf{i}b : b \in \mathbb{R}\}$, we observe that the above strategy only relies on the fact that θ is enclosed by the two vertical lines $\{\mathbf{i}b : b \in \mathbb{R}\}$ and $\{1 + \mathbf{i}b : b \in \mathbb{R}\}$, and we could have used any other region enclosing a neighborhood of real positive θ near zero, provided we can define the required holomorphic functions F_θ. We choose the half-circle (which is easy to work with because the Riemann map to the unit

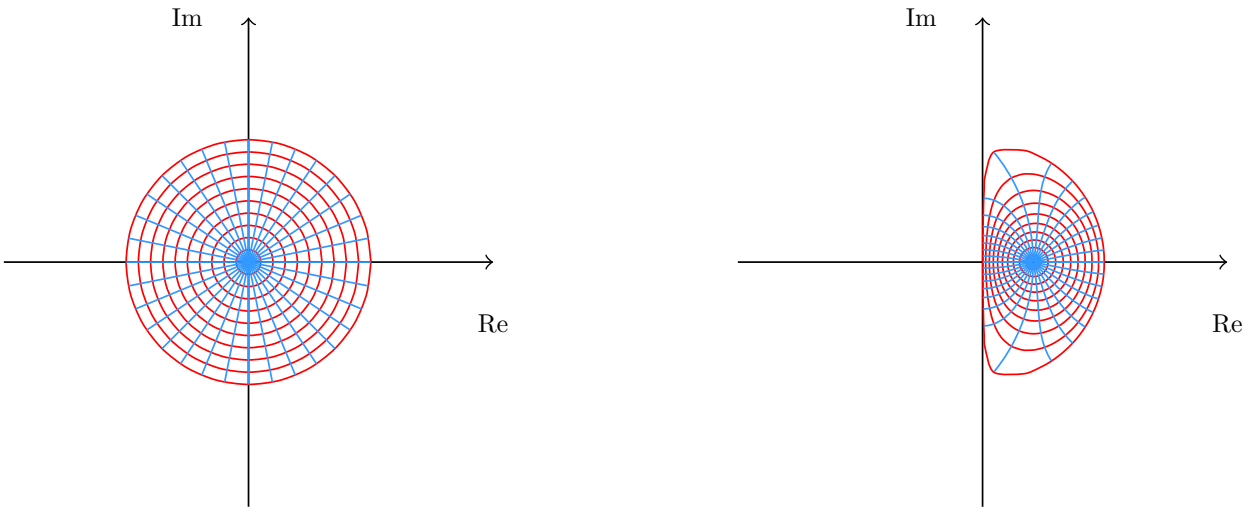

Figure 7.1: The function $h(z) = -\frac{1+z}{1-z} + \sqrt{\left(\frac{1+z}{1-z}\right)^2 + 1}$ maps the unit disk $\{z \in \mathbb{C} : |z| \leq 1\}$ to the half disk $\{z \in \mathbb{C} : |z| \leq 1 \text{ and } \mathrm{Re}(z) \geq 0\}$.

disk is explicit) and use it to derive a variant of the Riesz–Thorin theorem (Theorem 7.3.3), from which our new multi-matrix Golden-Thompson inequality follows by mimicking the remainder of the proof of 7.1.4 given in [SBT17].

7.3.1 Complex estimate on the half disk

In general, we can upper bound the value of any subharmonic function on a simply connected domain by mapping the domain to the unit disk via Riemann mapping theorem and applying the Poisson integral formula. In this section, we will give such estimate on a unit half disk.

The following lemma follows from the biholomorphic map from unit disk onto the half disk defined in Figure 7.1.

Lemma 7.3.1 (Poisson Integral Formula on the Half-Disk)**.** *For any analytic function F on*

the half disk $\{z \in \mathbb{C} : |z| \leq 1 \text{ and } \mathrm{Re}(z) \geq 0\}$, *we have that*

$$\log|F(x)| \leq \frac{1}{2\pi}\int_{-\pi}^{\pi} \log\left|F \circ h(e^{\mathbf{i}\varphi})\right| \frac{1-\rho^2}{1-2\rho\cos(\varphi)+\rho^2}\mathrm{d}\varphi \tag{7.6}$$

for any $0 \leq x \leq 1$ *where*

$$h(z) = -\frac{1+z}{1-z} + \sqrt{\left(\frac{1+z}{1-z}\right)^2 + 1} \quad \text{and} \quad \rho = \frac{x^2+2x-1}{x^2-2x-1}.$$

Proof. Note that the function $h(z)$ is a biholomorphic map from the unit disk $\{z \in \mathbb{C} : |z| \leq 1\}$ to the half disk $\{z \in \mathbb{C} : |z| \leq 1 \text{ and } \mathrm{Re}(z) \geq 0\}$. (We provide a proof for completeness, see Lemma 7.6.1 [2])

Since F and h are holomorphic, $\log|F \circ h(z)|$ is subharmonic. Therefore, we can apply the Poisson integral formula for subharmonic functions (Lemma 7.2.3) and get

$$\begin{aligned}
&\log|F \circ h(z)| \\
&\leq \frac{1}{2\pi}\int_{-\pi}^{\pi} \log\left|F \circ h(e^{\mathbf{i}\varphi})\right| \frac{1-|z|^2}{|e^{\mathbf{i}\varphi}-z|^2}\mathrm{d}\varphi \\
&= \frac{1}{2\pi}\int_{-\pi}^{\pi} \log\left|F \circ h(e^{\mathbf{i}\varphi})\right| \frac{1-\rho^2}{1-2\rho\cos(\theta-\varphi)+\rho^2}\mathrm{d}\varphi
\end{aligned}$$

for $z = \rho e^{\mathbf{i}\theta}$.

Setting $x = h(z)$, we obtain that

$$z = \frac{x^2+2x-1}{x^2-2x-1}.$$

[2] The similar version is an exercise 4 in page 163 (Section VII) of [Con78], and also can be found here, https://math.stackexchange.com/questions/882147/find-a-conformal-map-from-semi-disk-onto-unit-disk

Therefore, we have that

$$\theta = 0 \text{ and } \rho = \frac{x^2 + 2x - 1}{x^2 - 2x - 1}.$$

This gives the desired result.

□

The following lemma allows us to conveniently study the behavior of certain analytic functions near zero. The idea is that when $|F(z)|$ is at most 1 on the imaginary axis, $\log|F(\theta)|$ should be close to 0 for small θ, and the value of $\log|F(\theta)|/\theta$ can be upper bounded by a suitable average of the values on the boundary of the half disk.

Lemma 7.3.2. *Given any analytic function F on the half disk $\{z \in \mathbb{C} : |z| \le 1$ and $\mathrm{Re}(z) \ge 0\}$. Suppose that $|F(\mathbf{i}y)| \le 1$ for all $y \in [-1, 1]$. Then, for any $0 \le \theta \le 1/4$, we have*

$$\log|F(\theta)| \le \left(\frac{4\theta}{\pi} + O(\theta^2)\right) \int_{-\pi/2}^{\pi/2} \log\left|F(e^{\mathbf{i}\phi})\right| \mathrm{d}\mu_\theta(\phi)$$

where μ_θ is some probability distribution on $[-\frac{\pi}{2}, \frac{\pi}{2}]$ depending only on θ, and $\mu_\theta \to$ some probability distribution as $\theta \to 0^+$.

Proof. Since $\log|F(\mathbf{i}y)| \le 0$ for all $y \in [-1, 1]$ and since $h(e^{\mathbf{i}\varphi})$ is imaginary with modulus at most 1 whenever $|\varphi| \le \pi/2$, we can ignore these φ in the integral (7.6), namely,

$$\begin{aligned} &\log|F(x)| \\ &\le \frac{1}{2\pi} \int_{-\pi}^{\pi} \log\left|F \circ h(e^{\mathbf{i}\varphi})\right| \frac{1 - \rho^2}{1 - 2\rho\cos(\varphi) + \rho^2} \mathrm{d}\varphi \\ &\le \frac{1}{2\pi} \int_{\pi/2 \le |\varphi| \le \pi} \log\left|F \circ h(e^{\mathbf{i}\varphi})\right| \frac{1 - \rho^2}{1 - 2\rho\cos(\varphi) + \rho^2} \mathrm{d}\varphi. \end{aligned} \tag{7.7}$$

To bound the right hand side, for $\pi/2 \le |\varphi| \le \pi$ and $0 \le \rho \le 1$, we can prove the following statement using elementary calculations (see Lemma 7.6.4),

$$\frac{1-\rho^2}{1-2\rho\cos(\varphi)+\rho^2} = \frac{1-\rho}{1-\cos(\varphi)} \pm O(1-\rho)^2.$$

Note that $\rho = \frac{\theta^2+2\theta-1}{\theta^2-2\theta-1} \ge 1-4\theta$ for all $0 \le \theta \le 1/4$. Therefore, we have that $0 \le \rho \le 1$ and

$$\frac{1-\rho^2}{1-2\rho\cos(\varphi)+\rho^2} \le \frac{4\theta}{1-\cos(\varphi)} + O(\theta^2).$$

Putting this inequality into (7.7), we have that

$$\begin{aligned} &\log|F(x)| \\ &\le \frac{1}{2\pi}\int_{\pi/2\le|\varphi|\le\pi} \left(\frac{4\theta}{1-\cos(\varphi)} + O(\theta^2)\right) \log|F\circ h(e^{\mathbf{i}\varphi})|\mathrm{d}\varphi. \end{aligned}$$

We now observe that

$$\begin{aligned} &\int_{\pi/2\le|\varphi|\le\pi} \frac{1}{1-\cos(\varphi)}\mathrm{d}\varphi \\ &= \int_{-\pi}^{-\pi/2} \frac{1}{1-\cos(\varphi)}\mathrm{d}\varphi + \int_{\pi/2}^{\pi} \frac{1}{1-\cos(\varphi)}\mathrm{d}\varphi \\ &= 2. \end{aligned}$$

Note that h maps $e^{\mathbf{i}\varphi}$ for $\pi/2 \le |\varphi| \le \pi$ to the boundary of the half disk ($[-\pi/2, \pi/2]$), and let μ_θ be some probability distribution on $[-\frac{\pi}{2}, \frac{\pi}{2}]$ depending only on θ. Then we can have

$$\log|F(\theta)| \le \left(\frac{4\theta}{\pi} + O(\theta^2)\right) \int_{-\pi/2}^{\pi/2} \log\left|F(e^{\mathbf{i}\phi})\right| \mathrm{d}\mu_\theta(\phi).$$

Note that $\mu_\theta \to$ some probability distribution as $\theta \to 0^+$. □

7.3.2 Bounded Multimatrix Golden-Thompson type inequality

Plugging our new complex estimate into the proof of Theorem 3.1 in [SBT17], we obtain the following Riesz-Thorin-type inequality. We give a complete proof for completeness.

Theorem 7.3.3 (Riesz-Thorin-type inequality)**.** *Let* $S = \{z \in \mathbb{C} : |z| \leq 1 \text{ and } \mathrm{Re}(z) \geq 0\}$ *and let* G *be a holomorphic map from* S *to square matrices. Let* $p_0 \geq p_1 \in [1, \infty]$*, for* $\theta \in (0,1)$*, define* p_θ *by*

$$\frac{1}{p_\theta} = \frac{1-\theta}{p_0} + \frac{\theta}{p_1}.$$

If $z \to \|G(z)\|_{p_{\mathrm{Re}(z)}}$ *is uniformly bounded on* S *and* $\|G(\mathbf{i}t)\|_{p_0} \leq 1$*, then for any* $0 \leq \theta \leq 1/4$*,*

$$\log \|G(\theta)\|_{p_\theta} \leq \left(\frac{4\theta}{\pi} + O(\theta^2)\right) \int_{-\pi/2}^{\pi/2} \log \|G(e^{\mathbf{i}\phi})\|_{p_1} \mathrm{d}\mu_\theta(\phi)$$

where μ_θ *is some probability distribution on* $[-\frac{\pi}{2}, \frac{\pi}{2}]$ *depending only on* θ*.*

Proof. To apply Lemma 7.3.2, we want to define a holomorphic function $F(z)$ such that

$$|F(\mathbf{i}t)| \leq 1 \ , \ |F(z)| \leq \|G(z)\|_{p_1} \text{ and } F(\theta) = \|G(\theta)\|_{p_\theta}.$$

Now, we describe how to define such $F(z)$. For $x \in [0,1]$, define q_x as the Hölder conjugate of p_x such that $p_x^{-1} + q_x^{-1} = 1$. Hence, using the definition of p_x in the statement, we have

$$\frac{1}{q_x} = \frac{1-x}{q_0} + \frac{x}{q_1}.$$

Now for our fixed $\theta \in (0,1)$, let $G(\theta) = UV$ be the polar decomposition of $G(\theta)$, where V is positive definite since $G(\theta)$ is always invertible, and U is unitary. Finally, we define $X(z)$

and $F(z)$ by

$$X(z)^* = (V/c)^{p_\theta(\frac{1-z}{q_0}+\frac{z}{q_1})}U^*, \text{ where } c = \|V\|_{p_\theta} = \|G(\theta)\|_{p_\theta}$$
$$F(z) = \mathrm{tr}[X(z)^* G(z)].$$

Note that $F(z)$ is holomorphic. Due to the renormalization c, we can show $\|X(x+\mathbf{i}y))\|_{q_x}^{q_x} = 1$ for all $x \in [0,1]$:

$$\begin{aligned}
\|X(x+\mathbf{i}y)\|_{q_x}^{q_x} &= \mathrm{tr}\left[\sqrt{X^*(x+\mathbf{i}y)X(x+\mathbf{i}y)}^{q_x}\right] \\
&= \mathrm{tr}\left[(V/c)^{q_x p_\theta(\frac{1-x}{q_0}+\frac{x}{q_1})}\right] \\
&= \mathrm{tr}\left[(V/c)^{p_\theta}\right] \\
&= 1.
\end{aligned}$$

where the first step follows by definition of $\|\cdot\|_p$, the second step follows by $U^*U = I$, the third step follows by $\frac{1}{q_x} = \frac{1-x}{q_0} + \frac{x}{q_1}$, and the last step follows by $c = \|V\|_{p_\theta}$.

Therefore, $F(z)$ is bounded on S as follows

$$|F(x+\mathbf{i}y)| \le \|X(x+\mathbf{i}y)\|_{q_x} \cdot \|G(x+\mathbf{i}y)\|_{p_x} \le \|G(x+\mathbf{i}y)\|_{p_x}.$$

Using this, it is obvious that

$$|F(\mathbf{i}t)| \le \|G(\mathbf{i}t)\|_{p_0} \le 1, \text{ and } |F(z)| \le \|G(z)\|_{p_{\mathrm{Re}(z)}} \le \|G(z)\|_{p_1}.$$

for all $z \in S$ where we used that $p_0 \ge p_{\mathrm{Re}(z)} \ge p_1$.

Finally, we verify that $F(\theta) = \|G(\theta)\|_{p_\theta}$:

$$\begin{aligned} F(\theta) &= \operatorname{tr}[X(\theta)^* G(\theta)] \\ &= \operatorname{tr}[(V/c)^{p_\theta(\frac{1-\theta}{q_0}+\frac{\theta}{q_1})} U^* \cdot UV] \\ &= \operatorname{tr}[(V/c)^{p_\theta(\frac{1-\theta}{q_0}+\frac{\theta}{q_1})} V] \\ &= \operatorname{tr}[c^{-p_\theta/q_\theta} V^{1+p_\theta/q_\theta}] \\ &= \operatorname{tr}[c^{1-p_\theta} V^{p_\theta}] \\ &= c^{1-p_\theta} c^{p_\theta} \\ &= \|G(\theta)\|_{p_\theta}, \end{aligned}$$

where the first step follows by definition of X and G, the second step follows by $U^*U = I$, the third step follows by $\frac{1}{q_\theta} = \frac{1-\theta}{q_0} + \frac{\theta}{q_1}$, the fourth step follows by $p_\theta/q_\theta = p_\theta(1 - 1/p_\theta) = p_\theta - 1$, the fifth step follows by $(\operatorname{tr}[V^{p_\theta}])^{1/p_\theta} = c$, and the last step follows by $c = \|G(\theta)\|_{p_\theta}$.

Hence, the statement follows from Lemma 7.3.2. □

Now, we are ready to prove our variant of multimatrix Golden-Thompson inequality. It follows from plugging in Theorem 7.3.3 into the proof of Theorem 3.5 in [SBT17]. We give a complete proof for completeness.

Theorem 7.3.4 (Multimatrix Golden-Thompson inequality)**.** *For any k Hermitian matrices $H_1, \cdots, H_k$, we have:*

$$\log\left(\operatorname{tr}\left[\exp\left(\sum_{j=1}^{k} H_j\right)\right]\right) \leq \frac{4}{\pi}\int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} \log\left(\operatorname{tr}\left[\prod_{j=1}^{k}\exp\left(\frac{e^{\mathbf{i}\phi}}{2}H_j\right)\prod_{j=k}^{1}\exp\left(\frac{e^{-\mathbf{i}\phi}}{2}H_j\right)\right]\right)\mathrm{d}\mu(\phi)$$

where μ is some probability distribution on $[-\frac{\pi}{2}, \frac{\pi}{2}]$.

Proof. Define

$$G(z) = \prod_{j=1}^{k} \exp\left(\frac{z}{2} H_j\right).$$

Note that $\|G(\mathbf{i}y)\|_\infty = 1$ for all $y \in \mathbb{R}$. We now have:

$$\begin{aligned}
& \log\left(\operatorname{tr}\left[\exp\left(\sum_{j=1}^{k} H_j\right)\right]\right) \\
=\ & \log\left(\operatorname{tr}\left[\exp\left(\sum_{j=1}^{k} H_j/2 + \sum_{j=k}^{1} H_j/2\right)\right]\right) \\
=\ & \log\left(\operatorname{tr}\left[\lim_{\theta\to 0^+} (G(\theta)G(\theta)^*)^{1/\theta}\right]\right) \\
=\ & \lim_{\theta\to 0^+} \frac{2}{\theta} \log\left(\operatorname{tr}\left[(G(\theta)G(\theta)^*)^{1/\theta}\right]^{\theta/2}\right) \\
=\ & \lim_{\theta\to 0^+} \frac{2}{\theta} \log \|G(\theta)\|_{2/\theta} \\
\leq\ & \lim_{\theta\to 0^+} 2\left(\frac{4}{\pi} + O(\theta)\right) \int_{-\pi/2}^{\pi/2} \log \|G(e^{\mathbf{i}\phi})\|_2 \mathrm{d}\mu_\theta(\phi) \\
=\ & \lim_{\theta\to 0^+} \left(\frac{4}{\pi} + O(\theta)\right) \int_{-\pi/2}^{\pi/2} \log\left(\operatorname{tr}\left[G(e^{\mathbf{i}\phi})G(e^{\mathbf{i}\phi})^*\right]\right) \mathrm{d}\mu_\theta(\phi),
\end{aligned}$$

where the first step follows from by the Lie-Trotter formula, the second step follows from H_j are Hermitian, the third step follows from continuity of log away from 0, last inequality follows from Theorem 7.3.3 with $p_0 = \infty$ and $p_1 = 2$.

When $\theta \to 0^+$, $\mu_\theta(\phi)$ converges to some probability distribution μ. This completes the proof. □

Remark 7.3.1. We suspect the constant $4/\pi$ is tight and that any constant larger than one is unavoidable if we consider the maximum over a bounded domain inside the strip $\{z \in \mathbb{C} : 0 \leq \operatorname{Re}(z) \leq 1\}$.

7.4 Proof of Theorem 7.1.2

In this section we present the proof of Theorem 7.1.2. We restate it here (with explicit constants) for convenience.

Theorem 7.4.1. *Let G be a regular λ-expander on V and let f be a function $f : V \to \mathbb{C}^{d\times d}$ s.t.*

1. *For each $v \in V$, $f(v)$ is Hermitian and $\|f(v)\| \leq 1$.*
2. *$\sum_{v\in V} f(v) = 0$.*

If $v_1, \ldots, v_k$ is a stationary random walk on G, and $\epsilon \in (0, 1)$,

$$\Pr\left[\lambda_{\max}\left(\sum_{j=1}^{k} f(v_j)\right) \geq +k\epsilon\right] \leq d^{2-\pi/4} \cdot \exp\left(-\epsilon^2(1-\lambda)k/80\right),$$
$$\Pr\left[\lambda_{\min}\left(\sum_{i=1}^{k} f(v_j)\right) \leq -k\epsilon\right] \leq d^{2-\pi/4} \cdot \exp\left(-\epsilon^2(1-\lambda)k/80\right).$$

Remark 7.4.1. Depsite the exponent of d is different from Theorem 7.1.2, we note that since the left hand side (the probability) is at most 1, one can prove the same statement with any positive exponent by changing the constant 80.

Proof. Due to symmetry, it suffices to prove just one of the statements. Let $t > 0$ be a

parameter to be chosen later. Then

$$\begin{aligned}
&\Pr\left[\lambda_{\max}\left(\sum_{j=1}^{k} f(v_j)\right) \geq k\epsilon\right] \\
\leq\ &\Pr\left[\operatorname{tr}\left[\exp\left(t\sum_{j=1}^{k} f(v_j)\right)\right] \geq \exp(tk\epsilon)\right] \\
\leq\ &\frac{\mathbb{E}\left[\operatorname{tr}\left[\exp\left(t\sum_{j=1}^{k} f(v_j)\right)\right]\right]}{\exp(tk\epsilon)}.
\end{aligned} \tag{7.8}$$

The second inequality follows from Markov's inequality.

Now the question is how to bound $\mathbb{E}_{v_1,\cdots,v_k}[\operatorname{tr}[\exp(t\sum_{j=1}^{k} f(v_j))]]$. Using Theorem 7.3.4 and note that $\mu(\phi)$ is a probability distribution on $[-\frac{\pi}{2}, \frac{\pi}{2}]$, we have

$$\begin{aligned}
&\log\left(\operatorname{tr}\left[\exp\left(t\sum_{j=1}^{k} f(v_j)\right)\right]\right) \\
\leq\ &\frac{4}{\pi}\int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} \log\operatorname{tr}\left[\prod_{j=1}^{k}\exp\left(\frac{e^{\mathbf{i}\phi}}{2}tf(v_j)\right)\prod_{j=k}^{1}\exp\left(\frac{e^{-\mathbf{i}\phi}}{2}tf(v_j)\right)\right]\mathrm{d}\mu(\phi) \\
\leq\ &\frac{4}{\pi}\log\int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} \operatorname{tr}\left[\prod_{j=1}^{k}\exp\left(\frac{e^{\mathbf{i}\phi}}{2}tf(v_j)\right)\prod_{j=k}^{1}\exp\left(\frac{e^{-\mathbf{i}\phi}}{2}tf(v_j)\right)\right]\mathrm{d}\mu(\phi),
\end{aligned}$$

where the the second step follows by concavity of log function. This implies that

$$\begin{aligned}
&\operatorname{tr}\left[\exp\left(t\sum_{j=1}^{k} f(v_j)\right)\right] \\
\leq\ &\left(\int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} \operatorname{tr}\left[\prod_{j=1}^{k}\exp\left(\frac{e^{\mathbf{i}\phi}}{2}tf(v_j)\right)\prod_{j=k}^{1}\exp\left(\frac{e^{-\mathbf{i}\phi}}{2}tf(v_j)\right)\right]\mathrm{d}\mu(\phi)\right)^{\frac{4}{\pi}}.
\end{aligned} \tag{7.9}$$

Note that $\|x\|_p \leq d^{1/p-1}\|x\|_1$ for $p \in (0,1)$, choosing $p = \pi/4$ we have

$$\left(\operatorname{tr}\left[\exp\left(\frac{\pi}{4}t\sum_{j=1}^{k} f(v_j)\right)\right]\right)^{\frac{4}{\pi}} \leq d^{4/\pi-1}\operatorname{tr}\left[\exp\left(t\sum_{j=1}^{k} f(v_j)\right)\right]. \tag{7.10}$$

Combining Eq. (7.9) and Eq. (7.10), we have

$$\operatorname{tr}\left[\exp\left(\frac{\pi}{4}t\sum_{j=1}^{k} f(v_j)\right)\right] \leq d^{1-\pi/4}\int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} \operatorname{tr}\left[\prod_{j=1}^{k}\exp\left(\frac{e^{\mathbf{i}\phi}}{2}tf(v_j)\right)\prod_{j=k}^{1}\exp\left(\frac{e^{-\mathbf{i}\phi}}{2}tf(v_j)\right)\right]\mathrm{d}\mu(\phi). \tag{7.11}$$

The core of the proof is the following bound on the moment generating function-like expression that appears above, thinking of $\mathbf{i}\phi$ as $\gamma + \mathbf{i}b$ with $\gamma^2 + b^2 = 1$:

Lemma 7.4.2. *Let G be a regular λ-expander on V, let f be a function $f : V \to \mathbb{C}^{d\times d}$ and $\sum_{v\in V} f(v) = 0$, let $v_1, \cdots, v_k$ be a stationary random walk on G, for any $t > 0$, $\gamma \geq 0$, $b > 0$, $t^2(\gamma^2 + b^2) \leq 1$, and $t\gamma \leq \frac{1-\lambda}{4\lambda}$ we have*

$$\begin{aligned}&\mathbb{E}\left[\operatorname{tr}\left[\prod_{j=1}^{k}\exp\left(\frac{tf(v_j)(\gamma+\mathbf{i}b)}{2}\right)\prod_{j=k}^{1}\exp\left(\frac{tf(v_j)(\gamma-\mathbf{i}b)}{2}\right)\right]\right]\\ &\leq d\cdot\exp\left(kt^2(\gamma^2+b^2)(1+\frac{8}{1-\lambda})\right).\end{aligned}$$

Assuming this lemma, we can easily complete the proof of the theorem as:

$$
\begin{aligned}
&\mathop{\mathbb{E}}_{v_1,\cdots,v_k}\left[\operatorname{tr}\left[\exp\left(\frac{\pi}{4}t\sum_{j=1}^{k}f(v_j)\right)\right]\right] \\
&\leq d^{1-\pi/4}\mathop{\mathbb{E}}_{v_1,\cdots,v_k}\left[\int_{-\frac{\pi}{2}}^{\frac{\pi}{2}}\operatorname{tr}\left[\prod_{j=1}^{k}\exp\left(\frac{e^{\mathbf{i}\phi}}{2}tf(v_j)\right)\prod_{j=k}^{1}\exp\left(\frac{e^{-\mathbf{i}\phi}}{2}tf(v_j)\right)\right]\mathrm{d}\mu(\phi)\right] \\
&= d^{1-\pi/4}\int_{-\frac{\pi}{2}}^{\frac{\pi}{2}}\mathop{\mathbb{E}}_{v_1,\cdots,v_k}\left[\operatorname{tr}\left[\prod_{j=1}^{k}\exp\left(\frac{e^{\mathbf{i}\phi}}{2}tf(v_j)\right)\prod_{j=k}^{1}\exp\left(\frac{e^{-\mathbf{i}\phi}}{2}tf(v_j)\right)\right]\right]\mathrm{d}\mu(\phi) \\
&\leq d^{1-\pi/4}\int_{-\frac{\pi}{2}}^{\frac{\pi}{2}}d\exp\left(kt^2|e^{\mathbf{i}\phi}|^2(1+\frac{8}{1-\lambda})\right)\mathrm{d}\mu(\phi) \\
&= d^{2-\pi/4}\exp\left(kt^2(1+\frac{8}{1-\lambda})\right)\int_{-\frac{\pi}{2}}^{\frac{\pi}{2}}\mathrm{d}\mu(\phi) \\
&= d^{2-\pi/4}\exp\left(kt^2(1+\frac{8}{1-\lambda})\right), \qquad (7.12)
\end{aligned}
$$

where the first step follows by the Equation (7.11), the second step follows by swapping $\mathbb{E}$ and $\int$, the third step follows by Lemma 7.4.2 , the fourth step follows by $|e^{\mathbf{i}\phi}| = 1$, and the last step follows by $\int_{-\frac{\pi}{2}}^{\frac{\pi}{2}}\mathrm{d}\mu(\phi) = 1$.

Finally, putting it all together,

$$
\begin{aligned}
&\Pr_{v_1,\cdots,v_k}\left[\lambda_{\max}\left(\sum_{j=1}^{k}f(v_j)\right)\geq k\epsilon\right] \\
&\leq d^{2-\pi/4}\cdot\exp\left((4/\pi)^2kt^2\frac{9}{1-\lambda}-kt\epsilon\right) \\
&= d^{2-\pi/4}\cdot\exp\left((4/\pi)^2k\epsilon^2(1-\lambda)^2\frac{1}{36^2}\frac{9}{1-\lambda}-k\frac{(1-\lambda)\epsilon}{36}\epsilon\right) \\
&\leq d^{2-\pi/4}\cdot\exp\left(-k\epsilon^2(1-\lambda)/72\right).
\end{aligned}
$$

where the first step follows by Eq. (7.12) the second step follows by choosing $t = (1-\lambda)\epsilon/36$. □

We now give the proof of Lemma 7.4.2

Proof of Lemma 7.4.2. We start by writing the expected trace expression in terms of the transition matrix of the random walk. This is an analogue of a step which is common to most of the expander chernoff bound proofs in the scalar case. Let P be the normalized adjacency matrix of G and let $\widetilde{P} = P \otimes I_{d^2}$. Let E denote the $nd^2 \times nd^2$ block diagonal matrix where the v^{th} diagonal block is the matrix

$$M_v = \exp\left(\frac{tf(v)(\gamma + \mathbf{i}b)}{2}\right) \otimes \exp\left(\frac{tf(v)(\gamma - \mathbf{i}b)}{2}\right). \tag{7.13}$$

Then $\left(E\widetilde{P}\right)^k$ is an $nd^2 \times nd^2$ block matrix whose $(u,v)^{\text{th}}$ $(d^2 \times d^2)$ block is given by the matrix

$$\sum_{v_1,\ldots,v_{k-1}} P_{u,v_1} \cdot \left(\prod_{j=1}^{k-2} P_{v_j,v_{j+1}}\right) \cdot P_{v_{k-1},v} \cdot M_u \cdot \left(\prod_{j=1}^{k-1} M_{v_j}\right). \tag{7.14}$$

Let $z_0 \in \mathbb{C}^{nd^2}$ be the vector $\frac{\mathbf{1}}{\sqrt{n}} \otimes \text{vec}(I_d)$. Here $\mathbf{1}$ is the all 1's vector and $\text{vec}(I_d)$ is the vector form of the identity matrix. Then, by applying

$$\langle \text{vec}(I_d), A_1 \otimes A_2 \,\text{vec}(I_d)\rangle = \text{tr}\left[A_1 A_2^\top\right],$$

it follows that for a stationary random walk $v_1, \ldots, v_k$:

$$\begin{aligned}
&\mathbb{E}\left[\text{tr}\left[\prod_{j=1}^{k} \exp\left(\frac{tf(v_j)(\gamma + \mathbf{i}b)}{2}\right) \prod_{j=k}^{1} \exp\left(\frac{tf(v_j)(\gamma - \mathbf{i}b)}{2}\right)\right]\right] \\
=\ &\mathbb{E}\left[\left\langle \text{vec}(I_d), \prod_{i=1}^{k} M_{v_i} \text{vec}(I_d)\right\rangle\right] \\
=\ &\left\langle z_0, \left(E\widetilde{P}\right)^k z_0\right\rangle.
\end{aligned}$$

Hence we can focus our attention on $\left\langle z_0, \left(E\widetilde{P}\right)^k z_0 \right\rangle$.

Let $\mathbf{1}$ be the all 1's vector. For a vector $z \in \mathbb{C}^{nd^2}$, let $z^{\|}$ denote the component of z which lies in the subspace spanned by the d^2 vectors $\mathbf{1} \otimes e_i$, $1 \leq i \leq d^2$. Let $z^{\perp}$ denote the component in the orthogonal space. Letting $z_j = \left(E\widetilde{P}\right)^j z_0$, we are interested in bounding

$$\langle z_0, z_k \rangle = \langle z_0, z_k^{\|} \rangle \leq \|z_0\| \cdot \|z_k^{\|}\| = \sqrt{d} \cdot \|z_k^{\|}\|.$$

The following lemma is the analogue of the main lemma in Healy's proof for the scalar valued expander Chernoff bound [Hea08]. Roughly speaking, it tracks how much a vector can move in and out of the subspace we are interested in as the operator $E\widetilde{P}$ is applied.

Lemma 7.4.3. *Given four parameters $\lambda \in [0,1]$, $\gamma \geq 0$, $\ell \geq 0$, and $t > 0$. Let G be a regular λ-expander on V. Suppose each vertex v is assigned a matrix $H_v \in \mathbb{C}^{d^2 \times d^2}$ s.t. $\|H_v\| \leq \ell$ and $\sum_v H_v = 0$. Let P be the normalized adjacency matrix of G and let $\widetilde{P} = P \otimes I_{d^2}$. Let E denote the $nd^2 \times nd^2$ block diagonal matrix where the v-th diagonal block is the matrix $\exp(tH_v)$. Also suppose that $\|E\| = \max_{v \in V} \|\exp(tH_v)\| \leq \exp(\gamma t)$. Then for any $z \in \mathbb{C}^{nd^2}$, we have:*

1. $\|(E\widetilde{P}z^{\|})^{\|}\| \leq \alpha_1 \|z^{\|}\|$ *where* $\alpha_1 = \exp(t\ell) - t\ell$,
2. $\|(E\widetilde{P}z^{\|})^{\perp}\| \leq \alpha_2 \|z^{\|}\|$ *where* $\alpha_2 = \exp(t\ell) - 1$,
3. $\|(E\widetilde{P}z^{\perp})^{\|}\| \leq \alpha_3 \|z^{\perp}\|$ *where* $\alpha_3 = \lambda \cdot (\exp(t\ell) - 1)$,
4. $\|(E\widetilde{P}z^{\perp})^{\perp}\| \leq \alpha_4 \|z^{\perp}\|$ *where* $\alpha_4 = \lambda \cdot \exp(t\gamma)$.

Proof of Lemma 7.4.3. Part 1.

Note that

$$(E\widetilde{P}z^{\|})^{\|} = (Ez^{\|})^{\|}.$$

Let $\mathbf{1} \in \mathbb{R}^n$ denote all ones vector, suppose $z^{\|} = \mathbf{1} \otimes \mathbf{w}$ for some $\mathbf{w} \in \mathbb{C}^{d^2}$. Then $\|z^{\|}\| = \sqrt{n} \cdot \|\mathbf{w}\|$ and

$$(Ez^{\|})^{\|} = \mathbf{1} \otimes \left(\frac{1}{n} \sum_{v \in V} \exp(H_v)\mathbf{w} \right).$$

We can upper bound $\|\frac{1}{n}\sum_{v\in V}\exp(tH_v)\|$ in the following way,

$$\begin{aligned}
\left\| \frac{1}{n} \sum_{v \in V} \exp(tH_v) \right\| &= \left\| \frac{1}{n} \sum_{v \in V} \sum_{j=0}^{\infty} \frac{t^j H_v^j}{j!} \right\| \\
&= \left\| I + \frac{1}{n} \sum_{v \in V} \sum_{j=2}^{\infty} \frac{t^j H_v^j}{j!} \right\| \\
&\leq 1 + \frac{1}{n} \sum_{v \in V} \sum_{j \geq 2} \frac{t^j}{j!} \|H_v\|^j \\
&= 1 + \sum_{j \geq 2} \frac{(t\ell)^j}{j!} \\
&= \exp(t\ell) - t\ell,
\end{aligned}$$

where the first step follows by Taylor expansion, the second step follows by $\sum_{v\in V} H_v = 0$, the third step follows by triangle inequality, the fourth step follows by $|V| = n$ and $\|H_v\| \leq \ell$, and last step follows by Taylor expansion.

Thus,

$$\begin{aligned}
\|(Ez^{\|})^{\|}\| &= \sqrt{n} \left\| \frac{1}{n} \sum_{v \in V} \exp(tH_v) w \right\| \\
&\leq \sqrt{n} \|w\| (\exp(t\ell) - t\ell) \\
&= \|z^{\|}\| (\exp(t\ell) - t\ell).
\end{aligned}$$

Part 2. Note that $(E\widetilde{P}z^{\|})^{\perp} = (Ez^{\|})^{\perp} = ((E-I)z^{\|})^{\perp}$. and $(z^{\|})^{\perp} = 0$. We can upper bound $\|((E-I)z^{\|})^{\perp}\|$ in the following way,

$$\begin{aligned}
\|((E-I)z^{\|})^{\perp}\| &\leq \|(E-I)z^{\|}\| \\
&\leq \|E-I\| \cdot \|z^{\|}\| \\
&= \max_{v \in V} \|\exp(tH_v) - I\| \cdot \|z^{\|}\| \\
&= \max_{v \in V} \left\| \sum_{j=1}^{\infty} \frac{t^j}{j!} H_v^j \right\| \cdot \|z^{\|}\| \\
&\leq \left(\sum_{j=1}^{\infty} \frac{t^j \ell^j}{j!} \right) \cdot \|z^{\|}\| \\
&= (\exp(t\ell) - 1) \cdot \|z^{\|}\|,
\end{aligned}$$

where the second step follows by $\|Ax\| \leq \|A\| \cdot \|x\|$, the third step follows by definition of E, the fourth step follows by Taylor expansion, the fifth step follows by triangle inequality and $\|H_v\| \leq \ell$, and the last step follows by Taylor expansion.

Part 3. Note that $(E\widetilde{P}z^{\perp})^{\|} = ((E-I)\widetilde{P}z^{\perp})^{\|}$. This is because $(\widetilde{P}z^{\perp})^{\|} = 0$ since $\widetilde{P}$ preserves the property of being orthogonal to the space spanned by the vectors $\mathbf{1} \otimes e_i$ (these are the top eigenvectors of $\widetilde{P}$). Hence we can bound

$$\begin{aligned}
\left\| ((E-I)\widetilde{P}z^{\perp})^{\|} \right\| &\leq \left\| (E-I)\widetilde{P}z^{\perp} \right\| \\
&\leq \|E-I\| \cdot \left\| \widetilde{P}z^{\perp} \right\| \\
&\leq (\exp(t\ell) - 1) \cdot \lambda \cdot \left\| z^{\perp} \right\|.
\end{aligned}$$

Third inequality follows from the fact that $\|E-I\| \leq \exp(t\ell) - 1$ and that G is a λ-expander.

Part 4. We can bound

$$\|(E\widetilde{P}z^{\perp})^{\perp}\| \leq \|E\widetilde{P}z^{\perp}\| \leq \exp(t\gamma)\cdot\lambda\|z^{\perp}\|,$$

where the second step follows by $\|E\| \leq \exp(\gamma t)$ and G is a λ-expander.

□

We now use the above Lemma 7.4.3 to analyze the evolution of $z_j^{\|}$ and $z_j^{\perp}$. Recall the definition of H_v,

$$H_v = \frac{f(v)(\gamma + \mathbf{i}b)}{2} \otimes I_d + I_d \otimes \frac{f(v)(\gamma - \mathbf{i}b)}{2}.$$

which means

$$\begin{aligned}
\exp(tH_v) =&\ \exp\left(\frac{tf(v)(\gamma+\mathbf{i}b)}{2}\otimes I_d + I_d \otimes \frac{tf(v)(\gamma-\mathbf{i}b)}{2}\right)\\
=&\ \exp\left(\frac{tf(v)(\gamma+\mathbf{i}b)}{2}\right)\otimes \exp\left(\frac{tf(v)(\gamma-\mathbf{i}b)}{2}\right)\\
=&\ M_v,
\end{aligned}$$

where the the first step follows by definition of H_v, the second step follows by $\exp(A\otimes I_d + I_d \otimes B) = \exp(A)\otimes\exp(B)$, and the last step follows by Eq. (7.13).

We can upper bound $\|H_v\| \leq \sqrt{\gamma^2+b^2}$ and then set $\ell = \sqrt{\gamma^2+b^2}$. We can also upper bound $\|\exp(tH_v)\|$,

$$\begin{aligned}
\|\exp(tH_v)\| &= \|\exp(t\cdot \mathrm{Re}(H_v))\|\\
&= \left\|\exp\left(\gamma t\left(\frac{f(v)}{2}\otimes I_d + I_d\otimes\frac{f(v)}{2}\right)\right)\right\|\\
&\leq \exp(\gamma t).
\end{aligned}$$

Note that $\sum_{v\in V} H_v = 0$ since $\sum_{v\in V} f(v) = 0$.

Claim 7.4.4. $\|z_i^{\perp}\| \leq \frac{\alpha_2}{1-\alpha_4} \max_{j<i} \|z_j^{\|}\|$.

Proof.

$$\begin{aligned}
\|z_i^{\perp}\| &= \|(E\widetilde{P}z_{i-1})^{\perp}\| \\
&\leq \|(E\widetilde{P}z_{i-1}^{\|})^{\perp}\| + \|(E\widetilde{P}z_{i-1}^{\perp})^{\perp}\| \\
&\leq \alpha_2\|z_{i-1}^{\|}\| + \alpha_4\|z_{i-1}^{\perp}\| \\
&\leq (\alpha_2 + \alpha_2\alpha_4 + \alpha_2\alpha_4 + \cdots) \cdot \max_{j<i} \|z_j^{\|}\| \\
&\leq \frac{\alpha_2}{1-\alpha_4} \max_{j<i} \|z_j^{\|}\|,
\end{aligned}$$

where the first step follows by definition of z_i, the second step follows by triangle inequality, the third step follows by part 2 and 4 of Lemma 7.4.3. □

Claim 7.4.5. $\|z_i^{\|}\| \leq (\alpha_1 + \frac{\alpha_2\alpha_3}{1-\alpha_4}) \max_{j<i} \|z_j^{\|}\|$.

Proof.

$$\begin{aligned}
\|z_i^{\|}\| &= \|(E\widetilde{P}z_{i-1})^{\|}\| \\
&\leq \|(E\widetilde{P}z_{i-1}^{\|})^{\|}\| + \|(E\widetilde{P}z_{i-1}^{\perp})^{\|}\| \\
&\leq \alpha_1\|z_{i-1}^{\|}\| + \alpha_3\|z_{i-1}^{\perp}\| \\
&\leq \alpha_1\|z_{i-1}^{\|}\| + \alpha_3\frac{\alpha_2}{1-\alpha_4} \max_{j<i-1} \|z_j^{\|}\| \\
&\leq (\alpha_1 + \frac{\alpha_2\alpha_3}{1-\alpha_4}),
\end{aligned}$$

where the first step follows by definition of z_i, the second step follows by triangle inequality, the third step follows by part 1 and 3 of Lemma 7.4.3, the fourth step follows by Claim 7.4.4. □

Combining Claim 7.4.4 and Claim 7.4.5 gives

$$\|z_k^{\|}\| \leq (\alpha_1 + \frac{\alpha_2\alpha_3}{1-\alpha_4})^k \|z_0^{\|}\| = \sqrt{d} \cdot (\alpha_1 + \frac{\alpha_2\alpha_3}{1-\alpha_4})^k,$$

which implies that

$$\left\langle z_0, (E\widetilde{P})^k z_0 \right\rangle \leq d \cdot (\alpha_1 + \frac{\alpha_2\alpha_3}{1-\alpha_4})^k.$$

Now the question is how to bound $(\alpha_1 + \frac{\alpha_2\alpha_3}{1-\alpha_4})^k$.

We can upper bound α_1, $\alpha_2\alpha_3$ and α_4 in the following sense,

$$\alpha_1 = \exp(t\ell) - t\ell \leq 1 + t^2\ell^2 = 1 + t^2(\gamma^2 + b^2),$$

and

$$\alpha_2\alpha_3 = \lambda(\exp(t\ell) - 1)^2 \leq \lambda(2t\ell)^2 = 4\lambda t^2(\gamma^2 + b^2),$$

where the second step follows by $t\ell < 1$ (because $\exp(x) \leq 1 + 2x, \forall x \in [0, 1]$),

$$\alpha_4 = \lambda \cdot \exp(t\gamma) \leq \lambda(1 + 2t\gamma) \leq \frac{1}{2} + \frac{1}{2}\lambda,$$

where the second step follows by $t\gamma < 1$, and the third step follows by $t\gamma \leq (1-\lambda)/4\lambda$.

Thus,

$$\begin{aligned}(\alpha_1 + \frac{\alpha_2 \cdot \alpha_3}{1-\alpha_4})^k \leq & \left(1 + t^2(\gamma^2 + b^2) + \frac{4\lambda t^2(\gamma^2 + b^2)}{\frac{1}{2} - \frac{1}{2}\lambda}\right)^k \\ \leq & \exp\left(kt^2(\gamma^2 + b^2)(1 + \frac{8}{1-\lambda})\right).\end{aligned}$$

□

Remark 7.4.2. As is the case with Healy's proof [Hea08], our proof also works for the case when there are different mean zero functions $f_1, \ldots, f_k$ for the different steps of the walk and also when there are k λ-expanders $G_1, \ldots, G_k$ and the j^{th} step of the walk is taken according to G_j.

Remark 7.4.3. We suspect that with appropriate modifications, our proof should generalize to random walks on irregular undirected graphs (or reversible Markov chains) as was done for Healy's proof in [CLLM12].

Remark 7.4.4. Although we have stated the theorem for Hermitian matrices, the same result can be obtained for general matrices by a standard dilation trick, namely replacing every $d \times d$ matrix M that appears with the $2d \times 2d$ Hermitian matrix

$$\begin{bmatrix} 0 & M \\ M^* & 0 \end{bmatrix},$$

whose norm is always within a factor of two of M.

7.5 Proof of Theorem 7.1.6

Proof. Observe that for every $i = 2, \ldots, k$ we have

$$\mathbb{E}[f(v_i) \mid v_{i-1}] = \sum_{u \sim v_{i-1}} P(v_{i-1}, u) f(u) = Pf(v_{i-1}),$$

whence the random vectors

$$Y_i^{(1)} := f(v_i) - Pf(v_{i-1})$$

satisfy

$$\mathbb{E}[Y_i^{(1)} \mid v_1, \ldots, v_{i-1}] = 0$$

and thus form a martingale difference sequence with respect to the filtration generated by initial segments of $v_1, \ldots, v_k$. Denoting $Y_1^{(1)} := f(v_1)$, we can write the sum of interest as a martingale part plus a remainder, which is a sum of $k-1$ (i.e., one fewer) random variables:

$$S = \sum_{i=1}^{k} Y_i^{(1)} + \sum_{i=1}^{k-1} Pf(v_i).$$

Notice that Pf is also a mean zero function on G, and by Jensen's inequality we have

$$\|(Pf)(v)\|_* \leq M := \max_{v \in V} \|f(v)\|_* \qquad \text{for all } v.$$

The key point is that the remainder terms $Pf(v_i)$ are smaller on average than the original terms $f(v_i)$ in squared Euclidean norm, because P is a contraction orthogonal to the constant vector; in particular, by considering the action of P on each coordinate of f separately, we have:

$$\sum_v \|Pf(v)\|_2^2 \leq \lambda \cdot \sum_v \|f(v)\|_2^2. \tag{7.15}$$

Iterating this construction on the remainder a total of $T \leq k$ times, we obtain a sequence of martingales $1 \leq t \leq T$:

$$\begin{aligned} Y_1^{(t)} &:= P^{t-1} f(v_1) \\ Y_i^{(t)} &:= P^{t-1} f(v_i) - P^t f(v_{i-1}), i = 1, \ldots, k-(t-1) \end{aligned}$$

which are related to the original sum as:

$$S = \sum_{t=1}^{T} \sum_{i=1}^{k-t+1} Y_i^{(t)} + \sum_{i=1}^{k-T} P^T f(v_i).$$

Interchanging the order of summation, we find that the random matrices

$$Z_i := \sum_{t=1}^{\min\{(k+1-i),T\}} Y_i^{(t)}$$

themselves form a martingale difference sequence, with each

$$\|Z_i\|_* \leq \sum_t \|Y_i^{(t)}\|_* \leq TM.$$

We bound the error $W := \frac{1}{k} \sum_{i=1}^{k-T} (P^T f)(v_i)$ crudely as:

$$\begin{aligned} \|W\|_2 &\leq \frac{1}{k} \sum_{i=1}^{k-T} \|P^T f(v_i)\|_2 \\ &\leq \frac{k-T}{k} \sum_{v \in V} \|(P^T f)(v)\|_2 \\ &\leq \lambda^{T/2} F \\ &\leq \exp(-(1-\lambda)T/2) F, \end{aligned}$$

where $F := (\sum_{v \in V} \|f(v)\|_2^2)^{1/2}$, by applying (7.15). Rearranging and setting $T = 2\log(F/\epsilon)/(1-\lambda)$ yields the advertised bound on $\|Z_i\|_*$. □

7.6 Elementary calculations

Lemma 7.6.1. *We define function $h(z) : \mathbb{C} \to \mathbb{C}$ as follows*

$$h(z) = -\frac{1+z}{1-z} + \sqrt{\left(\frac{1+z}{1-z}\right)^2 + 1}.$$

Then function $h(z)$ maps the unit disk $\{z \in \mathbb{C} : |z| \leq 1\}$ to the half disk $\{z \in \mathbb{C} : |z| \leq 1 \text{ and } \mathrm{Re}(z) \geq 0\}$.

Proof. We first compute the inverse of function $h(z)$, let $f = h^{-1}$. By definition of $h(z)$, we can do the following elementary calculations,

$$\begin{aligned}
& h(z) + \frac{1+z}{1-z} = \sqrt{\left(\frac{1+z}{1-z}\right)^2 + 1} \\
\implies & \left(h(z) + \frac{1+z}{1-z}\right)^2 = \left(\frac{1+z}{1-z}\right)^2 + 1 \\
\implies & (h(z))^2 + 2h(z)\frac{1+z}{1-z} = 1 \\
\implies & (1-z)(h(z))^2 + 2h(z)(1+z) = (1-z) \\
\implies & (h(z))^2 + 2h(z) - 1 = z((h(z))^2 - 2h(z) - 1),
\end{aligned}$$

Thus, we obtain that

$$f(z) = \frac{z^2 + 2z - 1}{z^2 - 2z - 1}.$$

To finish the proof, we need Claim 7.6.2 and Claim 7.6.3.

Claim 7.6.2. *For all $z \in \{z \in \mathbb{C} : |z| \leq 1 \text{ and } \mathrm{Re}(z) \geq 0\}$,*

$$|f(z)| \leq 1.$$

Proof. Let $z = re^{\mathbf{i}\phi}$, where $r \in [0,1]$ and

$\phi \in [-\pi/2, \pi/2]$. It is easy to observe that $\cos(\phi) \in [0,1]$ We have

$$\begin{aligned} |f(z)| &= \left|\frac{z^2+2z-1}{z^2-2z-1}\right| \\ &= \left|\frac{r^2e^{\mathbf{i}2\phi}+2re^{\mathbf{i}\phi}-1}{r^2e^{\mathbf{i}2\phi}-2re^{\mathbf{i}\phi}-1}\right| \\ &= \frac{|r^2e^{\mathbf{i}2\phi}+2re^{\mathbf{i}\phi}-1|}{|r^2e^{\mathbf{i}2\phi}-2re^{\mathbf{i}\phi}-1|}. \end{aligned}$$

We can compute the numerator,

$$\begin{aligned} & |r^2e^{\mathbf{i}2\phi}+2re^{\mathbf{i}\phi}-1|^2 \\ &= |r^2\cos 2\phi + \mathbf{i}r^2\sin 2\phi + 2r\cos\phi + 2r\mathbf{i}\sin\phi - 1|^2 \\ &= (r^2\cos 2\phi + 2r\cos\phi - 1)^2 + (r^2\sin 2\phi + 2r\sin\phi)^2 \\ &= r^4 + 4r^2 + 1 - 2r^2\cos 2\phi + 4r^3\cos 2\phi\cos\phi \\ &\quad - 4r\cos\phi + 4r^3\sin 2\phi\sin\phi \\ &= r^4 + 4r^2 + 1 - 2r^2\cos 2\phi + 4r^3\cos\phi - 4r\cos\phi. \end{aligned}$$

We can compute the denominator,

$$\begin{aligned} & |e^{\mathbf{i}2\phi}-2e^{\mathbf{i}\phi}-1|^2 \\ &= |r^2\cos 2\phi + \mathbf{i}r^2\sin 2\phi - 2r\cos\phi - 2r\mathbf{i}\sin\phi - 1|^2 \\ &= (r^2\cos 2\phi - 2r\cos\phi - 1)^2 + (r^2\sin 2\phi - 2r\sin\phi)^2 \\ &= r^4 + 4r^2 + 1 - 2r^2\cos 2\phi - 4r^3\cos 2\phi\cos\phi \\ &\quad + 4r\cos\phi - 4r^3\sin 2\phi\sin\phi \\ &= r^4 + 4r^2 + 1 - 2r^2\cos 2\phi - 4r^3\cos\phi + 4r\cos\phi. \end{aligned}$$

Note that, in order to show $|f(z)| \leq 1$, it is sufficient to prove

$$4r^3 \cos\phi - 4r\cos\phi \leq -4r^3\cos\phi + 4r\cos\phi$$

which is equivalent to

$$8r(1-r^2)\cos\phi \geq 0.$$

It follows by definition of r and ϕ. Thus, we complete the proof. □

Next, we can show that

Claim 7.6.3. *For all z is on the boundary of half disk,*

$$|f(z)| = 1.$$

Proof. First, we want to show that $\forall z \in [-\mathbf{i}, \mathbf{i}]$, $|f(z)| = 1$. Let $b \in [0,1]$, let $z = \mathbf{i}b$, then we have

$$|f(z)| = |f(\mathbf{i}b)| = \left|\frac{-b^2 + 2b\mathbf{i} - 1}{-b^2 - 2b\mathbf{i} - 1}\right| = 1.$$

Second, we want to show that for all z on half circle, $|f(z)| = 1$. We replace z by $e^{\mathbf{i}\phi}$, where $\phi \in [-\pi/2, \pi/2]$. Then we have

$$\begin{aligned} |f(z)| &= \left|\frac{z^2 + 2z - 1}{z^2 - 2z - 1}\right| \\ &= \left|\frac{e^{\mathbf{i}2\phi} + 2e^{\mathbf{i}\phi} - 1}{e^{\mathbf{i}2\phi} - 2e^{\mathbf{i}\phi} - 1}\right| \\ &= \frac{|e^{\mathbf{i}2\phi} + 2e^{\mathbf{i}\phi} - 1|}{|e^{\mathbf{i}2\phi} - 2e^{\mathbf{i}\phi} - 1|}. \end{aligned}$$

We can compute the numerator,

$$\begin{aligned}
&|e^{\mathbf{i}2\phi} + 2e^{\mathbf{i}\phi} - 1| \\
&= |\cos 2\phi + \mathbf{i}\sin 2\phi + 2\cos\phi + 2\mathbf{i}\sin\phi - 1| \\
&= \left((\cos 2\phi + 2\cos\phi - 1)^2 + (\sin 2\phi + 2\sin\phi)^2\right)^{1/2} \\
&= (6 - 2\cos 2\phi + 4\cos 2\phi\cos\phi - 4\cos\phi + 4\sin 2\phi\sin\phi)^{1/2} \\
&= (6 - 2\cos 2\phi + 4\cos\phi - 4\cos\phi)^{1/2} \\
&= (6 - 2\cos 2\phi)^{1/2}.
\end{aligned}$$

We can compute the denominator,

$$\begin{aligned}
&|e^{\mathbf{i}2\phi} - 2e^{\mathbf{i}\phi} - 1| \\
&= |\cos 2\phi + \mathbf{i}\sin 2\phi - 2\cos\phi - 2\mathbf{i}\sin\phi - 1| \\
&= \left((\cos 2\phi - 2\cos\phi - 1)^2 + (\sin 2\phi - 2\sin\phi)^2\right)^{1/2} \\
&= (6 - 2\cos 2\phi - 4\cos 2\phi\cos\phi + 4\cos\phi - 4\sin 2\phi\sin\phi)^{1/2} \\
&= (6 - 2\cos 2\phi + 4\cos\phi - 4\cos\phi)^{1/2} \\
&= (6 - 2\cos 2\phi)^{1/2}.
\end{aligned}$$

Thus, we have $|f(z)| = 1$. □

Note the biholomorphic is basically follows from the formula of f and h, because they are composition of holomorphic function. □

Lemma 7.6.4. *For any $\rho \in [0,1]$ and $\cos\varphi \in [-1,0]$, we have*

$$\frac{1-\rho}{1-\cos\varphi} - (1-\rho)^2 \leq \frac{1-\rho^2}{1-2\rho\cos\varphi+\rho^2} \leq \frac{1-\rho}{1-\cos\varphi} + 2(1-\rho)^2.$$

Proof. This directly follows by combining Claim 7.6.5 and Claim 7.6.6 □

Claim 7.6.5. *There exists some sufficiently large constant $c \geq 1$ such that for any $\rho \in [0,1]$ and $\cos\varphi \in [-1,0]$, we have*

$$\frac{1-\rho^2}{1-2\rho\cos\varphi+\rho^2} \leq \frac{1-\rho}{1-\cos\varphi} + c(1-\rho)^2.$$

Proof. It is equivalent to

$$\begin{aligned}
\frac{1+\rho}{1-2\rho\cos\varphi+\rho^2} &\leq \frac{1}{1-\cos\varphi} + c(1+\rho) \\
(1+\rho)(1-\cos\varphi) &\leq 1-2\rho\cos\varphi+\rho^2 + c(1+\rho)(1-\cos\varphi)(1-2\rho\cos\varphi+\rho^2) \\
\rho-\cos\varphi &\leq -\rho\cos\varphi+\rho^2 + c(1+\rho)(1-\cos\varphi)(1-2\rho\cos\varphi+\rho^2)
\end{aligned}$$

which is equivalent to,

$$-\rho\cos\varphi+\rho^2-\rho+\cos\varphi + c(1+\rho)(1-\cos\varphi)(1-2\rho\cos\phi+\rho^2) \geq 0.$$

Since $1-2\rho\cos\varphi+\rho^2 \geq 1$, thus it suffices to show

$$(\rho-1)(\rho-\cos\varphi) + c(1+\rho)(1-\cos\varphi) \geq 0.$$

Note that $(\rho-1)(\rho-\cos\varphi) \geq -2$, by choosing $c \geq 2$, we complete the proof. □

Claim 7.6.6. *There exists some sufficiently large constant $c \geq 1$ such that for any $\rho \in [0,1]$ and $\cos\varphi \in [-1,0]$, we have*

$$\frac{1-\rho^2}{1-2\rho\cos\varphi+\rho^2} \geq \frac{1-\rho}{1-\cos\varphi} - c(1-\rho)^2.$$

Proof. It is equivalent to

$$\begin{aligned}
\frac{1+\rho}{1-2\rho\cos\varphi+\rho^2} &\geq \frac{1}{1-\cos\varphi} + c(1+\rho) \\
(1+\rho)(1-\cos\varphi) &\geq 1-2\rho\cos\varphi+\rho^2 - c(1+\rho)(1-\cos\varphi)(1-2\rho\cos\varphi+\rho^2) \\
\rho-\cos\varphi &\geq -\rho\cos\varphi+\rho^2 - c(1+\rho)(1-\cos\varphi)(1-2\rho\cos\varphi+\rho^2)
\end{aligned}$$

which is equivalent to,

$$-\rho\cos\varphi+\rho^2-\rho+\cos\varphi - c(1+\rho)(1-\cos\varphi)(1-2\rho\cos\phi+\rho^2) \leq 0$$

which is equivalent to

$$(\rho-1)(\rho-\cos\varphi) \leq c(1+\rho)(1-\cos\varphi)(1-2\rho\cos\varphi+\rho^2).$$

It suffices to choose $c=1$. □

Chapter 8

Matrix Chernoff Bound for Random Spanning Trees

Strongly Rayleigh distributions are a class of negatively dependent distributions of binary-valued random variables [Borcea, Brändén, Liggett JAMS 09]. Recently, these distributions have played a crucial role in the analysis of algorithms for fundamental graph problems, e.g. Traveling Salesman Problem [Gharan, Saberi, Singh FOCS 11]. We prove a new matrix Chernoff bound for Strongly Rayleigh distributions.

As an immediate application, we show that adding together the Laplacians of $\epsilon^{-2}\log^2 n$ random spanning trees gives an $(1\pm\epsilon)$ spectral sparsifiers of graph Laplacians with high probability. Thus, we positively answer an open question posed in [Baston, Spielman, Srivastava, Teng JACM 13]. Our number of spanning trees for spectral sparsifier matches the number of spanning trees required to obtain a cut sparsifier in [Fung, Hariharan, Harvey, Panigraphi STOC 11]. The previous best result was by naively applying a classical matrix Chernoff bound which requires $\epsilon^{-2}n\log n$ spanning trees. For the tree averaging procedure to agree with the original graph Laplacian in expectation, each edge of the tree should be reweighted by the inverse of the edge leverage score in the original graph. We also show that when using this reweighting of the edges, the Laplacian of single random tree is bounded above in the PSD order by the original graph Laplacian times a factor $\log n$ with high probability, i.e. $L_T \preceq O(\log n)L_G$.

We show a lower bound that almost matches our last result, namely that in some graphs, with high probability, the random spanning tree is *not* bounded above in the spectral order by $\frac{\log n}{\log \log n}$ times the original graph Laplacian.

We also show a lower bound that in $\epsilon^{-2} \log n$ spanning trees are necessary to get a $(1 \pm \epsilon)$ spectral sparsifier.

8.1 Introduction

The study of concentration of sums of random variables dates back to Central Limit Theorems, and hence de Moivre and Laplace [Tij], while modern concentration bounds for sums of random variables were perhaps first established by Bernstein [Ber24], and a popular variant now known as Chernoff bounds was introduced by Rubin and published by Chernoff [Che52].

Concentration of measure for matrix-valued random variables is the phenomenon that many matrix valued distributions are to close their mean with high probability, closeness usually being measured by spectral norm. Modern quantitative bounds of the form often used in theoretical computer science were derived by Rudelson [Rud99], while Ahlswede and Winter [AW02] established a useful matrix-version of the Laplace transform that plays a central role in scalar concentration results such as those of Bernstein. [AW02] combined this with the Golden-Thompson trace inequality to prove matrix concentration results. Tropp refined this approach, and by replacing the use of Golden-Thompson with deep a theorem on concavity of certain trace functions due to Lieb, Tropp was able to recover strong versions of a wide range of scalar concentration results, including matrix Chernoff bounds, Azuma and Freedman's inequalities for matrix martingales [Tro12].

Matrix concentration results have had an enormous range of applications in computer science, and are ubiquitous throughout spectral graph theory [ST04, SS11, CKP+17], sketching [Coh16a], approximation algorithms [HSSS16], and deep learning [ZSJ+17, ZSD17, SY19]. Most applications are based on results for independent random matrices, but more flexible bounds, such as Tropp's Matrix Freedman Inquality [Tro11a], have been used to greatly simplify algorithms, e.g. for solving Laplacian linear equations [KS16] and for semi-streaming

graph sparsification [AG09, KPPS17]. Matrix concentration results are also closely related to other popular tools sampling tools, such as Karger's techniques for generating sparse graphs that approximately preserve the cuts of denser graphs [BK96].

Negative dependence of random variables is an appealing property that intuition suggests should help with concentration of measure. Notions of negative dependence can be formalized in many ways. Roughly speaking, these notions characterize distributions where where some event occurring ensures that other events of interest become less likely. A simple example is the distribution of a sequence of coin flips, conditioned on the total number of heads in the outcome. In this distribution, conditioning on some coin coming out heads makes all other coins less likely to come out heads. Unfortunately, negative dependence phenomena are not as robust as positive association which can be established from local conditions using the powerful FKG theorem [FKG71].

Strongly Rayleigh distributions were introduced recently by Borcea, Brändén, and Liggett [BBL09] as a class of negatively dependent distributions of binary-valued random variables with many useful properties. Strongly Rayleigh distributions satisfy useful negative dependence properties, and retain these properties under natural conditioning operations. Strongly Rayleigh distributions also satisfy a powerful stability property under conditioning known as *Stochastic Covering* [PP14], which is useful for analyzing them through martingale techniques. A measure on $\{0,1\}^n$ is said to be Strongly Rayleigh if its generating polynomial is real stable [BBL09]. There are many interesting examples of Strongly Rayleigh distributions [PP14]: The example mentioned earlier of heads of independent coin flips conditional on the total number of heads in the outcome; symmetric exclusion processes; determinental point processes and determinental measures on a boolean lattice. An example of particu-

lar interest to us is the edges of uniform or weighted random spanning trees, which form a Strongly Rayleigh distribution.

We prove a Matrix Chernoff bound for the case of k-homogeneous Strongly Rayleigh distributions. Our bound is slightly weaker than the bound for independent variables. We give lower bounds that show our bounds are close to tight in some regimes, but importantly, our lower bounds do not establish separation from the behaviour of indepedent random matrices, leaving open the question of whether the true bound should match the independent case in all regimes – which seems plausible. We use our bound to show new concentration results related to random spanning trees of graphs. An open question is to find other interesting applications of our concentration result, e.g. by analyzing concentration for matrices generated by exclusion processes.

Random spanning trees are one among the most well-studied probabilistic objects in graph theory, going back to the work of Kirchoff [Kir47] in 1847, who gave formula relating the number of spanning trees in a graph to the determinant of the Laplacian of the same graph.

Algorithms for sampling of random spanning trees have been studied extensively, [Gue83, Bro89, Ald90, Kul90, Wil96, CMN96, KM09, MST15, HX16, DKP+17, DPPR17, Sch18], and a random spanning tree can now be sampled in almost linear time [Sch18].

In theoretical computer science, random spanning trees have found a number of applications, most notably in breakthrough results on approximating the traveling salesperson problem with symmetric [GSS11] and asymmetric costs [AGM+10]. Goyal et al. [GRV09] demonstrated that adding just two random spanning trees sampled from a bounded degree

graph gives a $O(\log n)$ cut sparsifier with probability $1 - o(1)$. Later, it was shown by Fung, Hariharan, Harvey, Panigraphi [FHHP11], that if we sample $O(\epsilon^{-2} \log^2 n)$ random spanning trees from a graph, reweight the tree edges by the inverse of their leverage scores in the original graph, and average them together, then whp. we get a graph where every the weight of edges crossing every cut is approximately the same in as in the original graph, up to a factor $(1 \pm \epsilon)$. We refer to this as an ϵ-cut sparsifier. The techniques of Fung et al. unfortunately do not extend to proving spectral sparsifiers.

Spectral graph sparsifiers were introduced by Spielman and Teng [ST04], who for any graph G showed how to construct a another graph H with $\epsilon^{-2} n \operatorname{poly} \log n$ edges s.t. $(1 - \epsilon) L_G \preceq L_H \preceq (1 + \epsilon) L_G$, which we refer to as an ϵ-spectral sparsifier. The construction was refined by Spielman and Srivastava [SS11], who suggested sampling edges independently[1] with probability proportional to their *leverage scores*, and brought the number of required samples down to $\epsilon^{-2} n \log n$. This analysis is tight in the sense that if fewer than $o(\epsilon^{-2} n \log n)$ samples are used, there will be at least a $1/\operatorname{poly}(n)$ probability of failure. Meanwhile, $\epsilon^{-2} n \frac{\log n}{\log \log n}$ independent samples in a union of cliques can be shown whp. to fail to give a cut sparsifier. This can be observed directly from the degree distribution of a single vertex in the complete graph. For a variant of [SS11] sampling based on flipping a single coin for each edge to decide whether to keep it or not, it can also be shown that when the expected number of edges is $\epsilon^{-2} n \frac{\log n}{\log \log n}$, whp. the procedure fails to give a cut sparsifier. For arbitrary sparsification schemes, bounds in [BSS12] show that $\Theta(\epsilon^{-2} n)$ edges are necessary and sufficient to give an ϵ-spectral sparsifier.

[1] [SS11] analyzed sampling with replacement, but based on [Tro12], a folklore result shows the same behavior can be obtained by doing independent coin flips for every edge with low leverage score, again with inclusion probabilities proportional to leverage scores.

The marginal probability of an edge being present in a random spanning tree is exactly the leverage score of the edge. This seems to suggest that combining $\epsilon^{-2} \operatorname{poly} \log n$ spanning trees might give a spectral sparsifier, but the lack of independence between the sampled edges means the process cannot be analyzed using existing techniques. Observing this, Baston, Spielman, Srivastava, Teng [BSST13] in their excellent 2013 survey on sparsification noted that *"it remains to be seen if the union of a small number of random spanning trees can produce a spectral sparsifier."* We answer this question in the affirmative. In particular, we show that adding together $O(\epsilon^{-2} \log^2 n)$ spanning trees with edges scaled proportional to inverse leverage scores in the original graph leads to an ϵ-spectral sparsifier. This matches the bound obtained for cut sparsifiers in [FHHP11]. Our result also implies their earlier bound since a spectral sparsifier is always a cut sparsifier with the same approximation quality. Before our result, only a trivial bound on the number of spanning trees required to build a spectral sparsifier was known. In particular standard matrix concentration arguments like those in [SS11] prove that $O(\epsilon^{-2} n \log n)$ spanning trees suffice. Lower bounds in [FHHP11] show that whp. $\Omega(\log n)$ random spanning trees are required to give a constant factor spectral sparsifier.

We show that whp. $\epsilon^{-2} \frac{\log n}{\log \log n}$ random spanning trees do not give an ϵ-spectral sparsifier. We also show that the Laplacian of a single random tree with edges weighted as above satisfies $L_T \preceq O(\log n) L_G$ whp., and we give an almost matching lower bound, showing that in some graphs whp. $L_T \not\preceq \frac{1}{8} \frac{\log n}{\log \log n} L_G$. Before our work, the main result known about approximating graphs using $O(1)$ random spanning trees is due to Goyal, Rademacher, Vempala [GRV09], who showed that surprisingly, when the original graph has bounded degree, adding two random spanning trees gives a graph whose cuts approximate the cuts in the

original graph up to a factor $O(\log n)$ with good probability. As our result for a single tree establishes only a one-sided bound an interesting open question remains: Does sampling $O(1)$ random spanning trees give a $\log n$-factor spectral sparsifier with, say, constant probability?

8.1.1 Previous work

Chernoff-type bound for matrices. Chernoff-like bounds for matrices appear in Rudelson [Rud99] and Ahlswede and Winter [AW02]. The latter introduced a useful matrix-variant of the Laplace transform that is central in concentration bounds for scalar-valued matrices. Their bounds restricted to iid random matrices, an artifact of their use of the Golden-Thompson inequality for bounding traces. In contrast, Tropp obtained more flexible concentration bounds for random matrices by using a result of Lieb to bound the expected trace of various operators [Tro12], including bounds for matrix martingales [Tro11c].

In a recent work by Garg, Lee, Song and Srivastava [GLSS18], they show a Chernoff bound for sums of matrix-valued random variables sampled via a random walk on an expander graph. This work confirms a conjecture due Wigderson and Xiao. The proof of Garg et al. is also concerned with matrices that are not fully independent. In this case the matrices are generated from random walks on an expander graph. The main idea to deal with dependence issue is using a new multi-matrix extension of the Golden-Thompson inequality and an adaptation of Healy's proof of the expander Chernoff bound in the scalar's case [Hea08] to matrix case. Their techniques deal with fairly generic types of dependence, and cannot leverage the very strong stability properties that arise from the negative dependence and stochastic covering properties of Strongly Rayleigh distributions. Harvey and Olver [HO14] proved a matrix concentration result for randomized pipage rounding, which can be used to

show concentration results for random spanning trees obtained from pipage rounding, but not for (weighted) uniformly random spaning trees. The central technical element of their proof is a new variant of a theorem of Lieb on concavity of certain matrix trace functions.

Matrix martingales have played a central role in a number of algorithmic results in theoretical computer science [KS16, CMP16, KPPS17], but beyond a reliance on Tropp's Matrix Freedman Inequality, these works have little in common with our approach. However, our bound does share a technical similarity with [KS16], namely that a sequence of increasingly restricted random choices in a martingale process lead to a $\log n$ factor in a variance bound.

Strongly Rayleigh Distributions in Theoretical Computer Science. Perhaps the most prominent result on Strongly Rayleigh distributions in theoretical computer science is the generalization of [MSS15b] to Strongly Rayleigh distributions.

The central technical result of [MSS15b] essentially shows that given a collection of independent random vectors $v_1, \ldots, v_m$ with finite support in $\mathbb{C}^n$ s.t. $\sum_{i=1}^m \mathbb{E}[v_i v_i^*] = I$ and for all i, $\|v_i\|^2 \leq \epsilon$, then $\Pr[\|\sum_{i=1}^m v_i v_i^*\| \leq (1+\sqrt{\epsilon})^2] > 0$. [AG15] establishes a related result for k-homogeneous Strongly Rayleigh distributions, though they require an additional constraint on the marginal probability that any given random variable is non-zero being bounded above by δ, and then establish $\Pr[\|\sum_{i=1}^m v_i v_i^*\| \leq 4(\epsilon+\delta)+2(\epsilon+\delta)^2] > 0$. Based on this, [AG15] shows[2] that given an unweighted k-edge connected graph G where every edge has leverage score at most ϵ, there exists an unweighted spanning tree s.t. $L_T \preceq O(\frac{1}{k}+\epsilon)\cdot L_G$. This is referred to as a spectrally thin tree with parameter $O(\frac{1}{k}+\epsilon)$.

[2]Their full statement is more general, see [AG15] Corollary 1.9.

[AGR16] showed how to algorithmically sample from k-homogeneous Determinental Point Process in time $\text{poly}(k)n\log(n/\epsilon)$, where n is the dimension of matrix giving rise to the determinental point process and ϵ is the allowed total variation distance. Their techniques are based on generalization proofs of expansion in the base graph associated with a balanced matroid, a result first established by [FM92].

Random spanning trees. Algorithms for sampling random spanning trees have a long history, but only recently have they explicitly used matrix concentration [DKP+17, DPPR17, Sch18]. The matrix concentration arguments in these papers, however, deal mostly with how modifying a graph results in changes to the distribution of random spanning trees in the graph. We instead study how closely random spanning trees resemble the graph they were initially sampled from. Whether our result in turn has applications for improving sampling algorithms for random spanning trees is unclear.

The fact that spanning tree edges exhibit negative dependence has been used strikingly in concentration arguments by Goyal et al. [GRV09] to show that two random spanning trees gives $O(\log n)$-factor approximate cut sparsifier in bounded degree graphs, with good probability. This is clearly false when sampling the same number of edges independently, because this graph has large probability of having isolated vertices. Goyal et al. improve over independent sampling by leveraging the fact that for a fixed tree, in some sense, very few cuts of a given size exist. This is a variant of Karger's famous cut-counting techniques [Kar93, KS96] specialized to unweighted trees.

Uses of negatively dependent Chernoff bounds applied to tree edges also appeared in works on approximation algorithms for TSP problems [GSS11, AGM+10], where additionally

the connectivity properties of the tree play an important role

In contrast, the techniques of Fung et al. [FHHP11] show that $O(\epsilon^{-2}\log^2 n)$ spanning trees suffice to give a $(1\pm\epsilon)$-cut sparsifier, but they do not show that tree-based sparsifiers improve over independent sampling, The focus of their paper is to establish that wide range of different techniques for choosing sampling probabilities all give cut sparsifiers, by establishing a more flexible framework than the original cut-sparsifier results of Benczur-Karger [BK96], using related cut-counting techniques (see [Kar93, KS96]). To extend their results to spanning trees, they simply observe that the (scalar-valued) Chernoff bounds they use directly apply to negatively dependent variables, and hence edges in spanning trees.

Fung et at. [FHHP11] also establish a lower bound, showing that for any constant c, there exists a graph for which obtaining a factor c-cut sparsifier by averaging trees requires using at least $\Omega(\log n)$ trees to succeed with constant probability.

8.1.2 Our results and techniques

Theorem 8.1.1 (First main result, a Matrix Chernoff Bound k-homogeneous Strongly Rayleigh Distributions)**.** *Suppose $(\xi_1,\ldots,\xi_m)\in\{0,1\}^m$ is a random vector of $\{0,1\}$ variables whose distribution is k-homogeneous and Strongly Rayleigh.*

Given a collection of PSD matrices $A_1,\ldots A_m\in\mathbb{R}^{n\times n}$ s.t. for all $e\in[m]$ we have $\|A_e\|\leq R$ and $\|\mathbb{E}[\sum_e \xi_e A_e]\|\leq\mu$.

Then for any $\epsilon>0$,

$$\Pr\left[\left\|\sum_e \xi_e A_e-\mathbb{E}\left[\sum_e \xi_e A_e\right]\right\|\geq\epsilon\mu\right]\leq n\exp\left(-\frac{\epsilon^2\mu}{R(\log k+\epsilon)}\Theta(1)\right).$$

This Matrix Chernoff bound matches the bounds due to Tropp [Tro12], up to the $\log k$ factor in the exponent. Our lower bounds rule out that a much stronger bound is true in the $\epsilon \approx \log k$ regime, since the level of concentration we prove at this ϵ is stronger than what is ruled out for $\epsilon \approx \frac{\log k}{\log \log k}$ by the lower bound in Theorem 8.1.3. However, this does *not* rule out that the $\log k$ factor in our bound is unnecessary. I.e. we cannot rule out that a stronger concentration statement might match the bound for the independent case given by Tropp [Tro12].

Remark 8.1.1. When the Strongly Rayleigh distribution is in fact a product distribution on a collection of l Strongly Rayleigh distributions that are each t-homogeneous, then the joint distribution is lt-homogeneous Strongly Rayleigh, but in Theorem 8.1.1, the factor $\log(lt)$ can be replaced by a factor $\log t$. This applies to the case of independent random spanning trees, but only gives a constant factor improvement in the number of trees required.

Our work is related to the concentration inequality of Peres and Pemantle [PP14], who showed a concentration result for scalar-valued Lipschitz functions of Strongly Rayleigh distributions. They used Doob martingales (martingales constructed from sequences of conditional expectations) to prove their result. We use a similar approach for matrices, constructing Doob matrix martingales from our Strongly Rayleigh distributions. In addition, we use the stochastic covering property of Strongly Rayleigh distributions observed by Peres and Pemantle, but implicitly derived in [BBL09]. This property leads to bounded differences in Doob martingale sequences for scalars. As in the scalar setting, it is possible to show concentration results for matrix-valued martingales. We use the Matrix Freedman inequality[3]

[3]Note, however, that we are able to prove deterministic bounds on the *predictable quadratic variation*

of Tropp. This inequality allows makes it possible to establish strong concentration bounds based on control of sample norms and control of the *predictable quadratic variation process* of the martingale, a matrix-valued object that is used to measure variance (see [Tro11c]). We show that as in the scalar setting, the stochastic covering property of Strongly Rayleigh distributions leads to bounded differences for Doob matrix martingales. But, we also combine the stochastic covering property with deceptively simple matrix martingale properties and a negative dependence condition to derive additional bounds on the predictable quadratic variation process of the martingale. The key negative dependence property we use is a simple observation that generalizes, to k-homogeneous Strongly Rayleigh distributions, the fact that in a random spanning tree, conditioning on the presence of a set of edges lowers the marginal probability of every other graph edge being in the tree (see Lemma 8.1.7). While we frame it differently, it is essentially an immediate consequence of statements in [BBL09]. The surprise here is how useful this simple observation is for removing issues with characterizing conditional k-homogeneous Strongly Rayleigh distributions. As a corollary we get our second main result.

Theorem 8.1.2 (Second main result, concentration bound of a batch of independent random spanning trees)**.** *Given as input a weighted graph G with n vertices and a parameter $\epsilon > 0$, let $T_1, T_2, \cdots, T_t$ denote t independent inverse leverage score weighted random spanning trees, if we choose $t = O(\epsilon^{-2} \log^2 n)$ then with probability $1 - 1/\operatorname{poly}(n)$,*

$$(1-\epsilon)L_G \preceq \frac{1}{t}\sum_{i=1}^{t} L_{T_i} \preceq (1+\epsilon)L_G.$$

process, which means the bound we use is more analogous to a matrix version Bernstein's inequality, adapted to martingales. We resort to the more complicated Freedman's inequality only because it gives a directly applicable statement that is known in the literature.

Prior to our work, only a trivial bound on the number of spanning trees required to build a spectral sparsifier was known, namely that standard matrix concentration arguments like those in [SS11] prove that $O(\epsilon^{-2} n \log n)$ spanning trees suffice. Note that, the number of spanning trees required to build spectral sparsifier in our Theorem 8.1.2 matches the number of spanning trees required to construct cut sparsifier in previous best result [FHHP11]. The total edge count we require is $\Theta(\epsilon^{-2} n \log^2 n)$, worse by a factor $\log n$ than the bound for independent edge sampling obtained in [SS11]. It is not clear whether this factor in necessary.

Remark 8.1.2. Suppose we apply our Theorem 8.1.3 to show that any single random spanning tree satisfies $L_T \preceq O(\log n) \cdot L_G$ whp. This is tight up a $\log \log n$ factor. Then, one can from use this to derive Theorem 8.1.2 based on a standard (and tight) Matrix Chernoff bound, and a (laborious) combination of Doob martingales and stopping time arguments similar to those found in [Tro12, KS16]. This line of reasoning will lead to the same bounds as Theorem 8.1.3. Thus, unless one proves more than just a norm bound for each individual tree, it is not possible improve over our result, except for $\log \log n$ factors.

Like the work of Fung et al. our results for spanning trees do not improve over the independent case. Fung et al. achieved their result by combining cut counting techniques with Chernoff bounds for scalar-valued negatively dependent variables. In our random matrix setting, there are no clear candidates for a Chernoff bound for negatively dependent random matrices that we can adopt, and this type of bound is exactly what we develop in the Strongly Rayleigh case.

We establish a one-sided concentration result for a single tree, namely that whp. $L_T \preceq O(\log n) \cdot L_G$. Again, this is a direct application of Theorem 8.1.1.

Theorem 8.1.3 (Third main result, upper bound for the concentration of one random spanning tree)**.** *Given a graph G, let T be a random spanning tree, then with probability at least* $1 - 1/\operatorname{poly}(n)$

$$L_T \preceq O(\log n) \cdot L_G.$$

This upper bound is tight up to a factor $\log \log n$ as shown by our almost matching lower bound stated below.

Theorem 8.1.4 (Lower bound for the concentration of one random spanning tree)**.** *For any $n \geq 2^{2^6}$, there is an unweighted graph G with n nodes, s.t. if we sample an inverse leverage score weighted random spanning tree T, then with probability at least $1 - e^{-n \cdot 4}$,*

$$L_T \not\preceq \frac{\log n}{8 \log \log n} \cdot L_G.$$

Trivially, the presence of degree one nodes in L_T means that in a complete graph, $L_G \not\preceq L_T$. So choosing any other scaling of the tree will make at least one of the inequalities $L_T \not\preceq \frac{1}{8} \log n / \log \log n \cdot L_G$ and $L_G \not\preceq L_T$ true with a larger gap. Note that in the complete unweighted graph the trees we consider have weight $\Theta(n)$ on each edge. A random spanning tree in the complete graph has diameter about $\sqrt{n}$ [RS67]. This can be shown to imply that for an *unweighted* random tree $\widehat{T}$, $L_G \not\preceq \sqrt{n} L_{\widehat{T}}$. But once we scale up every edge of the tree by a factor $\Theta(n)$, the diameter bound no longer directly implies a spectral gap of the form $L_G \not\preceq \alpha L_T$ for some α. In a ring graph, we get $L_G \not\preceq (n-2) L_T$ and $L_T \not\preceq L_G$.

We can also show in general that $L_T \not\preceq 10 \log n \cdot L_G$, but with a much smaller probability.

Theorem 8.1.5 (Lower bound for the concentration of one random spanning tree)**.** *For any $n \geq 4$, there is an unweighted graph G with n nodes, s.t. if we sample an inverse leverage score weighted random spanning tree T, then with probability at least $2^{-150 \log n \log\log n}$,*

$$L_T \not\preceq 10 \log n \cdot L_G.$$

And we show a lower bound for ϵ-spectral sparsifiers for random spanning trees.

Theorem 8.1.6 (Lower bound for the concentration of multiple random spanning trees)**.** *For any $n \geq 2^{100}$, there is an unweighted graph G with n nodes, s.t. for any accuracy parameter $\epsilon \in (5n^{-0.1}, 1/2)$, if we sample $t = 0.05\epsilon^{-2} \log n$ independent random spanning trees with edges weighted by inverse leverage score, then with probability at least $1 - e^{-n^{.39}}$,*

$$(1-\epsilon)L_G \not\preceq \frac{1}{t}\sum_{i=1}^{t} L_{T_i} \text{ and } \frac{1}{t}\sum_{i=1}^{t} L_{T_i} \not\preceq (1+\epsilon)L_G.$$

Our lower bound is incomparable with that of Fung et al.[FHHP11], who showed that for any constant c, there exists a graph for obtaining a factor c-cut sparsifier by averaging trees requires using at least $\Omega(\log n)$ trees to succeed with constant probability. Where Fung et. al [FHHP11] used triangles in their lower bound construction, our bad examples are based on collections of small cliques, which lets us ensure cut differences in even a single tree, by giving longer-tailed degree distributions. All of our lower bounds are based on simple constructions from collections of edge disjoint cliques, and use the fact that the exact distribution of degrees of a fixed vertex in a random spanning tree of the complete graph is known. Note that a lower bound for cut approximation implies a lower-bound for spectral approximation, because the contrapositive statement is true: spectral approximation implies cut approximation.

Remark 8.1.3. In fact, all our lower bounds also directly apply for cut approximation, which is a strictly stronger result. For example, there is an unweighted graph G, s.t. if we sample an inverse leverage score weighted random spanning tree T, then with probability at least $1 - e^{-n \cdot 4}$, T has a cut which is larger than the corresponding cut in G by a factor $\frac{\log n}{8 \log \log n}$.

Connection to Spectrally Thin Trees Using their MSS-type existence proof for "small norm outcomes" of homogeneous Strongly Rayleigh distributions, [AG15] showed that in an unweighted k-edge connected graph G where every edge has leverage score at most ϵ, there exists an unweighted spanning tree $\widehat{T}$ s.t. $L_{\widehat{T}} \preceq O(\frac{1}{k} + \epsilon) \cdot L_G$. This is referred to a spectrally thin tree with parameter $O(\frac{1}{k} + \epsilon)$.

In contrast, applying our k-homogeneous Strongly Rayleigh Matrix Chernoff bound to an unweighted graph G where every edge has leverage score at most ϵ, we can show that an unweighted *random* spanning tree satisfies $L_T \preceq O(\epsilon \log n) L_G$ with high probability. This follows immediately from our Theorem 8.1.3, because if we let T denote the unweighted spanning tree and $\widehat{T}$ corresponding spanning tree with edges weighted by inverse leverage scores, then

$$\begin{aligned} L_{\widehat{T}} &= \sum_{e \in T} w(e) b_e b_e^\intercal \\ &\preceq \epsilon \sum_{e \in T} \frac{1}{l(e)} w(e) b_e b_e^\intercal \\ &= \epsilon L_{\widehat{T}} \\ &\preceq O(\epsilon \log n) L_G \end{aligned}$$

whp.

The proof in [AG15] is based on an adaptation of the [MSS15b] proof, and does not have clear parallels with our approach. Whereas the key properties of Strongly Rayleigh distributions that we use are stochastic covering (a property that limits change in a distribution under conditioning) and conditional negative dependence, the central element of their approach is a proof that certain mixed characteristic polynomials associated with k-homogeneous distributions are real stable when the original distribution is Strongly Rayleigh.

The following Lemma captures a simple but crucial property of Strongly Rayleigh distributions.

Lemma 8.1.7 (Shrinking Marginals)**.** *Suppose* $(\xi_1, \ldots, \xi_m) \in \{0,1\}^m$ *is a random vector of* $\{0,1\}$ *variables whose distribution is* k*-homogeneous and Strongly Rayleigh, then any set* $S \subseteq [m]$ *with* $|S| \leq k$ *for all* $j \in [m] \setminus S$

$$\Pr[\xi_j = 1 | \xi_S = \mathbf{1}_S] \leq \Pr[\xi_j = 1].$$

We provide a proof in Section 8.7.

8.2 Notation

We use $[n]$ to denote set $\{1, 2, \cdots, n\}$. Given a vector x, we use $\|x\|_0$ to denote the number of non-zero entries in the vector.

Matrix and norms. For a matrix A, we use $A^\top$ to denote the transpose of A. We say matrix A is positive semi-definite (PSD) if $A = A^\top$ and $x^\top Ax \geq 0$ for all $x \in \mathbb{R}^n$. We use $\succeq, \preceq$ to denote the semidefinite ordering, e.g. $A \succeq 0$ denotes that A is PSD, and $A \succeq B$ means $A - B \succeq 0$. We say matrix A is positive definite (PD) if $A = A^\top$ and $x^\top Ax > 0$ for all $x \in \mathbb{R}^n - \{0\}$. $A \succ B$ means $A - B$ is PD.

For matrix $A \in \mathbb{R}^{n \times n}$, we define $\|A\|$ to be the spectral norm of A, i.e.,

$$\|A\| = \max_{\|x\|_2 = 1, x \in \mathbb{R}^n} x^\top Ax.$$

Let $\mathrm{tr}(A)$ denote the trace of a square matrix A. We use $\lambda_{\max}(A)$ to denote the largest eigenvalue of matrix A. For symmetric matrix $A \in \mathbb{R}^{n \times n}$, $\lambda_{\max}(A) = \|A\|$ and $\mathrm{tr}(A) \leq n\|A\|$.

The Laplacian matrix-related definitions. Let $G = (V, E, w)$ be a connected weighted undirected graph with n vertices and m edges and edge weights $w_e > 0$. If we orient the edges of G arbitrarily, we can write its Laplacian as $L = B^\top WB$, where $B \in \mathbb{R}^{m \times n}$ is the signed edge-vertex incidence matrix and defined as follows

$$B(e, v) = \begin{cases} 1, & \text{if } v \text{ is } e\text{'s head;} \\ -1, & \text{if } v \text{ is } e\text{'s tail;} \\ 0, & \text{otherwise.} \end{cases}$$

and $W \in \mathbb{R}^{m \times m}$ is the diagonal matrix with $W(e, e) = w_e$.

8.3 Preliminaries

8.3.1 Useful facts and tools

This section, we provide some useful tools.

Fact 8.3.1. *For any two square matrices A and B, we have*

$$\frac{1}{2}(A+B)^2 + \frac{1}{2}(A-B)^2 = A^2 + B^2$$

Proof.

$$\begin{aligned}\frac{1}{2}(A+B)^2 + \frac{1}{2}(A-B)^2 &= \frac{1}{2}(A+B)(A+B) + \frac{1}{2}(A-B)(A-B) \\ &= \frac{1}{2}(A^2 + BA + AB + B^2) + \frac{1}{2}(A^2 - BA - AB + B^2) \\ &= A^2 + B^2,\end{aligned}$$

which completes the proof. □

Fact 8.3.2. *For any two symmetric matrices*

$$(A-B)^2 \preceq 2A^2 + 2B^2.$$

Proof. Using Fact 8.3.1, we have

$$(A+B)^2 + (A-B)^2 = 2A^2 + 2B^2.$$

Because A and B are symmetric matrices, then $(A+B)^2 \succeq 0$. It implies that

$$(A-B)^2 \preceq 2A^2 + 2B^2,$$

which completes the proof. □

8.3.2 Strongly Rayleigh distributions

This section provides definitions related to Strongly Rayleigh distributions. For more details, we refer the readers to [BBL09, PP14].

Let $\mu : 2^{[n]} \to \mathbb{R}_{\geq 0}$ denote a probability distribution over $2^{[n]}$, and $\sum_{S \subseteq [n]} \mu(S) = 1$.

Let $x_1, x_2, \cdots, x_n$ denote n variables, we use x to denote $(x_1, x_2, \cdots, x_n)$. For each set $S \subseteq [n]$, we define $x_S = \prod_{i \in S} x_i$. We define the **generating polynomial** for μ as follows

$$f_\mu(x) = \sum_{S \subseteq [n]} \mu(S) \cdot x_S.$$

We say distribution μ is k-homogeneous if the polynomial f_μ is a homogeneous polynomial of degree k. In other words, for each $S \in \mathrm{supp}(\mu)$, $|S| = k$.

We say a polynomial $p(x_1, x_2, \cdots, x_n)$ is stable, if $\mathrm{Im}(x_i) > 0, \forall i \in [n]$, then $p(x_1, \cdots, x_n) \neq 0$. We say polynomial p is real stable, it is stable and all of its coefficients are real. We say μ is a **Strongly Rayleigh** distribution if f_μ is a real stable polynomial.

Fact 8.3.3 (Conditioning on subset of coordinates)**.** *Consider a random vector $(\xi_1, \ldots, \xi_m) \in \{0,1\}^m$ whose distribution is k-homogeneous Strongly Rayleigh. Suppose we get a binary vector $\mathbf{b} = (b_1, \ldots, b_t) \in \{0,1\}^t$ with $\|\mathbf{b}\|_0 = l \leq k$, and we get a set $S \subset [m]$ with $|S| = t$. Then conditional on $\xi_S = \mathbf{b}$, the distribution of $\xi_{[m] \setminus S}$ is $(k-l)$-homogeneous Strongly Rayleigh.*

This fact tells us that if we condition on the value of some entries in the vector, the remaining coordinates still have a Strongly Rayleigh distribution.

Fact 8.3.4 (Stochastic Covering Property)**.** *Consider a random vector* $(\xi_1, \ldots, \xi_m) \in \{0,1\}^m$ *whose distribution is* k*-homogeneous Strongly Rayleigh. Suppose we are given an index* $i \in [m]$*. Let* $\xi' = \xi_{[m]\setminus\{i\}}$ *be the distribution on entries of* ξ *except* i*. Let* ξ'' *be the distribution of* $\xi_{[m]\setminus\{i\}}$ conditional *on* $\xi_i = 1$*. Then, there exists a coupling between* ξ' *and* ξ'' *(i.e. a joint distribution the two vectors), s.t. in every outcome of the coupling the value of* ξ' *can be obtained from the value of* ξ'' *by either changing a single from* 0 *to* 1 *or by leaving all entries unchanged.*

This fact is known as the *Stochastic Covering Property* (see [PP14]). It gives us a convenient tool for relating the conditional distribution of a subset of the coordinates of the vector to the unconditional distribution.

Note that by Fact 8.3.3, the distribution of ξ'' used in Fact 8.3.4 is $k-1$ homogeneous. In contrast, the outcomes of ξ' may have k or $k-1$ ones. Fact 8.3.4 tells us that we can pair up all the outcomes of the conditional distribution ξ'' with outcome of the unconditional distribution ξ' s.t. only a small change is required to make them equal. This tells us that the distribution is in some sense not changing too quickly under conditioning.

8.3.3 Random spanning trees

We provide the formal definition of random spanning tree in this section.

We use the same definitions about spanning trees as [DKP+17]. Let $\mathcal{T}_G$ denote the set of all spanning subtrees of G. We now define a probability distribution on these trees.

Definition 8.3.1 (w-uniform distribution on trees)**.** Let $\mathcal{D}_G$ be a probability distribution

on $\mathcal{T}_G$ such that

$$\Pr_{X \sim \mathcal{D}_G}[X = T] \propto \prod_{e \in T} w_e.$$

We refer to $\mathcal{D}_G$ as the w-uniform distribution on $\mathcal{T}_G$. When the graph G is unweighted, this corresponds to the uniform distribution on $\mathcal{T}_G$. Crucially, random spanning tree distributions are Strongly Rayleigh, as shown in [BBL09].

Fact 8.3.5 (Spanning Trees are Strongly Rayleigh)**.** *In a connected weighted graph G, the w-uniform distribution on spanning trees is $(n-1)$-homogeneous Strongly Rayleigh.*

Definition 8.3.2 (Effective Resistance)**.** The effective resistance of a pair of vertices $u, v \in V_G$ is defined as

$$R_{\text{eff}}(u, v) = b_{u,v}^\top L^\dagger b_{u,v},$$

where $b_{u,v}$ is an all zero vector corresponding to V_G, except for entries of 1 at u and -1 at v.

The a reference for following standard fact about random spanning trees can be found in [DKP+17].

Definition 8.3.3 (Leverage Score)**.** The statistical leverage score, which we will abbreviate to leverage score, of an edge $e = (u, v) \in E_G$ is defined as

$$l_e = w_e R_{\text{eff}}(u, v).$$

Fact 8.3.6 (Spanning Tree Marginals)**.** *The probability $\Pr[e]$ that an edge $e \in E_G$ appears in a tree sampled w-uniformly randomly from $\mathcal{T}_G$ is given by*

$$\Pr[e] = l_e,$$

where l_e is the leverage score of the edge e.

8.4 A Matrix Chernoff Bound for Strongly Rayleigh Distributions

We first define a mapping which maps an element into a psd matrix.

Definition 8.4.1 (Y-operator)**.** We use Γ to denote $[m]$, we define a mapping $Y : \Gamma \to \mathbb{R}^{n\times n}$ such that Y_e is a psd matrix and $\|Y_e\| \leq R$.

Throughout this section, we will use $\xi \in \{0,1\}^m$ to denote a random length m boolean vector whose distribution is k-homogeneous Strongly Rayleigh. For any set $S \subseteq [m]$, we use ξ_S to denote the length $|S|$ vector that only chooses the entry from indices in S.

We will frequently need to work with a different representation of the random variable ξ. We use γ to denote this second representation. The random variable γ is composed of a sequence of k random indices $\gamma_1, \gamma_2, \cdots, \gamma_k$, each of which takes a value $e_1, e_2, \cdots, e_k \in [m]$. The indices give the locations of the ones in ξ, i.e. in an outcome of the two variables (ξ, γ), we always have $\xi_{\{\gamma_1,\gamma_2,\cdots,\gamma_k\}} = \mathbf{1}$ and $\xi_{[m]\setminus\{\gamma_1,\gamma_2,\cdots,\gamma_k\}} = \mathbf{0}$. Additionally, we want to ensure that the distribution of γ is invariant under permutation: This can clearly be achieved by starting with any distribution for γ that satisfies the coupling with ξ and the applying a uniformly random permutation to reorder the k indices of γ (see [PP14] for a further discussion).

For convenience, for each $i \in [k]$, we define $\gamma_{\leq i}$ and $\gamma_{\geq i}$ as abbreviated notation for

$$\gamma_1, \gamma_2, \cdots, \gamma_i \text{ and } \gamma_i, \gamma_{i+1}, \cdots, \gamma_k$$

respectively. Let $S = \{e_1, e_2, \cdots, e_i\} \subset [m]$ be one possible assignment for indices of a subset of the ones in ξ, (we require $i \leq k$). Then the distribution of $\xi_{[m]\setminus S}$ conditional on $\xi_S = \mathbf{1}$ is the same as the the distribution of $\xi_{[m]\setminus S}$ conditional on $(\gamma_1, \gamma_2, \cdots, \gamma_i) = (e_1, e_2, \cdots, e_i)$. In

other words, in terms of the resulting distribution of $\xi_{[m]\setminus S}$, it is equivalent to condition on either $\gamma_{\leq i}$ or $\xi_{\gamma_{\leq i}} = \mathbf{1}$. We define matrix $Z \in \mathbb{R}^{n\times n}$ as follows.

Definition 8.4.2 (Z)**.** Let Z denote $\sum_{e\in\Gamma} \xi_e \cdot Y_e$ where $\|\xi\|_0 = k$. Due to the relationship between ξ and γ, we can also write Z as

$$Z = \sum_{i=1}^{k} Y_{\gamma_i}.$$

For simplicity, for each $i \in [k]$, we define $Z_{\leq i}$ and $Z_{\geq i}$ as follows,

$$Z_{\leq i} = \sum_{j=1}^{i} Y_{\gamma_j} \text{ and } Z_{\geq i} = \sum_{j=i}^{k} Y_{\gamma_j}.$$

We define a series of matrices $M_i \in \mathbb{R}^{n\times n}$ as follows

Definition 8.4.3 (M_i, martingale)**.** We define $M_0 = \mathbb{E}[Z]$. For each $i \in \{1, 2, \cdots, k-1\}$, we define M_i as follows

$$M_i = \mathop{\mathbb{E}}_{\gamma_{\geq i+1}}[Z \mid \gamma_1, \cdots, \gamma_i].$$

It is easy to see that

$$\mathop{\mathbb{E}}_{\gamma_{i+1}}[M_{i+1}] = M_i,$$

which implies

$$\mathop{\mathbb{E}}_{\gamma_{i+1}}[M_{i+1} - M_i \mid \gamma_1, \cdots, \gamma_i] = 0. \tag{8.1}$$

Note that we can split Z up as

$$\begin{aligned} Z &= \sum_{j=i+2}^{k} Y_{\gamma_j} + Y_{\gamma_{i+1}} + \sum_{j=1}^{i} Y_{\gamma_j} \\ &= Z_{\geq i+2} + Y_{\gamma_{i+1}} + Z_{\leq i} \end{aligned} \tag{8.2}$$

And similarly $Z = Z_{\geq i+1} + Z_{\leq i}$.

In order to relate M_i and M_{i+1}, we will consider a fresh copy of $\gamma_{\geq i+1}$ which we denote by $\widehat{\gamma}_{\geq i+1}$. We denote the corresponding fresh copy of $Z_{\geq i+1}$, by $\widehat{Z}_{\geq i+1}$. We can now give an equivalent definition of M_i in terms of the expectation over $\widehat{\gamma}_{\geq i+1}$, while M_{i+1} is still defined in terms of the expectation over $\gamma_{\geq i+2}$, so that

$$M_i = \mathop{\mathbb{E}}_{\widehat{\gamma}_{\geq i+1}}[\widehat{Z}_{\geq i+1} + Z_{\leq i} \mid \gamma_1, \cdots, \gamma_i] \text{ and } M_{i+1} = \mathop{\mathbb{E}}_{\gamma_{\geq i+2}}[Z_{\geq i+2} + Y_{\gamma_{i+1}} + Z_{\leq i} \mid \gamma_1, \cdots, \gamma_i, \gamma_{i+1}] \tag{8.3}$$

Note that both still depend on the same $\gamma_{\leq i}$ vector, and M_{i+1} depends on γ_{i+1}, but M_i does not. So far, we have simply introduced a sligtly different notation for M_i, since the expectation operation ensures that the value of M_i is unchanged.

We let $\xi \in \{0,1\}^m$ denote the binary vector indicating the positions of indices $\gamma_1, \cdots, \gamma_i, \gamma_{i+1}, \cdots, \gamma_k$. while letting $\widehat{\xi} \in \{0,1\}^m$ indicate the positions of indices of $\gamma_1, \cdots, \gamma_i$, $\widehat{\gamma}_{i+1}, \cdots, \widehat{\gamma}_k$.

Note that k-homogeneous Strongly Rayleigh implies the stochastic covering property. By Fact 8.3.4, the stochastic covering property implies that a coupling exists s.t. adding either *one* or *no* extra "ones" to the vector $\xi_{[m]\setminus\gamma_{i+1}}$ results in the vector $\widehat{\xi}_{[m]\setminus\gamma_{i+1}}$. But, since $\xi_{[m]\setminus\gamma_{i+1}}$ is $k-1$ homogenous and $\widehat{\xi}_{[m]}$ is k-homogenous, we can conclude that $\widehat{\xi}_{[m]\setminus\gamma_{i+1}}$ is obtained from $\xi_{[m]\setminus\gamma_{i+1}}$ by adding *no* ones, if and only $\widehat{\xi}_{[m]}$ has a one at index γ_{i+1}. From this we conclude a more helpful form of stochastic covering: we can construct an index $\widetilde{\gamma}_{i+1}$ and a coupling s.t. conditional on γ_{i+1}, the indices $\widetilde{\gamma}_{i+1}, \gamma_{i+2}, \cdots, \gamma_k$ have the same distribution as $\widehat{\gamma}_{i+1}, \widehat{\gamma}_{i+2}, \cdots, \widehat{\gamma}_k$. Thus

$$Z_{\geq i+2} + Y_{\widetilde{\gamma}_{i+1}} = \widehat{Z}_{\geq i+1}. \tag{8.4}$$

We define $X_{i+1} = M_{i+1} - M_i$ and then by Eq. (8.1)

$$\mathop{\mathbb{E}}_{\gamma_{i+1}}[X_{i+1} \mid \gamma_1, \cdots, \gamma_i] = 0. \tag{8.5}$$

Then we can rewrite X_{i+1} in the following way,

Claim 8.4.1. *Let $\mathcal{D}_{\gamma_{\leq i+1}}$ denote the coupling distribution between $Z_{\geq i+2}$ and $Y_{\widetilde{\gamma}_{i+1}}$ such that Eq. (8.4) holds. Then*

$$X_{i+1} = Y_{\gamma_{i+1}} - \mathop{\mathbb{E}}_{(Z_{\geq i+2}, Y_{\widetilde{\gamma}_{i+1}}) \sim \mathcal{D}_{\gamma_{\leq i+1}}} [Y_{\widetilde{\gamma}_{i+1}} \mid \gamma_{\leq i+1}].$$

Proof. Note that in the following proof, we should think of $\gamma_{\leq i+1}$ as fixed.

$$\begin{aligned}
X_{i+1} &= M_{i+1} - M_i \\
&= \mathop{\mathbb{E}}_{\gamma_{\geq i+2}}[Z \mid \gamma_{\leq i+1}] - \mathop{\mathbb{E}}_{\gamma_{\geq i+1}}[Z \mid \gamma_{\leq i}] \\
&= \mathop{\mathbb{E}}_{\gamma_{\geq i+2}}\left[Z_{\geq i+2} + Y_{\gamma_{i+1}} + Z_{\leq i} \;\middle|\; \gamma_{\leq i+1}\right] - \mathop{\mathbb{E}}_{\widehat{\gamma}_{\geq i+1}}\left[\widehat{Z}_{\geq i+1} + Z_{\leq i} \;\middle|\; \gamma_{\leq i}\right] \\
&= \mathop{\mathbb{E}}_{\gamma_{\geq i+2}}\left[Z_{\geq i+2} + Y_{\gamma_{i+1}} + Z_{\leq i} \;\middle|\; \gamma_{\leq i+1}\right] - \mathop{\mathbb{E}}_{(Z_{\geq i+2}, Y_{\widetilde{\gamma}_{i+1}}) \sim \mathcal{D}_{\gamma_{\leq i+1}}}\left[Z_{\geq i+2} + Y_{\widetilde{\gamma}_{i+1}} + Z_{\leq i} \;\middle|\; \gamma_{\leq i+1}\right] \\
&= \mathop{\mathbb{E}}_{(Z_{\geq i+2}, Y_{\widetilde{\gamma}_{i+1}}) \sim \mathcal{D}_{\gamma_{\leq i+1}}}\left[Y_{\gamma_{i+1}} - Y_{\widetilde{\gamma}_{i+1}} \mid \gamma_{\leq i+1}\right] \qquad (8.6)
\end{aligned}$$

where the first equality follows by definition of X_{i+1}, the second equality follows by Definition 8.4.3, the third equality follows by Eq. (8.3), the fourth equality follows by Eq. (8.4), and the fifth equality is by linearity of expectation and cancellation of terms that agree.

Once we condition on $\gamma_{\leq i}$ and γ_{i+1} being fixed, then $Y_{\gamma_{i+1}}$ is also fixed. Thus in Eq. (8.6), we can move $Y_{\gamma_{i+1}}$ out of Expectation, so that the right hand side of Eq. (8.6) becomes

$$\mathop{\mathbb{E}}_{(Z_{\geq i+2}, Y_{\widetilde{\gamma}_{i+1}}) \sim \mathcal{D}_{\gamma_{\leq i+1}}}\left[Y_{\gamma_{i+1}} - Y_{\widetilde{\gamma}_{i+1}} \mid \gamma_{\leq i+1}\right] = Y_{\gamma_{i+1}} - \mathop{\mathbb{E}}_{(Z_{\geq i+2}, Y_{\widetilde{\gamma}_{i+1}}) \sim \mathcal{D}_{\gamma_{\leq i+1}}}[Y_{\widetilde{\gamma}_{i+1}} \mid \gamma_{\leq i+1}]. \tag{8.7}$$

□

Fact 8.4.2. *We condition on $\gamma_{\leq i+1}$. Let $\mathcal{D}_{\gamma_{\leq i+1}}$ denote the coupling distribution such that $Z_{\geq i+2} + Y_{\widetilde{\gamma}_{i+1}} = \widehat{Z}_{\geq i+1}$ holds. We define $U_{\gamma_{i+1}}$ as follows*

$$U_{\gamma_{i+1}} = \mathop{\mathbb{E}}_{(Z_{\geq i+2}, Y_{\widetilde{\gamma}_{i+1}}) \sim \mathcal{D}_{\gamma_{\leq i+1}}} [Y_{\widetilde{\gamma}_{i+1}} \mid \gamma_{\leq i+1}].$$

Then, we have the following four properties,

$$\begin{aligned}
&\text{(I)} \ \mathop{\mathbb{E}}_{\gamma_{i+1}} [U_{\gamma_{i+1}} \mid \gamma_{\leq i}] = \mathop{\mathbb{E}}_{\gamma_{i+1}} [Y_{\gamma_{i+1}} \mid \gamma_{\leq i}], \\
&\text{(II)} \ \|Y_{\gamma_{i+1}}\| \leq R, \|U_{\gamma_{i+1}}\| \leq R, \\
&\text{(III)} \ \|Y_{\gamma_{i+1}} - U_{\gamma_{i+1}}\| \leq R, \\
&\text{(IV)} \ Y_{\gamma_{i+1}}^2 \preceq R \cdot Y_{\gamma_{i+1}}, U_{\gamma_{i+1}}^2 \preceq R \cdot U_{\gamma_{i+1}}.
\end{aligned}$$

Proof. Proof of (I). We have

$$\begin{aligned}
\mathop{\mathbb{E}}_{\gamma_{i+1}} [U_{\gamma_{i+1}} \mid \gamma_{\leq i}] &= \mathop{\mathbb{E}}_{\gamma_{i+1}} \left[\mathop{\mathbb{E}}_{(Z_{\geq i+2}, Y_{\widetilde{\gamma}_{i+1}}) \sim \mathcal{D}_{\gamma_{\leq i+1}}} \left[Y_{\widetilde{\gamma}_{i+1}} \mid \gamma_{\leq i+1} \right] \,\middle|\, \gamma_{\leq i} \right] \\
&= \mathop{\mathbb{E}}_{\gamma_{i+1}} \left[\mathop{\mathbb{E}}_{(Z_{\geq i+2}, Y_{\widetilde{\gamma}_{i+1}}) \sim \mathcal{D}_{\gamma_{\leq i+1}}} \left[Y_{\widetilde{\gamma}_{i+1}} \mid \gamma_{\leq i+1} \right] - Y_{\gamma_{i+1}} + Y_{\gamma_{i+1}} \,\middle|\, \gamma_{\leq i} \right] \\
&= \mathop{\mathbb{E}}_{\gamma_{i+1}} \left[-X_{i+1} + Y_{\gamma_{i+1}} \mid \gamma_{\leq i} \right] \\
&= \mathop{\mathbb{E}}_{\gamma_{i+1}} \left[-X_{i+1} \mid \gamma_{\leq i} \right] + \mathop{\mathbb{E}}_{\gamma_{i+1}} \left[Y_{\gamma_{i+1}} \mid \gamma_{\leq i} \right] \\
&= \mathop{\mathbb{E}}_{\gamma_{i+1}} \left[Y_{\gamma_{i+1}} \mid \gamma_{\leq i} \right],
\end{aligned}$$

where the third step follows by Eq. (8.7) and Eq. (8.6), the fourth step follows by linearity of expectation, and the last step follows by $\mathbb{E}_{\gamma_{i+1}}[-X_{i+1} \mid \gamma_{\leq i}] = 0$.

Proof of (II).

By definition of Y, we have $\|Y_{\gamma_{i+1}}\| \leq R$.

$$\begin{aligned}\|U_{\gamma_{i+1}}\| &= \left\| \mathop{\mathbb{E}}_{(Z_{\geq i+2}, Y_{\widetilde{\gamma}_{i+1}}) \sim \mathcal{D}_{\gamma_{\leq i+1}}} [Y_{\widetilde{\gamma}_{i+1}} \mid \gamma_{\leq i+1}] \right\| \\ &\leq \mathop{\mathbb{E}}_{(Z_{\geq i+2}, Y_{\widetilde{\gamma}_{i+1}}) \sim \mathcal{D}_{\gamma_{\leq i+1}}} \left[\left\| Y_{\widetilde{\gamma}_{i+1}} \right\| \mid \gamma_{\leq i+1} \right] \\ &\leq R.\end{aligned}$$

Proof of (III). For any two PSD matrices A and B, we have $\|A-B\| \leq \max(\|A\|, \|B\|)$. Because both $Y_{\gamma_{i+1}}$ and $U_{\gamma_{i+1}}$ are PSD matrices and $\max(\|Y_{\gamma_{i+1}}\|, \|U_{\gamma_{i+1}}\|) \leq R$, we get the desired property.

Proof of (IV).

It follows by (II) and that $Y_{\gamma_{i+1}}$ and $U_{\gamma_{i+1}}$ are both PSD matrices. □

We can show

Claim 8.4.3.

$$\mathop{\mathbb{E}}_{\gamma_{i+1}} \left[(Y_{\gamma_{i+1}} - U_{\gamma_{i+1}})^2 \mid \gamma_{\leq i} \right] \preceq 4R \cdot \mathop{\mathbb{E}}_{\gamma_{i+1}} [Y_{\gamma_{i+1}} | \gamma_{\leq i}]$$

Proof.

$$\begin{aligned} & \mathop{\mathbb{E}}_{\gamma_{i+1}} \left[(Y_{\gamma_{i+1}} - U_{\gamma_{i+1}})^2 \mid \gamma_{\leq i} \right] \\ \preceq & \mathop{\mathbb{E}}_{\gamma_{i+1}} \left[2Y_{\gamma_{i+1}}^2 + 2U_{\gamma_{i+1}}^2 \mid \gamma_{\leq i} \right] \\ \preceq & \mathop{\mathbb{E}}_{\gamma_{i+1}} \left[2R \cdot Y_{\gamma_{i+1}} + 2R \cdot U_{\gamma_{i+1}} \mid \gamma_{\leq i} \right] \\ \preceq & \mathop{\mathbb{E}}_{\gamma_{i+1}} \left[4R \cdot Y_{\gamma_{i+1}} \mid \gamma_{\leq i} \right], \end{aligned}$$

where the first step follows by Fact 8.3.2, and the second step follows by $U_{\gamma_{i+1}}^2 \preceq R \cdot U_{\gamma_{i+1}}$ and $Y_{\gamma_{i+1}}^2 \preceq R \cdot Y_{\gamma_{i+1}}$. □

Lemma 8.4.4. *Let $\mathbb{E}[\sum_{e\in\Gamma} \xi_e Y_e] \preceq \mu I$. For each $i \in \{1, 2, \cdots, k\}$, we have*

$$\mathop{\mathbb{E}}_{\gamma_i}[Y_{\gamma_i} \mid \gamma_{\le i-1}] \preceq \frac{1}{k+1-i}\mu I.$$

Proof. We use $\mathbf{1}$ to denote a length $i-1$ vector where each entry is one. We can think of $\gamma_{\le i-1}$ as having its values already set to some edges in Γ, for example $\gamma_1 = e_1, \cdots, \gamma_{i-1} = e_{i-1}$. Note that all of the $e_1, \cdots, e_{i-1}$ must be distinct. Then we use $\Gamma\backslash\gamma_{\le i-1}$ to denote $\Gamma\backslash\{e_1, \cdots, e_{i-1}\}$.

$$\begin{aligned}
\mathbb{E}[Y_{\gamma_i} \mid \gamma_{\le i-1}] &= \sum_{e\in\Gamma\backslash\gamma_{\le i-1}} \Pr[\gamma_i = e \mid \gamma_{\le i-1}] \cdot Y_e \\
&= \sum_{e\in\Gamma\backslash\gamma_{\le i-1}} \frac{\Pr[\xi_e = 1 \mid \gamma_{\le i-1}]}{k-(i-1)} \cdot Y_e \\
&= \sum_{e\in\Gamma\backslash\gamma_{\le i-1}} \frac{\Pr[\xi_e = 1 \mid \xi_{\gamma_{\le i-1}} = \mathbf{1}]}{k-(i-1)} \cdot Y_e \\
&\preceq \sum_{e\in\Gamma\backslash\gamma_{\le i-1}} \frac{\Pr[\xi_e = 1]}{k-(i-1)} \cdot Y_e \\
&\preceq \sum_{e\in\Gamma} \frac{\Pr[\xi_e = 1]}{k-(i-1)} \cdot Y_e \\
&= \frac{1}{k-(i-1)} \mathbb{E}\left[\sum_e \xi_e Y_e\right] \\
&\preceq \frac{1}{k+1-i}\mu I
\end{aligned}$$

where the first step follows by definition of expectation, the second step follows by $\Pr[\gamma_i = e \mid \gamma_{\le i-1}] = \Pr[\xi_e = 1 \mid \gamma_{\le i-1}]/(k-(i-1))$, the third step follows because $[\cdot|\gamma_{\le i-1}]$ is equivalent to $[\cdot|\xi_{\gamma\le i-1} = \mathbf{1}]$, the fourth step follows by $(\Pr[\xi_e = 1 \mid \xi_{\gamma\ge i-1} = \mathbf{1}] \le \Pr[\xi_e = 1])$

from the Shrinking Marginals Lemma 8.1.7, the fifth step follows by relaxing $\Gamma \backslash \gamma_{\leq i-1}$, the sixth step follows by $\Pr[\xi_e = 1] = \mathbb{E}[\xi_e]$ and linearity of expectation, and the last step follows by $\mathbb{E}[\sum_{e \in \Gamma} \xi_e Y_e] \preceq \mu I$.

□

Lemma 8.4.5. *For each* $i \in \{1, 2, \cdots, k\}$

$$\mathop{\mathbb{E}}_{\gamma_i}\left[X_i^2 \mid \gamma_{\leq i-1}\right] \preceq 4\mu R \frac{1}{k+1-i} I.$$

Proof. It follows by combining Claim 8.4.3 and Lemma 8.4.4 directly. □

The above lemma implies this corollary directly

Corollary 8.4.6.

$$\sum_{i=1}^{k} \mathop{\mathbb{E}}_{\gamma_i}\left[X_i^2 \mid \gamma_{\leq i-1}\right] \preceq 10\mu R \log k \cdot I.$$

8.4.1 Main result

To prove our main theorem 8.1.1, we need a useful tool for random matrices: Freedman's inequality for matrices (Lemma A.2.1).

Proof. of Theorem 8.1.1.

We use Y to denote A and Γ to denote $[m]$.

In order to use Lemma A.2.1, we first we define W_i as follows

$$W_i = \sum_{j=1}^{i} \mathop{\mathbb{E}}_{\gamma_i}\left[X_i^2 \mid \gamma_{\leq i-1}\right].$$

According to definition of M_i, $\{M_0, M_1, M_2 \cdots\}$ is a matrix martingale and $M_k - M_0 = \sum_e \xi_e A_e - \mathbb{E}[\sum_e \xi_e A_e]$.

We have proved the following facts,

The first one is, $\mathbb{E}_{\gamma_i}[X_i|\gamma_{\leq i-1}] = 0$. It follows by Eq. (8.5)

The second one is

$$\lambda_{\max}(X_i) \leq R$$

It follows by combining Property (III) of Fact 8.4.2 and Claim 8.4.1.

The third one is

$$\|W_i\| \leq \sigma^2, \forall i \in [k]$$

where $\sigma^2 = 10\mu R \log k$. It follows by Corollary 8.4.6.

Thus,

$$\Pr\left[\lambda_{\max}(M_k - M_0) \geq \epsilon\mu\right] \leq n \exp\left(-\frac{(\epsilon\mu)^2/2}{\sigma^2 + R(\epsilon\mu)/3}\right).$$

We have

$$\begin{aligned} \frac{t^2/2}{\sigma^2 + Rt/3} &= \frac{\epsilon^2\mu^2/2}{10\mu R \log k + R\epsilon\mu/3} && \text{by choosing } t = \epsilon\mu \\ &= \frac{3\epsilon^2\mu}{(60\log k + 2\epsilon)R}. \end{aligned}$$

Thus we prove one side of the bound. Since $\mathbb{E}_{\gamma_i}[-X_i|\gamma_{\leq i-1}] = 0$ and $\mathbb{E}_{\gamma_i}[(-X_i)^2|\gamma_{\leq i-1}] = \mathbb{E}_{\gamma_i}[X_i^2|\gamma_{\leq i-1}]$, then following the similar procedure as proving $\lambda_{\max}$, we have bound for $\lambda_{\min}$

$$\Pr[\lambda_{\min}(M_k - M_0) \leq -\epsilon\mu] \leq n \exp\left(-\frac{3\epsilon^2\mu}{(60\log k + 2\epsilon)R}\right).$$

Putting two sides of the bound together, we complete the proof. □

8.5 Applications to Random Spanning Trees

In this section, we show how to use Theorem 8.1.1 to prove the bound for one random spanning and also summation of random spanning trees.

Proof. of Theorem 8.1.3.

Let $G = (V, E, w)$ be a undirected weighted graph, $w : E \to R$, which is connected. The Laplacian of G is $L_G = \sum_{e \in E} w(e) b_e b_e^\intercal$.

Let $T \subseteq E$ be a random spanning tree of G in the sense of Definition 8.3.1. Let the weights of the edges in T be given by $w' : T \to R$ where $w'(e) = w(e)/l_e$, where l_e is the leverage score of e in G. Thus the Laplacian of the tree is $L_T = \sum_{e \in T} w'(e) b_e b_e^\intercal = \sum_{e \in T} \frac{w(e)}{l_e} b_e b_e^\intercal$. Then by Fact 8.3.6, $Pr[e \in T] = l_e$, and hence $\mathbb{E}[L_T] = L_G$.

Note also that for all $e \in E$, $||(L_G^\dagger)^{1/2} w(e) b_e b_e^\intercal (L_G^\dagger)^{1/2}|| = l_e$. Consider the random matrix $(L_G^\dagger)^{1/2} L_T (L_G^\dagger)^{1/2}$. The distribution of edge in the spanning tree can be seen as an $n-1$ homogeneous vector in $\{0,1\}^m$ where $m = |E|$. To apply Theorem 8.1.1, let ξ_e be the eth entry of this random vector, and

$$A_e = (L_G^\dagger)^{1/2} w'(e) b_e b_e^\intercal (L_G^\dagger)^{1/2}$$

Note $A_e \succeq 0$. Now $||A_e|| = 1$ and $\mathbb{E}\left[\sum_e \xi_e A_e\right] = \mathbb{E}[(L_G^\dagger)^{1/2} L_T (L_G^\dagger)^{1/2}] = (L_G^\dagger)^{1/2} L_G (L_G^\dagger)^{1/2} = \Pi = I - \frac{1}{n}\mathbf{1}\mathbf{1}^\intercal$, where we used in the last equality that the null space of the Laplacian of a connected graph is the span of the all ones vector. Thus, as each we get $||\mathbb{E}\left[\sum_e \xi_e A_e\right]|| = 1$ This means we can apply Theorem 8.1.1 with $R = 1$, $\mu = 1$ and $\epsilon = 100 \log n$ to whp. $||(L_G^\dagger)^{1/2} L_T (L_G^\dagger)^{1/2} - \Pi|| \leq 100 \log n$.

As L_T is a Laplacian, it has $\mathbf{1}$ in the null space, so can conclude that $(L_G^\dagger)^{1/2} L_T (L_G^\dagger)^{1/2} \preceq 100 \log n \Pi$. Hence $L_T \preceq \log n L_G$.

□

Proof. of Theorem 8.1.2.

The proof is similar to the proof of Theorem 8.1.3. Now we view the edges of $t = O(\epsilon^{-2} \log^2 n)$ independent random spanning trees as a $t(n-1)$-homogeneous Strongly Rayleigh Distribution a vector in $\{0,1\}^{t|E|}$. Note that the product of independent Strongly Rayleigh distributions is Strongly Rayleigh [BBL09]. Again we get $|| \mathbb{E} [\sum_e \xi_e A_e] || = 1$, but now we can take $R = \frac{1}{t}$, and hence we obtain the desired result by plugging into Theorem 8.1.1. □

8.6 Lower bounds

8.6.1 Single spanning tree, low probability

The goal of this section is to prove Theorem 8.1.5. First, we recall a helpful fact estbliashed by Prüfer [Prü18].

Fact 8.6.1. *If T is a uniformly random spanning tree of the complete graph G on n vertices, the degree distribution of a fixed node v in T is $1 + Binomial(n-2, 1/n)$.*

We now prove two claims that will serve as helpful tools, Claims 8.6.2 and 8.6.3.

Claim 8.6.2. *Let G be complete graph K_n with $n \geq 4$, let T denote a random spanning tree, the probability that at least one node of the T has degree at least $b \log n$ is at least $2^{-b \log n \log(b \log n) - 3}$.*

Proof. By Fact 8.6.1, the degree distribution of a fixed node in T is, $1 + \text{Binomial}(n-2, 1/n)$.

For a random variable x sampled from $\text{Binomial}(n-2, 1/n)$, we use q_i to denote the probability that $x = i$.

Let $p = 1/n$. We consider $q_{b\log n}$, which is

$$\begin{aligned}
q_{b\log n} &= \binom{n-2}{b\log n} \cdot p^{b\log n} \cdot (1-p)^{n-2-b\log n} \\
&= \binom{n-2}{b\log n} \cdot (1/n)^{b\log n} \cdot (1-1/n)^{n-2-b\log n} && \text{by } p = 1/n \\
&\geq ((n-2)/(b\log n))^{b\log n} \cdot (1/n)^{b\log n} \cdot (1-1/n)^{n-2-b\log n} \\
&= (b\log n)^{-b\log n} \cdot ((n-2)/n)^{b\log n} \cdot (1-1/n)^{n-2-b\log n} \\
&\geq (b\log n)^{-b\log n} \cdot (1-2/n)^{b\log n} \cdot (1-2/n)^{n-2-b\log n} \\
&= (b\log n)^{-b\log n} \cdot (1-2/n)^{n-2} \\
&\geq (b\log n)^{-b\log n} \cdot \frac{1}{e^2} \\
&\geq 2^{-b\log n \cdot \log(b\log n) - 3}.
\end{aligned}$$

where the seventh step follows by $(1-2/n)^{n-2} \geq 1/e^2$ when $n \geq 4$.Then the desired probability is

$$\sum_{i=b\log n}^{n} q_i \geq 2^{-b\log n \cdot \log(b\log n) - 3}.$$

□

Claim 8.6.3. *Let G be a complete graph K_n, let T denote a random spanning tree, if T has a node with degree at least d, then the inverse leverage score weighted Laplacian of the tree satisfies*

$$L_T \not\preceq (d/2) \cdot L_G.$$

Proof. There are $n(n-1)/2$ edges in the graph G. Let l_e denote the leverage of each $e \in G$. The the sum of the leverage scores is $\sum_{e\in G} l_e = n-1$, e.g. see [SS11]. Since all the edges in the graph G are symmetric, we have $l_e = 2/n$ for all edge e in G.

Let v denote a fixed node in graph G and let d be the degree of v. Let L_v denote the Laplacian matrix of the subgraph of T consisting of edges incident on v, i.e. the star of $d+1$ nodes with v at the center, and with edge weights as in T (which differ from those in G). We should think of L_v as a $n \times n$ matrix with only $d+1$ nonzeros on the diagonal.

Observe that $\lambda_{\max}(L_v) \leq \frac{n}{2}\lambda_{\max}(L_{K_{d+1}}) \leq \frac{n}{2}(d+1)$. We can also exhibit a unit vector $x = \frac{1}{\sqrt{d^2+d}}(d, -1, \cdots, -1)$, for which $x^\top L_v x = \frac{n}{2}(d+1)$ which implies that $\lambda_{\max}(L_v) \geq \frac{n}{2}(d+1)$. Therefore $\lambda_{\max}(L_v) = \frac{n}{2}(d+1)$.

We can split the L_T into two parts,

$$L_T = L_v + L_{T \setminus v}$$

and both parts are PSD matrices. We also know that $\lambda_{\max}(L_G) = n$. Thus,

$$L_T \not\preceq (d/2) \cdot L_G.$$

□

Proof. of Theorem 8.1.5.

The proof is a direct combination of Claim 8.6.2 and Claim 8.6.3.

The approximation ratio is

$$\frac{d}{2} = \frac{b \log n}{2} = 10 \log n,$$

where the last step follows by choosing $b = 20$.

Then the probability is

$$\begin{aligned} 2^{-b\log n\log(b\log n)-3} &= 2^{-b\log n\log\log n-b\log n\log b-3} \\ &\geq 2^{-20\log n\log\log n-20\log n\log 20-3} \\ &\geq 2^{-150\log n\log\log n} \end{aligned}$$

where the last step follows by $\log\log n \geq 1$ when $n \geq 4$. □

8.6.2 Single spanning tree, high probability

Proof. of Theorem 8.1.4.

Let $C = 4$, and let $\delta = 1/(C\log\log n)$. Note we have assumed $n \geq 2^{2^6}$, which ensures that $\delta < 0.05$.

We constuct a graph of size n as a union of $n^{1-\delta}$ cliques of size $n^{1-\delta}$ that are disjoint except they all share one central vertex. Applying Claim 8.6.2 with n replaced by n^δ, and $b = 1$, and assuming $n^\delta \geq 8$, we get that for each clique, the probability that at least one node has degree at least $\log n^\delta$ in T is at least

$$2^{-\delta c_0\log n\cdot\log(\delta\log n)}$$

where $c_0 = 2$. We can lower bound this probability:

$$\begin{aligned} 2^{-\delta c_0\log n\cdot\log(\delta\log n)} &= 2^{-\frac{c_0\log n}{C\log\log n}\log(\frac{1}{C\log\log n}\log n)} \\ &\geq 2^{-\frac{c_0\log n}{C\log\log n}\log\log n} \\ &= 2^{-(c_0\log n)/C} \\ &= n^{-c_0/C}, \end{aligned}$$

where the first step follows by $\delta = 1/(C \log\log n)$.

The probability that at least one node in G has degree at least $\log n^\delta$ in T is at least

$$\begin{aligned}
1 - (1 - 2^{-\delta c_0 \log n \log(\delta \log n)})^{n^{1-\delta}} &= 1 - \left(1 - \frac{1}{n^{c_0/C}}\right)^{n^{1-\delta}} \\
&= 1 - \left(1 - \frac{1}{n^{c_0/C}}\right)^{n^{c_0/C} \cdot \frac{n^{1-\delta}}{n^{c_0/C}}} \\
&\geq 1 - (1/e)^{n^{1-\delta-c_0/C}} \\
&\geq 1 - (1/e)^{n^{0.4}},
\end{aligned}$$

where the last step follows by $\delta \leq 0.05$, $c_0 = 2$ and $C = 4$. Thus, we have the desired probability.

Using Claim 8.6.3, we have the approximation ratio

$$\frac{d}{2} = \frac{\log(n^\delta)}{2} = \frac{\delta \log n}{2} = \frac{\log n}{2C \log\log n} = \frac{\log n}{8 \log\log n}.$$

Note that we still need to make sure $n^\delta \geq 8$, which is implied by $2^{\log n/4 \log\log n} \geq 2^3$ which is equivalent to $\log n \geq 12 \log\log n$. This holds for all $n \geq 2^{2^6}$: At $n = 2^{2^6}$, $\log n = 2^6 > 60 = 12 \cdot 5 = 12 \log\log n$, and as n grows, the left hand side grows faster than the right hand side.

□

8.6.3 Sum of a batch of spanning trees

Proof. of Theorem 8.1.6.

We constuct a graph of size n as a union of $n^{1-\delta}$ cliques of size $n^{1-\delta}$ that are disjoint except they all share one central vertex. The parameter $\delta \in (0, 1)$ will be decided later.

We use H to denote the graph formed by a collection of trees $T_1, T_2, \cdots, T_t$. Let L_H denote the Laplacian matrix of new graph H.

We use $\deg(v)$ to denote the degree of a vertex v. We use $\text{wdeg}(v)$ to denote weighted degree (after re-weighting). In the original graph G and the new graph H, we have for each vertex v, that

$$\text{wdeg}_H(v) = \frac{d}{2t}\deg_H(v), \text{ and } \text{wdeg}_G(v) = \deg_G(v).$$

By our construction of the graph, it is easy to see that $\deg_G(v) = n^\delta$ for all vertices v except the special central vertex that appears in all the cliques. Let $d = n^\delta$. Let ξ_1 denote the event that there exists a vertex $x \in V$ such that

$$\text{wdeg}_H(x) > (1+\epsilon)\,\text{wdeg}_G(x),$$

and let ξ_2 denote that there exists a vertex $y \in V$, such that

$$\text{wdeg}_H(y) < (1-\epsilon)\,\text{wdeg}_G(y).$$

We want to show that events ξ_1 and ξ_2 both occur simultaneously with probability at least $1 - e^{-n^{0.39}}$, which implies absence of spectral $(1 \pm \epsilon)$ approximation, as desired. We first bound the probability of ξ_1. Note that

$$\begin{aligned}
\Pr[\text{wdeg}_H(v) \geq (1+\epsilon)\,\text{wdeg}_G(v)] &= \Pr\left[\frac{d}{2t}\deg_H(v) \geq (1+\epsilon)\deg_G(v)\right] \\
&\geq \Pr\left[\frac{d}{2t}\deg_H(v) \geq (1+\epsilon)d\right] \\
&= \Pr[\deg_H(v) \geq 2t(1+\epsilon)] \\
&= \Pr[\deg_H(v) - t \geq t(1+2\epsilon)].
\end{aligned}$$

By Fact 8.6.1, the degree of a fixed node in T_i is distributed as $1+\text{Binomial}(d-2, 1/d)$. Then as H is a union of independent spanning trees, the degree in H of a fixed node is distributed as $t + \text{Binomial}(t(d-2), 1/d)$.

For a random variable x sampled from $\text{Binomial}(t(d-2), 1/d)$, we know that $\mathbb{E}[x] = t(1-2/d)$. For $\epsilon > 5/d$

$$\begin{aligned} t(1+2\epsilon) &= t(1-2/d) + (2t/d - 2\epsilon t + 8\epsilon t/d) + 4\epsilon t(1-2/d) \\ &\leq t(1-2/d) + (10t/d - 2\epsilon t) + 4\epsilon t(1-2/d) && \text{by } \epsilon \leq 1 \\ &\leq t(1-2/d) + 4\epsilon t(1-2/d) && \text{by } \epsilon > 5/d. \end{aligned}$$

So it suffices to calculate the probability that

$$x \geq t(1-2/d) + 4\epsilon t(1-2/d). \tag{8.8}$$

For any $k \geq 10, p \in (0, 1/2), \epsilon \in (0, 1/2)$ with $\epsilon^2 pk \geq 3$, using Lemma A.1.8, we can prove the probability that Eq. (8.8) holds is at least $2^{-c\epsilon^2 kp}$, where $c = 9$. We choose $k = t(d-2)$ and $p = 1/d$, and get that this probability is at least $2^{-c\epsilon^2 t(d-2)/d}$. Now, the probability that event ξ_1 holds is at least

$$1 - (1 - 2^{-c\epsilon^2 t(1-2/d)})^{n^{1-\delta}}$$

We have

$$\begin{aligned} 2^{-c\epsilon^2 t(1-2/d)} &\geq 2^{-c\epsilon^2 t} \\ &\geq 1/n^{0.5} \end{aligned}$$

where the last step follows by $t \leq 0.5 \log n/(c\epsilon^2)$.

Thus, we have

$$\begin{aligned} 1-(1-2^{-c\epsilon^2 t(1-2/d)})^{n^{1-\delta}} &\geq 1-(1-1/n^{0.5})^{n^{1-\delta}} \\ &\geq 1-e^{-n^{1-\delta-0.5}} \\ &= 1-e^{-n^{0.4}} && \text{by } \delta = 0.1 \end{aligned}$$

We summarize the conditions for ϵ:

$$\begin{aligned} \epsilon &\geq \max(5/d, 3/\sqrt{pn}) \\ &= \max(5/n^{0.1}, 3/\sqrt{pn}) && \text{by } d = n^{0.1} \\ &\geq \max(5/n^{0.1}, 5/\sqrt{t}) \end{aligned}$$

Since we choose $t = 0.05\epsilon^{-2}\log n$, then as long as $\log n \geq 100$ we have $\epsilon \geq 5/\sqrt{t}$.

Similarly, we can control the probability of event ξ_2 similarly, completing the proof.

□

8.7 Shrinking Marginals Lemma

Lemma 8.7.1 (Restatement of Lemma 8.1.7, Shrinking Marginals)**.** *Suppose* $(\xi_1, \ldots, \xi_m) \in \{0,1\}^m$ *is a random vector of* $\{0,1\}$ *variables whose distribution is* k*-homogeneous and Strongly Rayleigh, then any set* $S \subseteq [m]$ *with* $|S| \leq k$ *for all* $j \in [m] \setminus S$

$$\Pr[\xi_j = 1 | \xi_S = \mathbf{1}_S] \leq \Pr[\xi_j = 1]$$

Proof. Note that by an immediate consequence of negative association, for any pair $i, j \in [m]$, with $i \neq j$,

$$\Pr[\xi_j = 1 \mid \xi_i = 1] \leq \Pr[\xi_j = 1 \mid \xi_i = 0].$$

Hence

$$\begin{aligned}\Pr[\xi_j = 1 \mid \xi_i = 1] \leq\ & \Pr[\xi_j = 1 | \xi_i = 1] \cdot \Pr[\xi_i = 1] + \Pr[\xi_j = 1 | \xi_i = 0] \cdot (1 - \Pr[\xi_i = 1]) \\ =\ & \Pr[\xi_j = 1]\end{aligned}$$

By [BBL09], the distribution of $\xi_{[m]\setminus\{i\}} \in \{0,1\}^{m-1}$ conditional on $\xi_i = 1$ is Strongly Rayleigh.

With loss of generality, let us order the indices s.t. $S = \{1, \ldots, s\}$, where $s \leq k$. We use $[i]$ to denote $\{1, 2, \cdots, i\}$. Using the above observations, we can now prove the lemma by induction. The induction hypothesis at the i-th step (where $i \leq k$), is that the following two statements are true.

1. $\forall j \in \{i+1, \ldots, m\}. \Pr[\xi_j = 1 \mid \xi_{[i]} = \mathbf{1}] \leq \Pr[\xi_j = 1]$
2. The distribution of the vector of random variables $\xi_{m\setminus[i]} \in \{0,1\}^{m-i}$ conditional on $\xi_{[i]} = \mathbf{1}$ is Strongly Rayleigh.

□

Chapter 9

Four Derivation Suffice for Rank 1 Matrix

We prove a matrix discrepancy bound that strengthens the famous Kadison-Singer result of Marcus, Spielman, and Srivastava. Consider any independent scalar random variables $\xi_1, \ldots, \xi_n$ with finite support, e.g. $\{\pm 1\}$ or $\{0, 1\}$-valued random variables, or some combination thereof. Let $u_1, \ldots, u_n \in \mathbb{C}^m$ and

$$\sigma^2 = \left\| \sum_{i=1}^{n} \mathbb{V}[\xi_i](u_i u_i^*)^2 \right\|.$$

Then there exists a choice of outcomes $\epsilon_1, \ldots, \epsilon_n$ in the support of $\xi_1, \ldots, \xi_n$ s.t.

$$\left\| \sum_{i=1}^{n} \mathbb{E}[\xi_i] u_i u_i^* - \sum_{i=1}^{n} \epsilon_i u_i u_i^* \right\| \leq 4\sigma.$$

A simple consequence of our result is an improvement of a Lyapunov-type theorem of Akemann and Weaver.

9.1 Introduction

Discrepancy theory is an area of combinatorics that studies how well continuous objects can be approximated by discrete ones. It lies at the heart of numerous problems in mathematics and computer science [Cha00]. Although closely tied to probability theory, direct randomized approaches rarely yield the best bounds. In a classical formulation in discrepancy theory, we have n sets on n elements, and would like to two-color the elements so that each set has roughly the same number of elements of each color. Using a simple random coloring, it is an easy consequence of Chernoff's bound that there exists a coloring such that the discrepancy in all n sets is $O(\sqrt{n \log n})$ [AS16]. However, in a celebrated result, Spencer showed that in fact there is a coloring with discrepancy at most $6\sqrt{n}$ [Spe85].

Recently, there has been significant success in generalizing Chernoff [Che52], Hoeffding, Bernstein, and Bennett-type concentration bounds for scalar random variables to matrix-valued random variables [Rud99, AW02, Tro12]. Consider the following matrix concentration bound, which is a direct consequence of a matrix Hoeffding bound.

Theorem 9.1.1 ([Tro12])**.** *Let $\xi_i \in \{\pm 1\}$ be independent, symmetric random signs and $A_1, \ldots, A_n \in \mathbb{C}^{m \times m}$ be positive semi-definite matrices. Suppose $\max_{i \in [n]} \|A_i\| \leq \epsilon$ and $\|\sum_{i=1}^n A_i\| \leq 1$. Then,*

$$\Pr\left[\left\|\sum_{i=1}^n \xi_i A_i\right\| \geq t\sqrt{\epsilon}\right] \leq 2m \exp(-t^2/2).$$

A consequence of this theorem is that with high probability

$$\left\|\sum_{i=1}^n \xi_i A_i\right\| = O(\sqrt{\log m})\sqrt{\epsilon}. \tag{9.1}$$

The Kadison-Singer theorem of [MSS15b] is essentially equivalent to the following statement (which can readily be derived from the bipartition statement in [MSS15b]).

Theorem 9.1.2 ([MSS15b]). *Let* $u_1, \ldots, u_n \in \mathbb{C}^m$ *and suppose* $\max_{i\in[n]} \|u_i u_i^*\| \leq \epsilon$ *and* $\sum_{i=1}^n u_i u_i^* = I$. *Then, there exists signs* $\xi_i \in \{\pm 1\}$ *s.t.*

$$\left\| \sum_{i=1}^n \epsilon_i u_i u_i^* \right\| \leq O(\sqrt{\epsilon}).$$

Thus, for rank 1 matrices the theorem improves on the norm bound in Equation (9.1), by a factor $\sqrt{\log m}$, in a manner analogous to the improvement of Spencer's theorem over the bound based on the scalar Chernoff bound.

For random signings of matrices one can establish bounds in some cases that are much stronger than Theorem 9.1.1.

Theorem 9.1.3 ([Tro12]). *Let* $\xi_i \in \{\pm 1\}$ *be independent random signs, and let* $A_1, \ldots, A_n \in \mathbb{C}^{m\times m}$ *be Hermitian matrices. Let* $\sigma^2 = \left\| \sum_{i=1}^n \mathbb{V}[\xi_i] A_i^2 \right\|$. *Then,*

$$\Pr\left[\left\| \sum_{i=1}^n \mathbb{E}[\xi_i] A_i - \sum_{i=1}^n \xi_i A_i \right\| \geq t \cdot \sigma \right] \leq 2m \exp(-t^2/2).$$

From this theorem we deduce that with high probability

$$\left\| \sum_{i=1}^n \mathbb{E}[\xi_i] A_i - \sum_{i=1}^n \xi_i A_i \right\| = O(\sqrt{\log m})\sigma. \tag{9.2}$$

Of course, this implies that there exists a choice of signs $\epsilon_1, \ldots, \epsilon_n \in \{\pm 1\}$ such that

$$\left\| \sum_{i=1}^n \mathbb{E}[\xi_i] A_i - \sum_{i=1}^n \epsilon_i A_i \right\| = O(\sqrt{\log m})\sigma.$$

Our main result demonstrates that for rank-1 matrices, there exists a choice of signs with a stronger guarantee.

Theorem 9.1.4 (Main Theorem)**.** *Consider any independent scalar random variables $\xi_1, \dots, \xi_n$ with finite support. Let $u_1, \dots, u_n \in \mathbb{C}^m$ and*

$$\sigma^2 = \left\| \sum_{i=1}^{n} \mathbb{V}[\xi_i](u_i u_i^*)^2 \right\|.$$

Then there exists a choice of outcomes $\epsilon_1, \dots, \epsilon_n$ in the support of $\xi_1, \dots, \xi_n$

$$\left\| \sum_{i=1}^{n} \mathbb{E}[\xi_i] u_i u_i^* - \sum_{i=1}^{n} \epsilon_i u_i u_i^* \right\| \leq 4\sigma.$$

For rank 1 matrices our theorem improves on the norm bound in Equation (9.2), by a factor $\sqrt{\log m}$. Note for example, if ξ_i is $\{\pm 1\}$-valued, then $\mathbb{V}[\xi_i] = 1 - \mathbb{E}[\xi_i]^2$.

Specializing to centered random variables, we obtain the following corollary, which in a simple way generalizes the Kadison-Singer theorem, although with a slightly worse constant.

Corollary 9.1.5. *Let $u_1, \dots, u_n \in \mathbb{C}^m$ and*

$$\sigma^2 = \left\| \sum_{i=1}^{n} (u_i u_i^*)^2 \right\|.$$

There exists a choice of signs $\epsilon_i \in \{\pm 1\}$ such that

$$\left\| \sum_{i=1}^{n} \epsilon_i u_i u_i^* \right\| \leq 4\sigma.$$

Notice that if $\max_i \|u_i u_i^*\| \leq \epsilon$ and $\sum_{i=1}^{n} u_i u_i^* = I$, then $\sigma^2 \leq \epsilon$, and we obtain Theorem 9.1.2 as consequence of the corollary.

Our Theorem 9.1.4 has multiple advantages over Theorem 9.1.2. It allows us to show existence of solutions close to the mean of arbitrarily biased ± 1 random variables, instead

of only zero mean distributions. If some variable ξ_i is extremely biased, its variance is correspondingly low, as $\mathbb{V}[\xi_i] = 1 - \mathbb{E}[\xi_i]^2$.

If only a small subset of the rank 1 matrices obtain the ϵ norm bound, and the rest are significantly smaller in norm, then we can have $\sigma^2 \approx \epsilon^2$, so we prove a bound of $O(\epsilon)$ instead of the $O(\sqrt{\epsilon})$ bound of the Kadison-Singer theorem. On the other hand, when the problem is appropriately scaled, we always have $\sigma \geq \epsilon^2$, so the gap between the two results can never be more than a square root. Additionally, note that although the Kadison-Singer theorem requires $\sum_{i=1}^n u_i u_i^* = I$, a multi-paving argument[1] can be used to instead relax this to $\| \sum_{i=1}^n u_i u_i^* \| \leq 1$.

Approximate Lyapunov Theorems. Marcus, Spielman and Srivastava resolved the Kadison-Singer problem by proving Weaver's conjecture [Wea04], which was shown to imply the Kadison-Singer conjecture. In [AW14], Akemann and Weaver prove a generalization of Weaver's conjecture [Wea04].

Theorem 9.1.6 ([AW14]). *Let $u_1, \ldots, u_n \in \mathbb{C}^m$ such that $\| \sum_{i=1}^n u_i u_i^* \| \leq 1$ and $\max_i \|u_i u_i^*\| \leq \epsilon$. For any $t_i \in [0,1]$ and $1 \leq i \leq n$, there exists a set of indices $S \subset \{1, 2, \ldots, n\}$ such that*

$$\left\| \sum_{i \in S} u_i u_i^* - \sum_{i=1}^n t_i u_i u_i^* \right\| = O(\epsilon^{1/8}).$$

Due to the classical Lyapunov theorem [Lya40] and its equivalent versions [Lin66], in their study of operator algebras, Akemann and Anderson [AA91] refer to a result as a Lyapunov theorem if the result states that for a convex set C, the image of C under an affine

[1] This was pointed out to us by Tarun Kathuria.

map is equal to the image of the extreme points of C. Theorem 9.1.6 is an approximate Lyapunov theorem as it can be interpreted as saying that the image of $[0,1]^n$ under the map

$$f : (t_1, \ldots, t_n) \to \sum_{i=1}^{n} t_i u_i u_i^*,$$

can be approximated by the image of one of the vertices of the hypercube $[0,1]^n$. A corollary of our main result, Theorem 9.1.4, is the following strengthening of Theorem 9.1.6. This result greatly improves the ϵ dependence of the original Lyapunov-type theorem and provides a small explicit constant.

Corollary 9.1.7. *Let $u_1, \ldots, u_n \in \mathbb{C}^m$ such that $\| \sum_{i=1}^n u_i u_i^* \| \leq 1$ and $\max_i \|u_i u_i^*\| \leq \epsilon$. For any $t_i \in [0,1]$ and $1 \leq i \leq n$, there exists a set of indices $S \subset \{1, 2, \ldots, n\}$ such that*

$$\left\| \sum_{i \in S} u_i u_i^* - \sum_{i=1}^{n} t_i u_i u_i^* \right\| = 2\,\epsilon^{1/2}.$$

The corollary follows immediately from Theorem 9.1.4 by choosing as the ξ_i a set of independent $\{0,1\}$-valued random variables with means $t_i \in [0,1]$. Note then that $\mathbb{V}[\xi_i] = t_i(1-t_i) \leq 1/4$, and so by the assumptions $\max_i \|u_i u_i^*\| \leq \epsilon$ and $\sum_{i=1}^n u_i u_i^* \preceq I$, we have $\sigma^2 \leq \epsilon/4$, and we obtain Theorem 9.1.2 as consequence of the corollary.

9.1.1 Related work and open questions

Our work is an extension of the the Kadison-Singer theorem of [MSS15b]. This result has a rich history of connections with theoretical computer science, and, we hope, may represent a step toward getting polynomial time algorithms for finding Kadison-Singer partitions.

Expanders are sparse graphs that exhibit good connectivity. One view on this is that an expander graph approximates a complete graph in some sense, e.g. the spectrum of the adjacency matrix or Laplacian matrix associated with the graph resembles that of the complete graph. Ramanujan graphs [Mar73, LPS88] are sparse d-regular graphs whose adjacency matrix eigenvalues essentially optimally approximates those of a complete graph among all d-regular graphs for a given degree d. These initial constructions of Ramanujan graphs relied on number-theoretic techniques and could not show existence of Ramanujan for all degrees and sizes.

Using the *method of interlacing families of polynomials*, [MSS15a, MSS18], finally showed the existence of *bipartite*[2] Ramanujan graphs of all degrees and of all sizes. The existential result of [MSS15a] was turned into a polynomial time algorithm in [Coh16b]. The restriction to bipartite Ramanujan graphs in these papers arose from the fact that interlacing families most naturally control only the largest eigenvalue of a matrix, while Ramanujan graphs require both the largest and the smallest eigenvalue to be controlled. [MSS15a] overcame this obstacle by studying only bipartite graphs, whose adjacency matrix eigenvalues are symmetric around zero and hence controlling the largest eigenvalue[3] implies also controlling the smallest. Our techniques for simultaneously controlling the smallest and largest eigenvalues of a matrix are very different from earlier interlacing family-based methods, and an intriguing open question is whether similar ideas can be used to construct non-bipartite Ramanujan graphs of all degrees and sizes.

[2]Which approximates the complete bipartite graph.

[3]More precisely, it is the largest non-trivial eigenvalue that is being controlled. The largest eigenvalue of the adjacency matrix of a d-regular graph is the trivial eigenvalue of d.

[ST04] gave nearly-linear time algorithms for producing sparse graphs (with non-uniform weights) that closely approximate a given input graph, in the sense that the spectral behavior of the Laplacian matrices associated with the graphs is very similar. A greatly simplified and stronger result was given in [SS11], still with a nearly linear time algorithm. When used to construct a sparse graph that spectrally approximates a complete graph of size n, the result of [SS11] has a worse average degree than a corresponding Ramanujan graph by a factor $\Theta(\log n)$. Later, this was improved to within a factor $O(1)$, still with a polynomial time algorithm, in [BSS12]. Finally, a series of papers turned this latter result into a nearly-linear time algorithm [LS18, LS17]. The resolution of the Kadison-Singer theorem was motivated by [BSS12][4]. A major open question in the area is whether a polynomial time algorithm for finding explicit solutions to the Kadison-Singer problem exists, and we hope that our strengthened form of the result may make the problem more tractable.

The Kadison-Singer theorem and our result can be interpreted as analogous to Spencer's theorem in a matrix setting, in recent years that has been tremendous progress in obtaining polynomial time algorithms for Spencer's theorem and related problems in other settings [Bou10, LM15, Rot17, BDG16, BG17, BDGL18, NDTTJ18]. Techniques developed in these papers have also found algorithmic uses in approximation algorithms beyond typical discrepancy statements [Rot13]. While interlacing families have notably been used to to bound integrality gaps for ATSP [AG14] algorithmic results based on these have been limited, with [Coh16b] providing the most notable example of a polynomial time algorithm based on interlacing families. It seems likely, however, that a deeper understanding of the limits of matrix rounding could have many applications in approximation algorithms.

[4]Gil Kalai suggested the connection between that result and the Kadison-Singer problem.

9.1.2 Our techniques

Our proof is based on the method of interlacing polynomials introduced in [MSS15a, MSS15b]. One difficulty in applying the method of interlacing polynomials is the inability to control both the largest and smallest eigenvalues of a matrix simultaneously. Various techniques and restrictions are used to overcome this problem in [MSS15a, MSS15b] (studying bipartite graphs, assuming isotropic position). We develop a seemingly more natural approach for simultaneously controlling both the largest and smallest roots of the matrices we consider. We study polynomials that can be viewed as expected characteristic polynomials, but are more easily understood as the expectation of a product of multiple determinants. The using a product of two determinants helps us bound the upper and lower eigenvalues both at the same time.

We introduce an analytic expression for the expected polynomials in terms of linear operators that use second order derivatives. This has the advantage of allowing us to gain stronger control over the movement of roots of polynomials under the linear operators we apply than those used by [MSS15b]. This is because movement of the roots now depends on the curvature of our polynomials in favorable way. Interestingly, linear operators containing second order derivatives also appear in the work of [AG14] but for different reasons. This lets us reuse one of their lemmas for bounding position of the roots of a real stable polynomial.

9.2 Preliminaries

We gather several basic linear algebraic and analytic facts in the following sections.

9.2.1 Linear Algebra

Lemma 9.2.1. *Let $x \in \mathbb{R}^n$. Then*

$$\det(I - txx^*) = 1 - tx^*x.$$

Fact 9.2.2 (Jacobi's Formula)**.** *For $A(t) \in \mathbb{R}^{n \times n}$ a function of t,*

$$\frac{d}{dt}\det(A(t)) = \det(A(t))\operatorname{tr}\left[A^{-1}(t)\frac{d}{dt}A(t)\right].$$

9.2.2 Real Stability

Definition 9.2.1. A multivariate polynomial $p(z_1, \ldots, z_n) \in \mathbb{C}[z_1, \ldots, z_n]$ is *stable* if it has no zeros in the region $\{(z_1, \ldots, z_n) : \Im(z_i) > 0 \text{ for all } 1 \leq i \leq n\}$. p is *real stable* if p is stable and the coefficients of p are real.

Lemma 9.2.3 (Corollary 2.8, [AOGSS18])**.** *If $p \in \mathbb{R}[z_1, \ldots, z_n]$ is real stable, then for any $c > 0$, so is*

$$(1 - c\partial_{z_i}^2)p(z_1, \ldots, z_n)$$

for all $1 \leq i \leq n$.

Lemma 9.2.4 (Proposition 2.4, [BB08])**.** *If $A_1, \ldots, A_n$ are positive semidefinite symmetric matrices, then the polynomial*

$$\det\left(\sum_{i=1}^{n} z_i A_i\right)$$

is real stable.

We also need that real stability is preserved under fixing variables to real values (see [Wag11, Lemma 2.4(d)]).

Proposition 9.2.5. *If $p \in \mathbb{R}[z_1, \ldots, z_m]$ is real stable and $a \in \mathbb{R}$, then $p|_{z_1=a} = p(a, z_2, \ldots, z_m) \in \mathbb{R}[z_2, \ldots, z_m]$ is real stable.*

9.2.3 Interlacing Families

We recall the definition and consequences of interlacing families from [MSS15a].

Definition 9.2.2. We say a real rooted polynomial $g(x) = C\prod_{i=1}^{n-1}(x - \alpha_i)$ *interlaces* the real rooted polynomial $f(x) = C'\prod_{i=1}^{n}(x - \beta_i)$ if

$$\beta_1 \leq \alpha_1 \leq \cdots \leq \alpha_{n-1} \leq \beta_n.$$

Polynomials $f_1, \ldots, f_k$ have a *common interlacing* if there is a polynomial g that interlaces each of the f_i.

The following lemma relates the roots of a sum of polynomials to those of a common interlacer.

Lemma 9.2.6 (Lemma 4.2, [MSS15a])**.** *Let $f_1, \ldots, f_k$ be degree d real rooted polynomials with positive leading coefficients. Define*

$$f_\emptyset := \sum_{i=1}^{k} f_i.$$

If $f_1, \ldots, f_k$ have a common interlacing then there exists an i for which the largest root of f_i is upper bounded by the largest root of $f_\emptyset$.

Definition 9.2.3. Let $S_1, \ldots, S_n$ be finite sets. For every $S \in \mathcal{F}$, we let $f_S(x)$ be a real rooted polynomial of degree d with positive leading coefficient. For a choice of assignment $s_1, \ldots, s_n \in S_1 \times \cdots \times S_n$, let $f_{s_1,\ldots,s_n}(x)$ be a real rooted degree d polynomial with positive leading coefficient. For a partial assignment $s_1, \ldots, s_k \in S_1 \times \cdots \times S_k$ for $k < n$, we define

$$f_{s_1,\ldots,s_k} := \sum_{s_{k+1} \in S_{k+1}, \ldots, s_n \in S_n} f_{s_1,\ldots,s_k,s_{k+1},\ldots,s_n}. \tag{9.3}$$

Note that this is compatible with our definition of $f_\emptyset$ from Definition 9.2.2. We say that the polynomials $\{f_{s_1,\ldots,s_n}\}$ form an *interlacing family* if for all $k = 0, \ldots, n-1$ and all $s_1, \ldots, s_k \in S_1 \times \cdots \times S_k$, the polynomials have a common interlacing.

The following lemma relates the roots of the interlacing family to those of $f_\emptyset$.

Lemma 9.2.7 (Theorem 4.4, [MSS15a])**.** *Let $S_1, \ldots, S_n$ be finite sets and let $\{f_{s_1,\ldots,s_n}\}$ be an interlacing family. Then there exists some $s_1, \ldots, s_n \in S_1 \times \cdots \times S_n$ so that the largest root of $f_{s_1,\ldots,s_n}$ is upper bounded by the largest root of $f_\emptyset$.*

Finally, we recall a relationship between real-rootedness and common interlacings which has been discovered independently several times [DG94, Fel80, CS07].

Lemma 9.2.8. *Let $f_1, \ldots, f_k$ be univariate polynomials of the same degree with positive leading coefficient. Then $f_1, \ldots, f_k$ have a common interlacing if and only if $\sum_{i=1}^k \alpha_i f_i$ is real rooted for all nonnegative α_i such that $\sum_i \alpha_i = 1$.*

9.3 Expected Characteristic Polynomial

Instead of working with the random polynomial $\det(xI - \sum_{i=1}^n \xi_i u_i u_i^*)$, we consider

$$\det\left(x^2 I - \Big(\sum_{i=1}^n \xi_i u_i u_i^*\Big)^2\right) = \det\left(xI - \sum_{i=1}^n \xi_i u_i u_i^*\right) \det\left(xI + \sum_{i=1}^n \xi_i u_i u_i^*\right).$$

Observe that the largest root $\lambda_{\max}$ of this polynomial is

$$\lambda_{\max}\left(\det\left(x^2 I - \Big(\sum_{i=1}^n \xi_i u_i u_i^*\Big)^2\right)\right) = \left\|\sum_{i=1}^n \xi_i u_i u_i^*\right\|. \tag{9.4}$$

We gather some results that will allow us to extract an analytic expression for the expected characteristic polynomial.

Lemma 9.3.1. *For positive semidefinite (PSD) matrices $M, N \in \mathbb{R}^{m\times m}$, $v \in \mathbb{R}^m$ and ξ a random variable with zero mean and variance τ^2,*

$$\mathop{\mathbb{E}}_{\xi}[\det(M - \xi vv^*)\det(N + \xi vv^*)] = \left(1 - \frac{1}{2}\frac{d^2}{dt^2}\right)\Bigg|_{t=0} \det(M + t\tau vv^*)\det(N + t\tau vv^*). \tag{9.5}$$

Proof. We can assume that both M and N are positive definitive and hence invertible. The argument for the the positive semi-definite case follows by a continuity argument (using Hurwitz's theorem from complex analysis, see also [MSS15b]).

We show that the two sides of (9.5) are equivalent to the same expression. Beginning on the left hand side,

$$\begin{aligned}
&\mathbb{E}[\det(M - \xi vv^*)\det(N + \xi vv^*)] \\
&\qquad = \det(M)\det(N)\,\mathbb{E}[\det(I - \xi M^{-1/2} vv^* M^{-1/2})\det(I + \xi N^{-1/2} vv^* N^{-1/2})] \\
&\qquad = \det(M)\det(N)\,\mathbb{E}[1 + \xi b^* b - \xi a^* a - \xi^2 a^* a b^* b] \\
&\qquad = \det(M)\det(N)(1 - \tau^2 a^* a b^* b)
\end{aligned}$$

where $a := M^{-1/2}v$ and $b := N^{-1/2}v$. For the right hand side of (9.5),

$$\begin{aligned}\left(1 - \frac{1}{2}\frac{d^2}{dt^2}\right)\Bigg|_{t=0} &\det(M + t\tau vv^*)\det(N + t\tau vv^*) \\ &= \det(M)\det(N)\left(1 - \frac{1}{2}\frac{d^2}{dt^2}\right)\Bigg|_{t=0} \det(I + t\tau aa^*)\det(I + t\tau bb^*) \\ &= \det(M)\det(N)(1 - \tau^2 a^* a b^* b)\end{aligned}$$

where the last line follows from Lemma 9.2.1. □

Centering our random variables and applying the previous lemma leads to the following corollary for non-centered random variables.

Corollary 9.3.2. *Let $M, N \in \mathbb{R}^{m\times m}$ be arbitrary PSD matrices, $v \in \mathbb{R}^m$ and ξ a random variable with expectation μ and variance τ^2.*

$$\mathop{\mathbb{E}}_{\xi}[\det(M - (\xi-\mu)vv^*)\det(N + (\xi-\mu)vv^*)] = \left(1 - \frac{1}{2}\frac{d^2}{dt^2}\right)\Bigg|_{t=0} \det(M + t\tau vv^*)\det(N + t\tau vv^*).$$

We can now derive an expression for the expected characteristic polynomial.

Proposition 9.3.3. *Let $u_1, \ldots, u_n \in \mathbb{R}^m$. Consider independent random variables ξ_i with means μ_i and variances τ_i^2. Let $Q \in \mathbb{R}^{m\times m}$ be a symmetric matrix.*

$$\begin{aligned}\mathop{\mathbb{E}}_{\xi}\left[\det\left(x^2 I - \left(Q + \sum_{i=1}^n (\xi_i - \mu_i)u_i u_i^*\right)^2\right)\right] = \prod_{i=1}^n \left(1 - \frac{\partial_{z_i}^2}{2}\right)\Bigg|_{z_i=0} &\det\left(xI - Q + \sum_{i=1}^n z_i\tau_i u_i u_i^*\right) \\ &\times \det\left(xI + Q + \sum_{i=1}^n z_i\tau_i u_i u_i^*\right),\end{aligned}$$

and this is a real rooted polynomial in x.

Proof. For each i, let β_i denote the maximum value of $|\xi_i|$ among outcomes in the (finite) support of ξ_i. We begin by restricting the domain of our polynomials to $x > \|Q\| + 2\sum_{i=1}^n \beta_i \|u_i u_i^*\|$. We then proceed by induction. Our induction hypothesis will be that for $0 \leq k \leq n$

$$\begin{aligned}
&\mathbb{E}\left[\det\left(x^2 I - \left(Q + \sum_{i=1}^n (\xi_i - \mu_i) u_i u_i^*\right)^2\right)\right] \\
&= \mathop{\mathbb{E}}_{\xi_{k+1},\ldots,\xi_n} \prod_{i=1}^k \left(1 - \frac{\partial_{z_i}^2}{2}\right)\Bigg|_{z_i=0} \det\left(xI - Q - \sum_{i=k+1}^n (\xi_i - \mu_i) u_i u_i^* + \sum_{j=1}^k z_j \tau_j u_j u_j^*\right) \\
&\qquad \times \det\left(xI + Q + \sum_{i=k+1}^n (\xi_i - \mu_i) u_i u_i^* + \sum_{j=1}^k z_j \tau_j u_j u_j^*\right) \qquad (9.6)
\end{aligned}$$

The base case, $k = 0$ is trivially true as we get the same formula on both sides after recalling that for any matrix Y

$$\det\left(x^2 I - Y^2\right) = \det(xI - Y)\det(xI + Y).$$

By our assumption that $x > \|Q\| + 2\sum_{i=1}^n \beta_i \|u_i u_i^*\|$,

$$xI - \sum_{i=k+2}^n (\xi_i - \mu_i) u_i u_i^* + \sum_{j=1}^k z_j \tau_j u_j u_j^*$$

is PSD for any realization of $\xi_{k+2}, \ldots, \xi_n$ and in a neighborhood of zero for each z_j. Applying Corollary 9.3.2 to the right hand side of (9.6), yields

$$\begin{aligned}
&\mathbb{E}\left[\det\left(x^2 I - \left(Q + \sum_{i=1}^n (\xi_i - \mu_i) u_i u_i^*\right)^2\right)\right] \\
&= \mathop{\mathbb{E}}_{\xi_{k+2},\ldots,\xi_n} \prod_{i=1}^{k+1} \left(1 - \frac{\partial_{z_i}^2}{2}\right)\Bigg|_{z_i=0} \det\left(xI - Q - \sum_{i=k+2}^n (\xi_i - \mu_i) u_i u_i^* + \sum_{j=1}^{k+1} z_j \tau_j u_j u_j^*\right) \\
&\qquad \times \det\left(xI + Q + \sum_{i=k+2}^n (\xi_i - \mu_i) u_i u_i^* + \sum_{j=1}^{k+1} z_j \tau_j u_j u_j^*\right)
\end{aligned}$$

which completes the induction. To extend the proof to all x, we remark that we have shown the equivalence of two polynomials in the interval $x > \|Q\| + 2\sum_{i=1}^{n} \beta_i \|u_i u_i^*\|$, and two polynomials that agree on an interval are identical.

Real-rootedness of the right hand side follows by Lemma 9.2.4, Lemma 9.2.3, and that by Proposition 9.2.5 restriction to $z = \mathbf{0}$ preserves real-stability, and a univariate real stable polynomial is real rooted. □

9.4 Defining the Interlacing Family

The next proposition establishes that it suffices to bound the largest root of $q_\emptyset$.

Proposition 9.4.1. *There exists a choice of outcomes $\epsilon_1, \ldots, \epsilon_n$ in the finite support of $\xi_1, \ldots, \xi_n$, s.t.*

$$\left\| \sum_{i=1}^{n} \epsilon_i u_i u_i^* - \sum_{i=1}^{n} \mu_i u_i u_i^* \right\|$$

is less than the largest root of

$$\mathop{\mathbb{E}}_{\xi_1,\cdots,\xi_n} \left[\det \left(x^2 I - \Big(\sum_{i=1}^{n} (\xi_i - \mu_i) u_i u_i^* \Big)^2 \right) \right].$$

where $\mathbb{E}[\xi_i] = \mu_i, \forall i \in [n]$.

Proof. For a vector of independent random variables $(\xi_1, \ldots, \xi_n)$ with finite support, let $p_{i,x}$ be the probability that $\xi_i = x$. For $s = (\epsilon_1, \ldots, \epsilon_n)$ in the support of $\xi_1, \ldots, \xi_n$, we define

$$q_s(x) := \prod_{i=1}^{n} p_{i,\epsilon_i} \det \left(x^2 I - \Big(\sum_{i=1}^{n} (\epsilon_i - \mu_i) u_i u_i^* \Big)^2 \right).$$

Let t be a vector of k outcomes in the support of $\xi_1, \ldots, \xi_k$, i.e. a partial assignment of assignment of outcomes. Then we consider the conditional expected polynomial

$$q_t(x) := \left(\prod_{i=1}^{k} p_{i,t_i} \right) \mathop{\mathbb{E}}_{\xi_{k+1},\ldots,\xi_n} \left[\det \left(x^2 I - \left(\sum_{i=1}^{k} (t_i - \mu_i) u_i u_i^* + \sum_{j=k+1}^{n} (\xi_j - \mu_j) u_j u_j^* \right)^2 \right) \right]$$

which coincides with (9.3). We show that q_s is an interlacing family. Let $r_{k+1}^{(1)} \ldots r_{k+1}^{(l)}$ be the outcomes in the support of ξ_{k+1}. For a given t and $r \in \{r_{k+1}^{(1)}, \ldots, r_{k+1}^{(l)}\}$, let (t, r) denote the vector $(t_1, \ldots, t_k, r)$. By Lemma 9.2.8, it suffices to show that for any choice of non-negative numbers $\alpha_1, \ldots, \alpha_l$ such that $\sum_j \alpha_j = 1$, the polynomial

$$\sum_j \alpha_j q_{t, r_{k+1}^{(j)}}(x)$$

is real rooted. We can consider these α's as a probability distribution and define $p_{k+1,r_{k+1}^{(j)}} = \alpha_j$. Therefore,

$$\begin{aligned}
q_t(x) &= \left(\prod_{i=1}^{k} p_{i,t_i}\right) \mathop{\mathbb{E}}_{\xi_{k+1},\ldots,\xi_n} \left[\det\left(x^2 I - \left(\sum_{i=1}^{k}(t_i-\mu_i)u_i u_i^* + \sum_{j=k+1}^{n}(\xi_j-\mu_j)u_j u_j^*\right)^2\right)\right] \\
&= \sum_j \left(\prod_{i=1}^{k} p_{i,t_i}\right) p_{k+1,r_{k+1}^{(j)}} \\
&\quad \times \mathop{\mathbb{E}}_{\xi_{k+2},\ldots,\xi_n} \left[\det\left(x^2 I - \left(\sum_{i=1}^{k}(t_i-\mu_i)u_i u_i^* - (r_{k+1}^{(j)}-\mu_{k+1})u_{k+1}u_{k+1}^* - \sum_{j=k+2}^{n}(\xi_j-\mu_j)u_j u_j^*\right)^2\right)\right] \\
&= \sum_j \alpha_j q_{t,r_{k+1}^{(j)}}(x).
\end{aligned}$$

By Proposition 9.3.3, q_t is real rooted, which completes the proof that q_s is an interlacing family. Finally, by Lemma 9.2.7, there exists a choice of t so that the largest root of q_t is upperbounded by $q_\emptyset$.

□

9.5 Largest Root of the Expected Characteristic Polynomial

We use the barrier method approach to control the largest root [MSS15b].

Definition 9.5.1. For a multivariate polynomial $p(z_1, \ldots, z_n)$, we say $z \in \mathbb{R}^n$ is *above* all the roots of p if for all $t \in \mathbb{R}^n_+$,

$$p(z + t) > 0.$$

We use $\mathbf{Ab}_p$ to denote the set of points that are above all the roots of p.

We use the same barrier function as in [BSS12, MSS15b].

Definition 9.5.2. For a real stable polynomial p and $z \in \mathbf{Ab}_p$, the barrier function of p in direction i at z is

$$\Phi^i_p(z) := \frac{\partial_{z_i} p(z)}{p(z)}.$$

We will also make use of the following lemma that controls the deviation of the roots after applying a second order differential operator. The lemma is a slight variation of Lemma 4.8 in [AG14].

Lemma 9.5.1. *Suppose that p is real stable and $z \in \mathbf{Ab}_p$.*

If $\Phi^j_p(z) < \sqrt{2}$, then $z \in \mathbf{Ab}_{(1-\frac{1}{2}\partial^2_{z_j})p}$. If additionally for $\delta > 0$,

$$\frac{1}{\delta}\Phi^j_p(z) + \frac{1}{2}\Phi^j_p(z)^2 \leq 1,$$

then and for all i,

$$\Phi^i_{(1-\frac{1}{2}\partial^2_{z_j})p}(z + \delta \cdot \mathbf{1}_j) \leq \Phi^i_p(z).$$

We provide a proof in the Appendix 9.6 for completeness.

We can now bound the largest root of the expected characteristic polynomial for subisotropic vectors.

Proposition 9.5.2. *Let $\xi_1, \dots, \xi_n$ be independent scalar random variables with finite support, with $\mathbb{E}[\xi_i] = \mu_i$, and let $\tau_i^2 = \mathbb{E}[(\xi_i - \mu_i)^2]$.*

Let $v_1, \dots, v_n \in \mathbb{R}^n$ such that $\sum_{i=1}^n \tau_i^2 (v_i v_i^*)^2 \preceq I$. Then the largest root of

$$p(x) := \mathop{\mathbb{E}}_{\xi_1, \cdots, \xi_n} \left[\det \left(x^2 I - \Big(\sum_{i=1}^n (\xi_i - \mu_i) v_i v_i^* \Big)^2 \right) \right]$$

is at most 4.

Proof. Note that we must have

$$\max_{i \in [n]} \tau_i v_i^* v_i \leq 1, \tag{9.7}$$

since otherwise $\sum_{i=1}^n \tau_i^2 (v_i v_i^*)^2 \preceq I$ is false.

Let

$$Q(x, z) = \left(\det \left(xI + \sum_{i=1}^n z_i \tau_i v_i v_i^* \right) \right)^2.$$

For $t > 0$, define $\delta_i = t \tau_i v_i^* v_i$. For $t < \alpha(t)$ a parameter to be chosen later, we evaluate

our polynomial to find that

$$\begin{aligned}
Q(\alpha, -\delta_1, \ldots, -\delta_n) &= \left(\det\left(\alpha I - \sum_{i=1}^n \delta_i \tau_i v_i v_i^*\right)\right)^2 \\
&= \left(\det\left(\alpha I - t\sum_{i=1}^n \tau_i^2 (v_i^* v_i) v_i v_i^*\right)\right)^2 \\
&= \left(\det\left(\alpha I - t\sum_{i=1}^n \tau_i^2 (v_i v_i^*) v_i v_i^*\right)\right)^2 \\
&\geq \left(\det\left((\alpha - t) I\right)\right)^2 \\
&> 0.
\end{aligned}$$

where the second last step follows by $\sum_{i=1}^n \tau_i^2 (v_i v_i^*) v_i v_i^* \preceq I$.

This implies that $(\alpha, -\delta) \in \mathbb{R}^{n+1}$ is above the roots of $Q(x, z)$. We can upper bound $\Phi_Q^i(\alpha, -\delta)$ via Fact 9.2.2 as follows

$$\begin{aligned}
\Phi_Q^i(\alpha, -\delta) &= \left.\frac{\partial_{z_i} Q}{Q}\right|_{x=\alpha, z=-\delta} \\
&= \left.\frac{2\det\left(xI + \sum_{i=1}^n z_i \tau_i v_i v_i^*\right) \partial_{z_i} \det\left(xI + \sum_{i=1}^n z_i \tau_i v_i v_i^*\right)}{\left(\det\left(xI + \sum_{i=1}^n z_i \tau_i v_i v_i^*\right)\right)^2}\right|_{x=\alpha, z=-\delta} \\
&= 2\,\mathrm{tr}\left[\left(xI + \sum_{i=1}^n z_i \tau_i v_i v_i^*\right)^{-1} \tau_i v_i v_i^*\right]\Bigg|_{x=\alpha, z=-\delta} \\
&= 2\,\mathrm{tr}\left[\left(\alpha I - t\sum_{i=1}^n \tau_i^2 (v_i v_i^*)^2\right)^{-1} \tau_i v_i v_i^*\right] \\
&\leq 2\,\mathrm{tr}\left[\left(\alpha - t\right)^{-1} \tau_i v_i v_i^*\right] \\
&= \frac{2\tau_i v_i^* v_i}{\alpha - t},
\end{aligned}$$

where the fifth step follows by $\sum_{i=1}^n \tau_i^2 (v_i v_i^*) v_i v_i^* \preceq I$.

Choosing $\alpha = 2t$ and $t = 2$, and recalling Condition (9.7) we get

$$\Phi_Q^i(\alpha, -\delta) \leq \frac{2\tau_i v_i^* v_i}{\alpha - t} \leq 1 < \sqrt{2}.$$

By Lemma 9.2.3, $(1 - \frac{1}{2}\partial_{z_i}^2)Q$ is real stable. By Lemma 9.5.1, and $(4, z) \in \mathbf{Ab}_{(1-\frac{1}{2}\partial_{z_i}^2)Q}$ and hence $(4, z + \delta_i \mathbf{1}_i) \in \mathbf{Ab}_{(1-\frac{1}{2}\partial_{z_i}^2)Q}$. Also

$$\begin{aligned}
\frac{1}{\delta_i}\Phi_Q^i(\alpha, -\delta) + \frac{1}{2}\Phi_Q^i(\alpha, -\delta)^2 &\leq \frac{1}{t\tau_i v_i^* v_i}\frac{2\tau_i v_i^* v_i}{t} + \frac{1}{2}\left(\frac{2\tau_i v_i^* v_i}{t}\right)^2 \\
&\leq \frac{4}{t^2} \\
&= 1.
\end{aligned}$$

Therefore, by Lemma 9.5.1, for all j

$$\Phi^j_{(1-\frac{1}{2}\partial_{z_i}^2)Q}(4, z + \delta_i \mathbf{1}_i) \leq \Phi_Q^j(4, z).$$

Repeating this argument for each $i \in [n]$ demonstrates that $(4, 0, \ldots, 0)$ lies above the roots of

$$\prod_{i=1}^n \left(1 - \frac{\partial_{z_i}^2}{2}\right)\left(\det\left(xI + \sum_{i=1}^n z_i \tau_i u_i u_i^*\right)\right)\left(\det\left(xI + \sum_{i=1}^n z_i \tau_i u_i u_i^*\right)\right).$$

After restricting to $z_i = 0$ for all i, we then conclude by Proposition 9.3.3 is equivalent to a bound on the largest root of the expected characteristic polynomial. □

Having developed the necessary machinery, we now prove our main theorem.

Proof of Theorem 9.1.4. Define $v_i = \frac{u_i}{\sqrt{\sigma}}$. Then, $\| \sum_{i=1}^n \tau_i^2 (v_i v_i^*)^2 \| = 1$. Applying Proposition 9.5.2 and Proposition 9.4.1, we conclude that there exists a choice of outcomes ϵ_i such

that

$$\left\| \sum_{i=1}^{n} (\epsilon_i - \mu_i) v_i v_i^* \right\| \leq 4.$$

From this, we conclude that

$$\left\| \sum_{i=1}^{n} (\epsilon_i - \mu_i) u_i u_i^* \right\| \leq 4\sigma.$$

□

9.6 Omitted Proofs

9.6.1 Proof of Lemma 9.5.1

Choosing $c = 1/2$ in Lemma 9.6.1 gives a proof of Lemma 9.5.1.

Lemma 9.6.1 (Generalization of Lemma 4.8 in [AG14])**.** *Suppose that $p(z_1, \cdots, z_m)$ is real stable and $z \in Ab_p$. For any $c \in [0, 1]$.*

If $\Phi_p^j(z) < \sqrt{1/c}$, then $z \in \mathbf{Ab}_{(1-c\partial_{z_j}^2)p}$. If additionally for $\delta > 0$,

$$c \cdot \left(\frac{2}{\delta} \Phi_p^j(z) + (\Phi_p^j(z))^2 \right) \leq 1,$$

then, for all $i \in [m]$,

$$\Phi_{(1-c\partial_j^2)p}^i(z + \delta \mathbf{1}_j) \leq \Phi_p^i(z).$$

Proof. We write ∂_i instead of ∂_{z_i} for ease of notation. By Lemma 9.2.3, $(1 - c\partial_j^2)p$ is real stable. Recall the definitions of $\Phi_p^j(z)$ and $\Psi_p^j(z)$

$$\Phi_p^j(z) = \frac{\partial_{z_j} \det(M)}{\det(M)} = \frac{\partial_j p}{p} \text{ and } \Psi_p^j(z) = \frac{\partial_j^2 \det(M)}{\det(M)} = \frac{\partial_j^2 p}{p}.$$

Consider a non-negative vector t. By Lemmas 4.6 and 4.5 in [AG14], we have

$$\Phi_p^j(z + t) \leq \Phi_p^j(z), \qquad \Psi_p^j(z + t) \leq \Phi_p^j(z + t)^2 \leq \Phi_p^j(z)^2. \tag{9.8}$$

Thus, $\Psi_p^j(z + t) \leq \Phi_p^j(z)^2 < 1/c$ so $c \cdot \partial_j^2 p(z + t) < p(z + t)$, i.e. $(1 - c\partial_j^2)p(z + t) > 0$. Thus $z \in \mathbf{Ab}_{(1-c\partial_{z_j}^2)p}$.

Next, we write $\Phi^i_{p-c\cdot\partial_j^2 p}$ in terms of Φ^i_p and Ψ^j_p and $\partial_i \Psi^j_p$.

$$\begin{aligned}
\Phi^i_{p-c\cdot\partial_j^2 p} &= \frac{\partial_i(p - c\cdot\partial_j^2 p)}{p - c\cdot\partial_j^2 p} \\
&= \frac{\partial_i((1-c\cdot\Psi^j_p)p)}{(1-c\cdot\Psi^j_p)p} \\
&= \frac{(1-c\cdot\Psi^j_p)(\partial_i p)}{(1-c\cdot\Psi^j_p)p} + \frac{(\partial_i(1-c\cdot\Psi^j_p))p}{(1-c\cdot\Psi^j_p)p} \\
&= \Phi^i_p - \frac{c\cdot\partial_i\Psi^j_p}{1-c\cdot\Psi^j_p}.
\end{aligned}$$

We would like to show that $\Phi^i_{p-c\cdot\partial_j^2 p}(z+\delta\mathbf{1}_j) \le \Phi^i_p(z)$. Equivalently, it is enough to show that

$$-\frac{c\cdot\partial_i\Psi^j_p(z+\delta\mathbf{1}_j)}{1-c\cdot\Psi^j_p(z+\delta\mathbf{1}_j)} \le \Phi^i_p(z) - \Phi^i_p(z+\delta\mathbf{1}_j).$$

By convexity, it is enough to show that

$$-\frac{c\cdot\partial_i\Psi^j_p(z+\delta\mathbf{1}_j)}{1-c\cdot\Psi^j_p(z+\delta\mathbf{1}_j)} \le \delta\cdot(-\partial_j\Phi^i_p(z+\delta\mathbf{1}_j)).$$

By monotonicity, $\delta\cdot(-\partial_j\Phi^i_p(z+\delta\mathbf{1}_j)) > 0$ so we may divide both sides of the above inequality by this term and obtain that the above is equivalent to

$$\frac{-c\cdot\partial_i\Psi^j_p(z+\delta\mathbf{1}_j)}{-\delta\cdot\partial_i\Phi^j_p(z+\delta\mathbf{1}_j)}\cdot\frac{1}{1-c\Psi^j_p(z+\delta\mathbf{1}_j)} \le 1,$$

where we also used $\partial_j\Phi^i_p = \partial_i\Phi^j_p$. By Lemma 4.10 in [AG14], $\frac{\partial_i\Psi^j_p}{\partial_i\Phi^j_p} \le 2\Phi^j_p$. So, we can write,

$$\frac{2c}{\delta}\Phi^j_p(z+\delta\mathbf{1}_j)\cdot\frac{1}{1-c\cdot\Psi^j_p(z+\delta\mathbf{1}_j)} \le 1.$$

By Equation (9.8), with $t = \delta\mathbf{1}_j$,

$$\Phi^j_p(z+\delta\mathbf{1}_j) \le \Phi^j_p(z), \qquad \Psi^j_p(z+\delta\mathbf{1}_j) \le \Phi^j_p(z+\delta\mathbf{1}_j)^2 \le \Phi^j_p(z)^2.$$

So, it is enough to show that

$$\frac{2c}{\delta}\Phi_p^j(z) \cdot \frac{1}{1 - c \cdot \Phi_p^j(z)^2} \leq 1.$$

Using $\Phi_p^j(z) < 1$ and $c \in [0, 1]$ we know that $1 - c \cdot \Phi_p^j(z)^2 < 1$. We can multiply both sides with $1 - c \cdot \Phi_p^j(z)^2$ and we obtain that it suffices to have

$$c \cdot \left(\frac{2}{\delta}\Phi_p^j(z) + \Phi_p^j(z)^2\right) \leq 1,$$

which is true by assumption. □

Part III

Compressive Sensing and Sparse Fourier Transform

Chapter 10

Compressive Sensing

We consider the extensively studied problem of ℓ_2/ℓ_2 compressed sensing. The main contribution of our work is an improvement over [Gilbert, Li, Porat and Strauss, STOC 2010] with faster decoding time and significantly smaller column sparsity, answering two open questions of the aforementioned work.

Previous work on sublinear-time compressed sensing employed an iterative procedure, recovering the heavy coordinates in phases. We completely depart from that framework, and give the first sublinear-time ℓ_2/ℓ_2 scheme which achieves the optimal number of measurements without iterating; this new approach is the key step to our progress. Towards that, we satisfy the ℓ_2/ℓ_2 guarantee by exploiting the heaviness of coordinates in a way that was not exploited in previous work. Via our techniques we obtain improved results for various sparse recovery tasks, and indicate possible further applications to problems in the field, to which the aforementioned iterative procedure creates significant obstructions.

10.1 Introduction

Compressed Sensing, or sparse recovery, is a powerful mathematical framework the goal of which is to reconstruct an approximately k-sparse vector $x \in \mathbb{R}^n$ from linear measurements $y = \Phi x$, where $\Phi \in \mathbb{R}^{m \times n}$. The most important goal is to reduce the number of measurements m needed to approximate the vector x, avoiding the linear dependence on n. In discrete signal processing, where this framework was initiated [CRT06b, Don06], the core principle that the sparsity of a signal can be exploited to recover it using much fewer samples than the Shannon-Nyquist Theorem. We refer to the matrix Φ as the sketching or sensing matrix, and $y = \Phi x$ as the sketch of vector x.

Sparse recovery is the primary task of interest in a number of applications, such as image processing [TLW+06, LDP07a, DDT+08], design pooling schemes for biological tests [ECG+09, DWG+13], pattern matching [CEPR07], combinatorial group testing [SAZ09, ESAZ09, KBG+10], localizing sources in sensor networks [ZBSG05, ZPB06], as well as neuroscience [GS12]. Furthermore, not surprisingly, tracking heavy hitters in data streams, also known as frequent items, can be captured by the sparse recovery framework [Mut05a, CH09, KSZC03, Ind07]. In practice, streaming algorithms for detecting heavy hitters have been used to find popular destination addresses and heavy bandwidth users by AT&T [CJK+04] or answer "iceberg queries" in databases [FSGM+99].

Sparse recovery attracts researchers from different communities, from both theoretical and practical perspective. During the last ten years, hundreds of papers have been published by theoretical computer scientists, applied mathematicians and electrical engineers that specialize in compressed sensing. While numerous algorithms using space linear in the universe size n are known, [Don06, CRT06b, IR08a, NT09a, BIR08a, BD09a, SV16]

to name a few, our goal is to obtain algorithms that are sublinear, something that is crucial in many applications.

The desirable quantities we want to optimize may vary depending on the application. For example, in network management, x_i could denote the total number of packets with destination i passing through a network router. In such an application, storing the sketching matrix explicitly is typically not a tenable solution, since this would lead to an enormous space consumption; the number of possible IP addresses is 2^{32}. Moreover, both the query and the update time should be very fast, in order to avoid congestion on the network. Incremental updates to x come rapidly, and the changes to the sketch should also be implemented very fast; we note that in this case, even poly-logarithmic factors might be prohibitive. Interested readers can refer to [KSZC03, EV03] for more information about streaming algorithms for network management applications.

"The goal of that research is to obtain encoding and recovery schemes with good compression rate (i.e., short sketch lengths) as well as good algorithmic properties (i.e., low encoding, update and recovery times)." – *Anna Gilbert and Piotr Indyk* [GI10]

Sparse recovery schemes that are optimal across all axis are a challenge and an important theoretical and practical problem. For most sparse recovery tasks, we have algorithms that achieve different trade-offs for the various parameters of interest. One exception is the ℓ_∞/ℓ_2 guarantee, for which the breakthrough work of Larsen, Nelson, Nguyên and Thorup [LNNT16] shows that this trade-off is unnecessary.

10.1.1 Previous work

Since compressed sensing has been extensively studied in the literature for more than a decade, different guarantees of interest have been suggested (x_{-k} is the vector that occurs after zeroing out every i that does not belong among the largest k coordinates). In what follows $x \in \mathbb{R}^n$ is the vector we want to sketch, x' is the approximation to x, k is the sparsity and ϵ is the fineness of the approximation.

There are two different guarantees researchers consider in compressed sensing, one is the for-all guarantee and the other is the for-each guarantee. In the for-all guarantee, one wants to design a sketch that gives the desired result for all vectors $x \in \mathbb{R}^n$. In the for-each guarantee, one wants to design a distribution over sketches that gives the desired result for a fixed vector $x \in \mathbb{R}^n$. We note that ℓ_∞/ℓ_2, ℓ_2/ℓ_2 are impossible in the for-all model, unless $\Omega(n)$ measurements are used [CDD09]. The standard approach for the for-all guarantee is via RIP matrices, satisfying the so-called Restricted Isometry Property. In what follows, we will refer to the for-each model, unless stated otherwise.

- $\ell_2/\ell_2 : \|x - x'\|_2 \leq (1+\epsilon)\|x_{-k}\|_2$.
- $\ell_1/\ell_1 : \|x - x'\|_1 \leq (1+\epsilon)\|x_{-k}\|_1$.
- $\ell_\infty/\ell_2 : \|x - x'\|_\infty \leq (1+\epsilon)\frac{1}{\sqrt{k}}\|x_{-k}\|_2$.
- $\ell_2/\ell_1 : \|x - x'\|_2 \leq (1+\epsilon)\frac{1}{\sqrt{k}}\|x_{-k}\|_1$.

The first set of schemes that initiated the research on compressed sensing are given in [CRT06b, Don06]. There the authors show, for any $x \in \mathbb{R}^n$, given $y = \Phi x$, it is possible to satisfy the ℓ_2/ℓ_1 guarantee for all vectors, if Φ is a Gaussian matrix with $O(k \log(n/k))$ rows. The schemes in [CM06, CCF02] achieve the ℓ_∞/ℓ_2 guarantee with $O(k \log n)$ measurementz, matching known lower bounds [JST11], $O(n \log n)$ decoding time and $O(\log n)$

update time. The state of the art for ℓ_∞/ℓ_2 is [LNNT16], which gives optimal number of measurements, sublinear decoding time, $O(\log n)$ update time and $1/\operatorname{poly}(n)$ failure probability. Price and Woodruff [PW11] show that in order to get ℓ_2/ℓ_2 with constant failure probability$< 1/2$ with the output being exactly k-sparse output requires $\Omega(\epsilon^{-2}k)$ measurements. They also showed non-k-sparse output requires $\Omega(\epsilon^{-1}k\log(n/k))$ measurements in the regime $\epsilon > \sqrt{k\log n/n}$, and gave an upper bound of $O(\epsilon^{-1}k\log n)$ measurements, showing thus a separation in the measurement complexity between k-sparse and $O(k)$-sparse output. Later, in the breakthrough work of Gilbert, Li, Porat and Strauss [GLPS10] an algorithm that runs in sublinear time, and has $O(\log(n/k)\log^2 k)$ column sparsity, was devised. On generic norms, nearly optimal bounds have been given by Backurs, Indyk, Razenshteyn and Woodruff [BIRW16]. We note, however, that their schemes are not computationally efficient: they have exponential running time, except in the case of Earth-Mover-Distance, which has time polynomial in n and $\log^k n$.

Measurements. The number of measurements corresponds to physical resources: memory in monitoring devices of data streams, number of screens in biological applications, or number of filters in dynamic spectrum access (DSA) of radio signal [HMT+13].

In applications such as medical imaging, it is crucial to reduce the number of measurements, since the radiation used in CT scans could potentially increase cancer risks for patients. For instance, [PSL+12] showed that a positive association between radiation exposure from CT scans in childhood and subsequent risk of leukemia and brain tumors.

For more applications, we refer the readers to [QBI+13].

Encoding Time. Designing algorithms with fast update/encoding time is a well-motivated task for streaming algorithms, since the packets arrive at an extremely fast rate [TZ12]; even logarithmic factors are crucial in these applications. Also in digital signal processing applications, in the design of cameras or satellites which demand rapid imaging, when we observe a sequence of images that are close to each other, we may not need to encode the new signal from the beginning, rather than encode only that part which differs from the current signal; the delay is then defined by the update time of our scheme. Moreover, in Magnetic Resonance Imaging (MRI) update time or encoding time defines the time the patient waits for the scan to happen. Improvement of the runtime has benefits both for patients and for healthcare economics [LDSP08].

A natural question is the following: what are the time limitations of our data structures, regarding update time? Regarding the streaming setting, the first lower bounds are given in [LNN15] for non-adaptive algorithms. An algorithm is called non-adaptive if, during updates, the memory cells are written and read depend only on the index being updated and the random coins tossed before the stream is started to being processed. The lower bounds given concern both randomized and deterministic algorithms; the relevant bounds to sparse recovery are for ℓ_p/ℓ_q estimation. However, for constant failure probability their results do not give anything useful, since their lower bounds start to kick in when the failure probability becomes very small, namely $o(2^{-\sqrt{m \cdot \log n}})$.

For the column sparsity (which could be smaller than update time, and hence the lower bounds in [LNN15] might not apply[1]), the only known lower bounds are known for

[1]the lower bounds in [LNN15] also depend heavily on the streaming model, so they do not transfer necessarily to all scenarios where sparse recovery finds application.

RIP matrices, which are used in the for-all setting. To the best of our knowledge, the first non-trivial lower bounds were given by Nachin [Nac10], and then extended by Indyk and Razenshteyn in [IR13] for RIP-1 model-based compressed sensing matrices. Lower bounds for the column sparsity of RIP-2 matrices were given in Nelson and Nguyên [NN13b], and then to RIP-p matrices in Allen-Zhu, Gelashvili and Razenshteyn [AGR16]. Roughly speaking, the lower bounds for ℓ_2 indicate that if one aims for optimal measurements, $m = k \log(n/k)$, in the regime $k < n/\log^3 n$, one cannot obtain column sparsity better than $\Omega(m)$. This indicates that the for-all case should be significantly worse, in terms of column sparsity, than the for-each case.

Decoding Time. Another very important quantity we want to minimize is the time needed to reconstruct the approximation of x from its compressed version. This quantity is of enormous significance in cases where the universe size is huge and we cannot afford to iterate over it. This is often the case in networking applications, where the universe size is the number of distinct IP addresses. In MRI applications the decoding time corresponds to the time needed to reconstruct the image after the scan has been performed. Decoding time is highly important also in satellite systems, modern radars and airspace surveillance, where compressed sensing have found extensive application [End10].

The sparse Fourier transform can be regarded as another variant of the sparse recovery problem, the results developed along that line being incomparable with traditional sparse recovery results, where we have freedom over the design of the sketching matrix. Sparse Fourier transforms can be divided into two categories, one being sparse discrete Fourier transform, and the other being sparse continuous Fourier transform [BCG+12, Moi15, PS15, CKPS16].

The sparse discrete Fourier transform also can be split into two lines, the first category of results [GGI+02, GMS05, HIKP12a, HIKP12b, Iwe13, IKP14, IK14, Kap16, CKSZ17, Kap17, KVZ19] carefully choose measurements that allow for sublinear recovery time, and the second category of results [CRT06a, RV08, Bou14, HR16] focus proving Restricted Isometry Property. The techniques used in sparse Fourier transforms are related to standard compressed sensing, since the main approaches try to implement arbitrary linear measurements via sampling Fourier coefficients.

10.1.2 Our result

Our main result is a novel scheme for ℓ_2/ℓ_2 sparse recovery. Our contribution lies in obtaining better decoding time, and $O(\log(n/k))$ column sparsity via new techniques. The problem of improving the column sparsity to $O(\log(n/k))$ was explicitly stated in [GLPS10] as an open problem. We completely resolve the open problem. Moreover, as an important technical contribution, we introduce a different approach for sublinear-time optimal-measurement sparse recovery tasks. Since this iterative loop is a crucial component of almost all algorithms in sublinear-time compressed sensing [IPW11, PS12, HIKP12a, GNP+13, IKP14, Kap16, GLPS17, CKSZ17, Kap17, LNW18, NSWZ18], we believe our new approach and ideas will appear useful in the relevant literature, as well as be a starting point for re-examining sparse recovery tasks under a different lens, and obtaining improved bounds.

10.1.3 Notation

For $x \in \mathbb{R}^n$ we let $H(x,k)$ to be the set of the largest k in magnitude coordinates of x. We also write x_S for the vector obtained after zeroing out every $x_i, \notin S$, and $x_{-k} = x_{[n]\setminus H(x,k)}$.

Table 10.1: (A list of ℓ_2/ℓ_2-sparse recovery results). We ignore the "O" for simplicity. LP denotes the time of solving Linear Programs [CLS19], and the state-of-the-art algorithm takes n^ω time where ω is the exponent of matrix multiplication. The results in [Don06, CRT06b, NT09a] do not explicitly state the ℓ_2/ℓ_2 guarantee, but their approach obtains it by an application of the Johnson-Lindenstrauss Lemma; they also cannot facilitate $\epsilon < 1$, obtaining thus only a 2-approximation. The c in previous work is a sufficiently large constant, not explicitly stated, which is defined by probabilistically picking an error-correcting code of short length and iterating over all codewords. We estimate $c \geq 4$. We note that our runtime is (almost) achieved

We use $\| \cdot \|_p$ to denote the ℓ_p norm of a vector, i.e. $\|x\|_p = (\sum_{i=1}^n |x_i|^p)^{1/p}$.

10.1.4 Technical statements

We proceed with the definition of the ℓ_2/ℓ_2 sparse recovery problem.

Problem 10.1.1 (ℓ_2/ℓ_2 sparse recovery)**.** *Given parameters ϵ, k, n, and a vector $x \in \mathbb{R}^n$. The goal is to design some matrix $\Phi \in \mathbb{R}^{m \times n}$ and a recovery algorithm $\mathcal{A}$ such that we can output a vector x' based on measurements $y = \Phi x$,*

$$\|x' - x\|_2 \leq (1+\epsilon) \min_{k\text{-sparse}} \|z - x\|_2.$$

We primarily want to minimize m (which is the number of measurements), the running time of $\mathcal{A}$ (which is the decoding time) and column sparsity of Φ.

In table 10.1, we provide a list of the previous results and compare with ours. Here, we formally present our main result.

Theorem 10.1.2 (stronger ℓ_2/ℓ_2 sparse recovery)**.** *There exists a randomized construction of a linear sketch $\Phi \in \mathbb{R}^{m\times n}$ with $m = O(\epsilon^{-1}k\log(n/k))$ and column sparsity $O(\log(n/k))$, such that given $y = \Phi x$, we can find an $O(k)$-sparse vector $x' \in \mathbb{R}^n$ in $O(m \cdot \log(n/k))$ time such that*

$$\|x' - x\|_2 \leq (1+\epsilon) \min_{k\text{-sparse } z\in\mathbb{R}^n} \|z - x\|_2.$$

holds with 9/10 probability.

Remark 10.1.1. In the regime where k is very close to n, for example $k = n/\text{poly}(\log n)$, we get an exponential improvement on the column sparsity over [GLPS10]. In many applications of compressed sensing, this is the desired regime of interest, check for example Figure 8 from [BI08]: $n = 71,542$ while $m \geq 10,000$, which corresponds to k being very close to n.

Remark 10.1.2. As can be inferred from the proof, our algorithms runs in time $O((k/\epsilon)\log^2(\epsilon n/k) + (k/\epsilon)\log(1/\epsilon))$, which is slightly better than the one stated in Theorem 10.1. The algorithm in [HIKP12a] achieves also the slightly worse running time of $O((k/\epsilon)\log n\log(n/k))$. That algorithm was the first algorithm that achieved running time $O(n\log n)$ for all values of k, ϵ for which the measurement complexity remained sublinear, smaller than γn, for some absolute constant γ. A careful inspection shows that our algorithm achieves running time that is **always** sublinear, as long as the measurement complexity remains smaller than γn.

10.1.5 Overview of techniques and difference with previous work

This subsection is devoted to highlighting the difference between our approach and the approach of [GLPS10]. We first give a brief high-level description of the state of the art algorithm before our work, then discuss our techniques, and try to highlight why the previous approach could not obtain the stronger result we present in this paper. Lastly, we show how our ideas can be possibly applied to other contexts.

10.1.5.1 Summary of [GLPS10].

The algorithm of [GLPS10] consists of $O(\log k)$ rounds: in the r-th round the algorithm finds a constant fraction of the remaining heavy hitters. Beyond this iterative loop lies the following idea about achieving the ℓ_2/ℓ_2 guarantee: in order to achieve it, you can find all but $\frac{k}{3^r}$ heavy hitters i such that $|x_i|^2 = \Omega(\frac{2^r\epsilon}{k}\|x_{-k}\|_2^2)$. This means that the algorithm is allowed to "miss" a small fraction of the heavy hitters, depending on their magnitude. For example, if all heavy hitters are as small as $\Theta(\sqrt{\epsilon/k}\|x_{-k}\|_2)$, a correct algorithm may even not find any of them. This crucial observation leads naturally to the main iterative loop of combinatorial compressed sensing, which, as said before, loop proceeds in $O(\log k)$ rounds. Every round consists of an identification and an estimation step: in the identification step most heavy hitters are recognized, while in the estimation step most of them are estimated correctly. Although in the estimation step some coordinates might have completely incorrect estimates, this is guaranteed (with some probability) be fixed in a later round. The reason why this will be fixed is the following. If a coordinate i is badly estimated, then it will appear very large in the residual signal and hence will be identified in later rounds, till it is estimated correctly. One can observe that the correct estimation of that round for coordinate

i cancels out (remedies) the mistakes of previous rounds on coordinate i. Thus, the identification and estimation procedure, which are interleaved, work complementary to each other. The authors of [GLPS10] were the first that carefully managed to argue that identifying and estimating a constant fraction of heavy hitters per iteration, gives the optimal number of measurements.

More formally, the authors prove the following iterative loop invariant, where $k_r = k3^{-r}, \epsilon_r = \epsilon_r 2^{-r}$ for $r \in [R]$ with $R = \log k$: Given $x \in \mathbb{R}^n$ there exists a sequence of vectors $\{x^{(r)}\}_{r\in[R]}$, such that $x^{(r+1)} = x^{(r)} - \widehat{x}^{(r)}$ and

$$\|(x - \widehat{x})_{-k_r}\|_2^2 \leq (1 + \epsilon_r)\|x_{-k_r}\|_2^2. \tag{10.1}$$

In the end, one can apply the above inequality inductively to show that

$$\|x - \sum_{r=1}^{R} \widehat{x}^{(r)}\|_2^2 \leq (1 + \epsilon)\|x_{-k}\|_2^2.$$

We now proceed by briefly describing the implementations of the identification and the estimation part of [GLPS10]. In the identification part, in which lies the main technical contribution of that work, every coordinate $i \in [n]$ is hashed to $O(k/\epsilon)$ buckets and in each bucket $O(\log(\epsilon n/k))$-measurement scheme based on error-correcting codes is used to identify a heavy hitter; the authors carefully use a random error-correcting code of length $O(\log\log(\epsilon n/k))$, so they afford to iterate over all codewords and employ a more sophisticated approach and use nearest-neighbor decoding. This difference is one of the main technical ideas that allow them to obtain $O(\epsilon^{-1}k\log(n/k))$ measurements, beating previous work, but it is also the main reason why they obtain $k \cdot \text{poly}(\log n)$ decoding time[2]: performing

[2]The authors do not specifically address the exponent in the $\text{poly}(\log n)$, but we estimate it to be ≥ 4.

nearest neighbor decoding and storing the code per bucket incurs additional poly$(\log n)$ factors. Moreover, for every iteration r they need to repeat the identification scheme r times in order to bring down the failure probability to 2^{-r}, so that they afford a union-bound over all iterations. This leads to an additional $O(\log^2 k)$ factor in the update time. The estimation step consists of hashing to $O(k/\epsilon)$ buckets and repeating $O(\log(1/\epsilon))$ times. Since the identification step returns $O(k/\epsilon)$ coordinates, the $O(\log(1/\epsilon))$ repetitions of the estimation step ensure that at most $k/3$ coordinates out of the $O(k/\epsilon)$ will not be estimated correctly. This is a desired property, since it allows the algorithm to keep the $2k$ coordinates with the largest estimates, subtract them from x and iterate.

In the next section, we will lay out our approach which improves the decoding time and the column sparsity of [GLPS10]. The iterative procedure of [GLPS10] lies in the heart of most compressed sensing schemes, so we believe that this new approach could be applied elsewhere in the sparse recovery literature.

10.1.5.2 Our approach

As we mentioned before, our approach is totally different from previous work, avoiding the iterative loop that all algorithms before applied. Our algorithm consists of four steps, each one being a different matrix responsible for a different task. The first matrix, with a constant number of rows allows us to approximate the tail of the vector x, an approximation that will appear useful in the next step. The second matrix along with its decoding procedure, which should be regarded as the identification step, enables us to find a list L of size $O(k/\epsilon)$

that contains k coordinates[3], which are sufficient for the ℓ_2/ℓ_2 guarantee. This matrix has $O(\epsilon^{-1}k \cdot \log(\epsilon n/k)))$ rows. The third matrix with its decoding procedure, which should be regarded as the pruning step, takes the aforementioned list L, and prunes it down to $O(k)$ coordinates, which are sufficient for the ℓ_2/ℓ_2 guarantee. This matrix again has $O(\epsilon^{-1}k \cdot \log(1/\epsilon))$ rows, for a total of $O(\epsilon^{-1}k\log(n/k))$ rows. The last matrix is a standard set-query sketch.

Step 1: Tail Estimation

Lemma 10.1.3 (tail estimation)**.** *Let $c_1 \geq 1$ denote some fixed constant. There is an oblivious construction of matrix $\Phi \in \mathbb{R}^{m\times n}$ with $m = O(\log(1/\delta))$ and column sparsity $O(\log(1/\delta))$ such that, given Φx, there is an algorithm that outputs a value $V \in \mathbb{R}$ in time $O(m)$ such that*

$$\frac{1}{10k}\|x_{-c_1\cdot k}\|_2^2 \leq V \leq \frac{1}{k}\|x_{-k}\|_2^2$$

holds with probability $1-\delta$.

Our first step towards the way for stronger sparse recovery is the design a routine that estimates the ℓ_2 norm of the tail of a vector $x \in \mathbb{R}^n$, which we believe might be interesting in its own right. More generally, our algorithm obtains a value V such that $\frac{1}{10k}\|x_{-c_1\cdot k}\|_p^p \leq V \leq \frac{1}{k}\|x_{-k}\|_p^p$, using $O(1)$ measurements. Here c_1 is some absolute constant. To obtain this result we subsample the vector at rate $\Theta(1/k)$ and then use a p-stable distribution to approximate the subsampled vector. While the upper bound is immediate, the Paley-Zygmund inequality

[3]We note that this term is exactly k, not $O(k)$. Although not important for our main result, it will be crucial for some of our applications of our techniques.

does not give a sufficient result for the lower bound, so more careful arguments are needed to prove the desired result. We obtain our result by employing a random walk argument.

One additional possible application in sparse recovery applications where a two-stage scheme is allowed, e.g. [DLTY06, DDT+08], would be to first use the above routine to roughly estimate how many heavy coordinates exist, before setting up the measurements. For example, we could first run the above routine for $k = 1, 2, 2^2, \ldots, 2^{\log n}$, obtaining values $V_1, V_2, V_4, \ldots, V_{\log n}$, and then use these values to estimate the size of the tail of the vector is, or equivalently approximate the size of the set of the heavy coordinates by a number k'. We can then run a sparse recovery algorithm with sparsity k'. Details can be found in Section 10.4.

Step 2: The Identification Step The goal of this step is to output a list L of size $O(k/\epsilon)$ that contains a set of k coordinates that are sufficient to satisfy the ℓ_2/ℓ_2 guarantee. The column sparsity we are shooting for at this point is $O(\log(\epsilon n/k))$, and the decoding time should be $O(m \log(\epsilon n/k))$.

Lemma 10.1.4 (identification sketch)**.** *There exists a randomized construction of a matrix $\Phi \in \mathbb{R}^{m \times n}$, with $m = O(\epsilon^{-1} k \cdot \log(\epsilon n/k))$ and column sparsity $O(\log(\epsilon n/k))$, such that given $y = \Phi x$, one can find a set L of size $O(k/\epsilon)$ in $O(m \log(\epsilon n/k))$ time, such that*

$$\exists T \subset S, |T| \leq k : \|x - x_T\|_2 \leq (1 + \epsilon)\|x_{-k}\|_2,$$

holds with probability at least $9/10$.

For this routine, we will set up a hierarchical separation of $[n]$ to trees. We will call this separation interval forest. we set $\tau = k/\epsilon$. Then we partition $[n]$ into τ intervals of

length $q = n/\tau$, and set up an interval tree for each interval in the following way: every interval tree has branching factor

$$\frac{\log q}{\log \log q}$$

with the same height (this is consistent with the fact that every tree contains q nodes). At the leaves of every interval tree there are the nodes of the corresponding interval.

Our approach consists is now the following. For each level of the interval forest we hash everyone to k/ϵ buckets in the following way: if two coordinates i, i' are in the same interval (node of the interval forest) they are hashed to the same bucket. The above property can be regarded as "hashing interval to buckets". Moreover, every x_i is multiplied by a **Gaussian** random variable. We repeat this process for $\log \log(\epsilon n/k)$ per level.

The decoding algorithm is the following. First, we obtain a value V using the routine in Step 1, Lemma 10.1.3. Then we proceed in a breadth-first (or depth-first, it will make no difference) search manner and find an estimate for every interval, similarly to [LNNT16, CH09], by taking the median of the $\log \log(\epsilon n/k)$ buckets it participates to. There are two technical things one needs to show: First, we should bound the decoding time, as well as the size of the output list L. Second, we need to show that there exists a set T' of size at most k that satisfies the guarantee of the Lemma 10.1.4. For the first part, we show that the branching process defined by the execution of the algorithm is bounded due to the $\log \log(\epsilon n/k)$ repetitions per level. For the second part, we show that for every coordinate $i \in H(x, k)$ the probability that $i \in L$ is proportional to $k|x_i|^2/(\epsilon \|x_{-k}\|_2^2)$. Then we show that the expected ℓ_2^2 mass of coordinates $i \in L \setminus H(x, k)$ is $\epsilon \|x_{-k}\|_2^2$. This suffices to give the desired guarantee for Lemma 10.1.4. We provide details in Section 10.2.

Step 3: The Pruning Step

Lemma 10.1.5 (pruning sketch)**.** *Let $c_2, c_3 > 1$ denote two fixed constants. There exists a randomized construction of a matrix $\Phi \in \mathbb{R}^{m \times n}$, with $m = O(\epsilon^{-1}k \cdot \log(1/\epsilon))$, with column sparsity $O(\log(1/\epsilon))$ such that the following holds :*
Suppose that one is given a (fixed) set $L \subseteq [n]$ such that

$$|L| = O(k/\epsilon), \qquad \exists T \subset L, |T| \leq k : \|x - x_T\|_2 \leq (1+\epsilon)\|x_{-k}\|_2.$$

Then one can find a set S of size $c_2 \cdot k$ in time $O(m)$, such that

$$\|x - x_S\|_2 \leq (1 + c_3 \cdot \epsilon)\|x_{-k}\|_2$$

holds with probability $9/10$.

We will now prune the list L obtained from the previous step, to $O(k)$ coordinates. We are going to use $O(\epsilon^{-1}k \cdot \log(1/\epsilon))$ measurements. We hash every coordinate to k/ϵ buckets, combining with **Gaussians**, and repeating $O(\log(1/\epsilon))$ times. A similar matrix was also used in [GLPS10], but there the functionality and the analysis were very different; moreover, the authors used random signs instead of Gaussians. We will heavily exploit the fact that a standard normal g satisfies $\Pr[|g| < x] = O(x)$. The reasons why we need Gaussians is the following: if we have a lot of large coordinates which are equal and much larger than $\sqrt{\epsilon}\|x_{-k}\|_2$, we want to find all of them, but due to the use of random signs, they might cancel each other in a measurement. Switching to Gaussians is the easiest way of avoiding this undesirable case.

Our algorithm computes, for every $i \in L$, an estimate $\widehat{x}_i$ by taking the median of the $O(\log(1/\epsilon))$ buckets it participates to, and then keeps the largest $O(k)$ coordinates in

magnitude to form a set S. We then show that these coordinates satisfy the ℓ_2/ℓ_2 guarantee. We will say that a coordinate is well-estimated if $|\widehat{x}_i| = \Theta(|x_i|) \pm \sqrt{\epsilon k^{-1}}\|x_{-k}\|_2$. For the analysis, we define a threshold $\tau = \|x_{-k}\|_2/\sqrt{k}$, and classify coordinates based on whether $|x_i| \geq \tau$ or not.

- In the case $|x_i| \geq \tau$ the expected mass of these coordinates $i \notin S$ is small;
- In the other case the number of coordinates i with $|x_i| < \tau$ are $O(k)$. This allows us to employ an exchange argument, similar to previous work, e.g. [PW11], but more tricky due to the use of Gaussians instead of random signs.

We note that the way we compute the estimates $\widehat{x}_i$ is different from previous work: one would expect to divide the content of a bucket that i hashed to by the coefficient assigned to x_i, in order to get an unbiased estimator, but this will not work. The details can be found in Section 10.3.

In the end, this step gives us a set S suitable for our goal, but **does not** give good estimations of the coordinates inside that set. For that we need another, standard step.

Step 4: Set Query We estimate every coordinate in S using a set query algorithm of Price [Pri11], obtaining the desired guarantee. This matrix needs only $O(k/\epsilon)$ measurements, and runs in $O(k)$ time, while having constant column sparsity.

Lemma 10.1.6 (set query, [Pri11])**.** *For any $\epsilon \in (0, 1/10]$. There exists a randomized construction of a matrix $\Phi \in \mathbb{R}^{m \times n}$, with $m = O(k/\epsilon)$ and column sparsity $O(1)$, such that given $y = \Phi x$ and a set $S \subseteq [n]$ of size at most k, one can find a k-sparse vector $\widehat{x}_S$, supported*

on S in $O(m)$ time, such that

$$\|\widehat{x}_S - x_S\|_2^2 \leq \epsilon \|x_{[n]\setminus S}\|_2^2.$$

holds with probability at least $1 - 1/\operatorname{poly}(k)$.

Our Theorem 10.1.2 follows from the above four steps by feeding the output of each step to the next one. In the end, we rescale ϵ. More specifically, by the identification step we obtain a set L of size $O(k/\epsilon)$ which contains a subset of size k that satisfies the ℓ_2/ℓ_2 guarantee. Then, the conditions for applying the pruning step are satisfied, and hence we can prune the set L down to $O(k)$ coordinates, which satisfy the ℓ_2/ℓ_2 guarantee. Then we apply the set-query sketch to obtain estimates of these coordinates.

In what follows we ignore constant terms. The number of measurements in total is

$$\underbrace{1}_{\text{tail estimation}} + \underbrace{(k/\epsilon)\log(\epsilon n/k)}_{\text{identification step}} + \underbrace{(k/\epsilon)\log(1/\epsilon)}_{\text{pruning step}} + \underbrace{(k/\epsilon)}_{\text{set query}}.$$

The decoding time equals

$$\underbrace{1}_{\text{tail estimation}} + \underbrace{(k/\epsilon)\log(\epsilon n/k)\log(\epsilon n/k)}_{\text{identification step}} + \underbrace{(k/\epsilon)\log(1/\epsilon)}_{\text{pruning step}} + \underbrace{k}_{\text{set query}}.$$

The column sparsity equals

$$\underbrace{1}_{\text{tail estimation}} + \underbrace{\log(\epsilon n/k)}_{\text{identification step}} + \underbrace{\log(1/\epsilon)}_{\text{pruning step}} + \underbrace{1}_{\text{set query}}.$$

10.1.6 Possible applications of our approach to other problems

Exactly k-sparse signals. When the vector we have to output has to be k-sparse, and not $O(k)$-sparse, the dependence on ϵ has to be quadratic [PW11]. Our algorithm yields a

state of the art result for this case, too. One can observe that the analysis of the algorithm in the Identification Linear Sketch outputs a $O(k/\epsilon)$-sized set which contains a set T of size k that allows ℓ_2/ℓ_2 sparse recovery. Performing a CountSketch with $O(k/\epsilon^2)$ columns and $O(\log(k/\epsilon)$ rows, and following a standard analysis, one can obtain a sublinear algorithm with measurement complexity $O(\epsilon^{-1}k\log(\epsilon n/k)+\epsilon^{-2}k\log(k/\epsilon))$. This is an improvemnet on both the runtime and measurement complexity over previous work [CCF02].

Block-Sparse Signals. Our algorithm easily extends to block-sparse signals. For a signal of block size b we obtain sample complexity $O(k/(\epsilon b)\log(bn/k)+(k/\epsilon))$, with a running time nearly linear in k. This matches the sample complexity of previous super-linear algorithms [BCDH10, CIHB09], which also could not facilitate $\epsilon < 1$.

Phaseless Compressed Sensing. In Phaseless Compressed Sensing, one wants to design a matrix Φ with m rows, such that given $y = \Phi x$, one can find a vector $\widehat{x}$ such that $\min_{\theta\in[0,2\pi]}\|x-e^{i\theta}\widehat{x}\|_2 \leq (1+\epsilon)\|x_{-k}\|_2$. This problem has received a fair amount of attention [OYDS11, LV13, CBJC14, YLPR15, PYLR17, Nak17a, LN18], and the state of the art algorithm has $O(k\log n)$ measurement complexity [Nak17a, LN18]. One of the problems is that the iterative loop approach cannot be used here, since it is heavily based on the linearity of the sketch. However, our identification and pruning step do not use the linearity of the sketch, and work also with phaseless measurements. Previous algorithms such as [Nak17a, LN18] suffered a $k\log n$ factor in the number of measurements already from the first step, but this is avoidablue using our new approach. We hope to see an extension down this avenue that gives $O(k\log(n/k))$ measurements.

One-Bit Compressed Sensing. Another important subfield of Sparse Recovery is one-bit compressed sensing, where one has access only to one-bit measurements, i.e. $y = \text{sign}(Ax)$, where the sign function on vectors should be understood as pointwise application of the sign function on each entry. Sublinear algorithms appear in [Nak17b, Nak19], but they both do not obtain the optimal number of measurements in terms of k and n, which is $k \log(n/k)$, but rather the slightly suboptimal $k \log n$. One of the most important reasons is that the iterative loop cannot be implemented in such a scenario. It is a natural question whether our new approach can give the optimal number of measurements. The thresholding step, namely the part where we take use V to filter out non-heavy intervals cannot be implemented here, but perhaps there is still a way to make a similar argument. One first approach should be to show that sublinear decoding with optimal measurements is achieved using non-adaptive threshold measurements, such as in [KSW16] and [BFN+17] (note that the latter one uses adaptive measurements though).

Sparse Fourier Transform. The standard approach to discrete sparse Fourier transform, is to implement linear measurements by using Fourier measurements [GGI+02, GMS05, HIKP12a, HIKP12b, Iwe13, IKP14, IK14, Kap16, CKSZ17, Kap17]. The idea is to hash the spectrum to B buckets by carefully multiplying in the time-domain the vector x with a sparse vector z. In the frequency domain this corresponds to convolving the spectrum of the x with an approximation of the filter of an indicator function of an interval of length roughly B. Due to the Uncertainty Principle, however, one has to exchange measurement complexity and decoding time with the quality of the filter. For example, implementing hashing to buckets using "crude" filters leads to leakage in subsequent buckets, giving additional error terms.

When iterating as usual, these errors accumulate and make identification much harder. The sophisticated approach of [Kap17] manages to design an iterative algorithm, in the same vein with previous algorithms, which takes $O(\epsilon^{-1}k \log n)$ measurements. It would be interesting to see if the approach we suggest avoids some of the problems created by this iterative loop, and can give simpler and faster sparse Fourier transform schemes. It would be interesting to obtain such a result even using adaptive measurements. The work [CKSZ17] has some interesting ideas in the context of block-sparse vectors that could be relevant.

10.2 The Identification Linear Sketch

The goal of this section is to prove the following result,

Theorem 10.2.1 (Restatement of Lemma 10.1.4)**.** *Let $C_L > 1$ be a fixed constant. There exists a randomized construction of a matrix $\Phi \in \mathbb{R}^{m \times n}$, with*

$$m = O(\epsilon^{-1} k \log(\epsilon n/k)),$$

with column sparsity $O(\log(\epsilon n/k))$ such that given $y = \Phi x$, one can find in time $O(m \log(n/k))$ a set L of size $C_L \cdot k/\epsilon$, such that

$$\exists T \subset L, |T| \leq k : \|x - x_T\|_2 \leq (1+\epsilon)\|x_{-k}\|_2,$$

with probability 9/10*.*

In Section 10.2.1, we provide the definition of sketching matrix Φ and present the decoding algorithm. We proved some concentration result in Section 10.2.2. We analyzed the running time of algorithm in Section 10.2.3. We proved the guarantees of the algorithm in Section 10.2.4. Finally, we bound the number of measurements in Section 10.2.5.

10.2.1 Design of the sketch and decoding algorithm

We are going to use a hierarchical separation of $[n]$ into intervals. We will call this separation an interval forest.

Before discussing the matrix, we need the following definitions. We define

Definition 10.2.1 (size of the each tree in the forest)**.** Let

$$\tau = k/\epsilon,$$

Notation	Choice	Statement	Parameter
C_H	4	Definition 10.2.2	H
C_R	100	Definition 10.2.3	R
C_B	10^5	Definition 10.2.4	B
C_0	10^3	Lemma 10.4.3	Blow up on tail size
C_L	10^4	Lemma 10.2.5	L
η	$1/9$	Lemma 10.2.2,10.2.3	Shrinking factor on V
ζ	$1/4000$	Lemma 10.2.2,10.2.3	$\zeta \leq \eta/400$

Table 10.2: Summary of constants in Section 10.2, the column "Parameter" indicates which parameter is depending on that constant. Note that constants C_H, C_R, C_B, C_0, η are used in both algorithm and analysis, but constants C_L and ζ are only being used in analysis. C_L is the related to the guarantee of the output of the algorithm.

assuming that $k/\epsilon \leq n/16$. The size of each tree in the forest is

$$q = n/\tau = n\epsilon/k$$

Definition 10.2.2 (degree and height of the interval forest)**.** Let $C_H > 1$ be a sufficiently large constant such that

$$(\log q/\log\log q)^{C_H \log q/\log\log q} \geq q.$$

Let D denote the degree of the tree, and let H denote the height of the tree. We set D and H, $D = \lceil \log q/\log\log q \rceil$, and $H = \lceil C_H \log q/\log\log q \rceil$.

Definition 10.2.3 (number of repetitions per level)**.** Let R denote the number of repetitions in each level. Let $C_R > 1$ denote some sufficiently large constant. We set $R = C_R \log\log q$.

For $\ell \in \{0, 1, \ldots, H\}$ we define $\mathcal{I}_\ell$, which is a family of sets. Every set $\mathcal{I}_\ell$ is a decomposition of $[n]$ to τD^ℓ intervals of (roughly) the same length. The set $\mathcal{I}_0$ is a decomposition

of $[n]$ to τ intervals of (roughly) the same length length q. If needed, we can round q to a power of 2. This means that

$$\mathcal{I}_0 = \{I_{0,1}, I_{0,2}, \ldots\}$$

where

$$I_{0,1} = [1, \tau], I_{0,2} = [\tau + 1, 2\tau], \ldots$$

We can conceptualize these sets as a forest consisting of τ trees, each of branching factor D and height H, where the ℓ-th level partitions $[n]$ into disjoint τD^ℓ intervals of length $n/(\tau \cdot D^\ell) = q \cdot D^{-\ell}$. For $\ell \in \{0, \ldots, H\}$, interval $I_{\ell,j}$ is decomposed to D disjoint and continuous intervals

$$I_{\ell+1,j\cdot D+1}, \ldots, I_{\ell+1,(j+1)\cdot D}$$

of the same length, except possibly the last interval.

We say that an interval $I_{\ell+1,j}$ is a child of interval $I_{\ell,j'}$ if $j' = \lceil j/D \rceil$.

Definition 10.2.4 (sketching matrix Φ)**.** Let $C_B > 1$ be a sufficiently large constant. Let $B = C_B k/\epsilon$. Let matrices $\Phi^{(1)}, \ldots, \Phi^{(H)}$, where every matrix $\Phi^{(\ell)}$ consists of R submatrices $\{\Phi_r^{(\ell)}\}_{r\in[R]}$. For every $\ell \in [H]$ and $r \in [R]$, we pick 2-wise independent hash functions $h_{\ell,r} : [\tau D^\ell] \to [B]$.

We define measurement $y_{\ell,r,b} = (\Phi_r^{(\ell)} x)_b$ as:

$$y_{\ell,r,b} = \sum_{j \in h_{\ell,r}^{-1}(b)} \sum_{i \in I_{\ell,j}} g_{i,\ell,r} x_j,$$

where $g_{i,\ell,r} \sim \mathcal{N}(0,1)$, i.e. independent standard Gaussians.

We slightly abuse notation and treat y as matrix the mapping to vector should be clear.

Note that C_B should be chosen such that $C_B \gg C_0$, where C_0 appears in tail estimation in Lemma 10.4.3.

10.2.2 Concentration of estimation

In the following lemmata, $\zeta, \eta \in (0,1)$ are absolute constants with $1 > \eta > 1/10 > \zeta$ (See a choice for our application in Table 10.2). The exact values of the constants will be chosen below.

The following lemma handles the probability of detecting a heavy interval at level ℓ.

Lemma 10.2.2 (handling the probability of catching a heavy hitter)**.** *Let $\overline{V}$ be the value in Line 8 of Algorithm 10.1. Let $V = \epsilon\overline{V}$ be the value in Line 9 of Algorithm 10.1. Let $j' \in T_{\ell-1}$, and let j be one of its children. Let z_j be defined as follows,*

$$z_j = \operatorname*{median}_{r\in[R]} \left|y_{\ell,r,h_{\ell,r}(j)}\right|^2.$$

If $\|x_{I_{\ell,j}}\|_2^2 \geq C_j \frac{\epsilon}{k}\|x_{-k}\|_2^2$, where $C_j \geq 2$, then with probability $1 - C_j^{-R/6}$ (over the randomness of $h_{\ell,r}$ and $g_{i,\ell,r}$ for $r \in [R], i \in [n]$ in Definition 10.2.4), we have that

$$z_j \geq \eta V.$$

Proof. Fix $r \in [R]$. Let $b = h_{\ell,r}(j)$, and define $J = \cup_{t\in h_{\ell,r}^{-1}(b)} I_{\ell,t}$. We observe that

$$|y_{\ell,r,b}|^2 = \|x_J\|_2^2 g^2, \text{ where } g \sim \mathcal{N}(0,1).$$

end procedure

By property of Gaussian distribution, we have

$$\Pr\left[|y_{\ell,r,b}|^2 \leq (\eta/C_j)\|x_J\|_2^2\right] \leq \frac{2}{\sqrt{2\pi}}\sqrt{\frac{\eta}{C_j}} \leq \sqrt{\frac{2\eta}{\pi C_j}},$$

It implies, since $\|x_J\|_2^2 \geq \|x_{I_{\ell,j}}\|_2^2 \geq C_j \frac{\epsilon}{k}\|x_{-k}\|_2^2$, that

$$\Pr\left[|y_{\ell,r,b}|^2 \leq \eta \frac{\epsilon}{k}\|x_{-k}\|_2^2\right] \leq \sqrt{\frac{2\eta}{\pi C_j}}.$$

Since Lemma 10.4.3, we have $\overline{V} \leq \frac{1}{k}\|x_{-k}\|_2^2$. Because $V = \epsilon\overline{V}$,

$$\Pr\left[|y_{\ell,r,b}|^2 \leq \eta V\right] \leq \sqrt{\frac{2\eta}{\pi C_j}}.$$

The R repetitions ensure that the failure probability can be driven down to $C_j^{-R/6}$, because

$$\begin{aligned}
\Pr[z_j \leq \eta V] &\leq \binom{R}{R/2} \cdot \left(\sqrt{\frac{2\eta}{\pi C_j}}\right)^{R/2} \\
&\leq 2^R \cdot (2\eta/\pi)^{R/4} \cdot C_j^{-R/4} \\
&\leq (2^R \cdot (2\eta/\pi)^{R/4} \cdot 2^{-R/12}) \cdot C_j^{-R/6} \\
&\leq \left(2^{11} \cdot (2/9\pi)^3\right)^{R/12} \cdot C_j^{-R/6} \\
&\leq C_j^{-R/6},
\end{aligned}$$

where the first step follows from a union bound, the third step follows from $C_j \geq 2$, and the forth step follows from $\eta \leq 1/9$.

□

The following lemma handles the probability of a non-heavy interval being considered "heavy" by the algorithm at level ℓ.

Lemma 10.2.3 (handling the probability of false positives)**.** *Let V be the value in Line 9 of Algorithm 10.1. Let j' be an index in $T_{\ell-1}$, and let j be one of its children. If $\|x_{I_{\ell,j}}\|_2^2 \leq$*

$\zeta\frac{\epsilon}{k}\|x_{-C_0k}\|_2^2$, *then with probability* $1-2^{-R/3}$ *(over the randomness of* $h_{\ell,r}$ *and* $g_{i,\ell,r}$ *for* $r\in[R], i\in[n]$ *in Definition 10.2.4) we have that*

$$z_j < \eta V.$$

Proof. Fix $\ell\in[H]$ and consider the set H_ℓ that contains the C_0k coordinates j'' with the largest $\|x_{I_{\ell,j''}}\|_2^2$ values. Define $H_\ell^{(j)} = H_\ell\setminus\{j\}$. Fix $r\in[R]$ and observe that by a union-bound we get that

$$\Pr\left[\exists j''\in H_\ell^{(j)} \;\middle|\; h_{\ell,r}(j)=h_{\ell,r}(j'')\right] \le C_0k\cdot\frac{1}{C_Bk/\epsilon} = \frac{C_0\epsilon}{C_B}\le\frac{1}{20},$$

because $C_B\ge 20C_0$.

We condition on the event $\forall j''\in H_\ell^{(j)} : h_{\ell,r}(j)\neq h_{\ell,r}(j'')$. A standard calculation now shows that

$$\begin{aligned}\mathbb{E}\left[|y_{\ell,r,h_{r,\ell}(j)}|^2\right] &\le \|x_{I_{\ell,j}}\|_2^2 + \frac{1}{C_B}\frac{\epsilon}{k}\|x_{-C_0k}\|_2^2\\ &\le \zeta\frac{\epsilon}{k}\|x_{-C_0k}\|_2^2 + \frac{1}{C_B}\frac{\epsilon}{k}\|x_{-C_0k}\|_2^2\\ &\le \frac{2\zeta\epsilon}{k}\|x_{-C_0k}\|_2^2,\end{aligned}$$

where the last step follows from $\frac{1}{C_B}<\zeta$.

We now apply Markov's inequality to obtain

$$\begin{aligned}\Pr\left[|y_{\ell,r,h_{\ell,r}(j)}|^2\ge\eta V\right] &\le \Pr\left[|y_{\ell,r,h_{\ell,r}(j)}|^2\ge\frac{\eta\epsilon}{10k}\|x_{-C_0k}\|_2^2\right]\\ &\le \frac{\frac{2\zeta\epsilon}{k}\|x_{-C_0k}\|_2^2}{\frac{\eta\epsilon}{10k}\|x_{-C_0k}\|_2^2}\\ &= \frac{20\zeta}{\eta}\\ &\le \frac{1}{20}, && \text{by } \zeta\le\eta/400.\end{aligned}$$

By a union bound, the unconditional probability $\Pr\left[|y_{\ell,r,h_{\ell,r}(j)}|^2 \geq \eta V\right] \leq \frac{1}{10}$. Finally, we can upper bound the probability that $z_j = \text{median}_{r\in[R]}|y_{\ell,r,h_{\ell,r}(j)}|^2$ is greater than ηV,

$$\begin{aligned}\Pr[z_j \geq \eta V] &\leq \binom{R}{R/2}(1/10)^{R/2} \\ &< 2^R \cdot 2^{-\frac{3}{2}R} \\ &= 2^{-\frac{R}{2}} \\ &< 2^{-\frac{R}{3}}.\end{aligned}$$

□

10.2.3 Analysis of running time

Lemma 10.2.4 (bounds of D, H with respect to R)**.** *Let D, H as in Definition 10.2.2. It holds that $D \leq 2^{\frac{R}{6}-10}$, and $H \leq 2^{\frac{R}{6}-10}$.*

Proof. Since $H \geq D$, it suffices to prove the claim only for H.

$$H = C_H \frac{\log q}{\log\log q} < C_H \log q = C_H \log(\epsilon n/k) = C_H 2^{\log\log(\epsilon n/k)} \leq 2^{\frac{R}{6}-10},$$

where the third step follows from $q = \epsilon n/k$, and the last step follows from $\log\log(\epsilon n/k) + \log C_H \leq (C_R/6)\log\log(\epsilon n/k) - 10$ and note that $\log\log(\epsilon n/k) \geq 2$ because we assume $k/\epsilon \leq n/16$.

□

Lemma 10.2.5 (running time)**.** *Let R as in Definition 10.2.3 and D, H as in Definition 10.2.2. Let T_H be the set obtained by applying procedure* RecursiveBTree *H times (lines*

11-13) of Algorithm 10.1, and let $C_L > 1$ be some sufficiently large absolute constant. With probability $1 - H \cdot 2^{-R/6+1}$ we have that:

- $|T_H| \leq C_L \cdot k/\epsilon$,
- *The running time of* BTreeSparseRecovery *is*

$$O\left(\epsilon^{-1} k \cdot \log(\epsilon n/k) \cdot D\right).$$

Proof. Let $C_L = 2(C_0 + 1/\zeta)$.

First, it is easy to see that $|T_0|$ is bounded by

$$|T_0| = \tau = k/\epsilon < C_L k/\epsilon.$$

We claim that if we condition on the event that $|T_{\ell-1}| \leq C_L k/\epsilon$, then with probability $1 - 2^{-R/6+1}$, $|T_\ell| \leq C_L k/\epsilon$. The proof of both bullets will then follow by a union-bound over all H levels. Indeed, consider the set Q_ℓ containing the $|T_{\ell-1}|D \leq C_L \cdot (k/\epsilon) \cdot D$ coordinates j that are children of some $j' \in T_{\ell-1}$. Define

$$B_\ell = \left\{ j \in Q_\ell \;\middle|\; \|x_{I_{\ell,j}}\|_2^2 \leq \zeta \frac{\epsilon}{k} \|x_{-C_0 k}\|_2^2 \right\}.$$

By definition of B_ℓ and Q_ℓ, we have

$$|B_\ell| \leq |Q_\ell| \leq C_L \cdot (k/\epsilon) \cdot D.$$

Moreover, Lemma 10.2.3 gives

$$\forall j \in B_\ell, \Pr\left[z_j \geq \eta V\right] \leq 2^{-R/3}$$

Define random variables W_j to be 1 if $z_j \geq \eta V$, and 0 otherwise. Then

$$\mathbb{E}\left[\sum_{j \in B_\ell} W_j\right] \leq \frac{C_L k}{\epsilon} D \cdot 2^{-R/3}$$

An application of Markov's inequality gives

$$\Pr\left[\sum_{j \in B_\ell} W_j \geq \frac{C_L k}{2\epsilon} D \cdot 2^{-R/6}\right] \leq 2^{-R/6+1}.$$

Conditioning on $\sum_{j \in B_\ell} W_j \leq \frac{C_L k}{2\epsilon} D \cdot 2^{-R/6}$ we will upper bound the size of T_ℓ.

First, observe that there exist at most $(C_0 k + k/(\zeta\epsilon))$ $j \in \mathcal{I}_\ell$ for which $\|x_{I_{\ell,j}}\|_2^2 > \zeta \frac{\epsilon}{k} \|x_{-C_0 k}\|_2^2$. This gives

$$|T_\ell| \leq \left(C_0 k + \frac{k}{\zeta\epsilon}\right) + \frac{C_L k}{2\epsilon} D 2^{-R/6}. \tag{10.2}$$

If $C_L \geq 2(C_0 + 1/\zeta)$, then we can upper bound the first term in Eq. (10.2),

$$C_0 k + \frac{k}{\zeta\epsilon} \leq \left(C_0 + \frac{1}{\zeta}\right) \frac{k}{\epsilon} \leq \frac{1}{2} \frac{C_L k}{\epsilon}.$$

For the second term in Eq. (10.2), we can show that

$$\frac{C_L k}{2\epsilon} \cdot D 2^{-R/6} \leq \frac{1}{2} \frac{C_L k}{\epsilon},$$

or equivalently $D \leq 2^{R/6}$, which holds by Lemma 10.2.4.

We have D levels, and at each level ℓ we have $|T_\ell| = O(k/\epsilon)$, conditioned on the aforementioned events happening. The children of T_ℓ is then $O(k/\epsilon \cdot D)$. Since we have R repetitions the total running time per level is $O((k/\epsilon) \cdot D \cdot R)$, and the total running time is

$$O((k/\epsilon) \cdot D \cdot R \cdot H) = O\left((k/\epsilon) \cdot D \cdot \log\log q \cdot \frac{\log q}{\log\log q}\right) = O\left((k/\epsilon) \cdot D \cdot \log(\epsilon n/k)\right),$$

where the first step follows from definition of R and H, and the last step follows from definition of q.

Therefore, it gives the desired result. □

10.2.4 Guarantees of the algorithm

Lemma 10.2.6 (guarantees)**.** *Let $L = T_H$ be the set obtained by applying procedure* RecursiveBTree *R times (lines 11-13) of Algorithm 10.1, we have that, with probability* $9/10$*, there exist $T' \subseteq L$ of size at most k, such that*

$$\|x - x_{T'}\|_2^2 \leq (1+\epsilon)\|x_{-k}\|_2^2.$$

Proof. Define

$$\mathcal{H} = \left\{ j \in H(x,k) \;\middle|\; \exists C_j \geq 2, |x_j|^2 \geq C_j \frac{\epsilon}{k} \|x_{-k}\|_2^2 \right\}.$$

Moreover, associate every $j \in \mathcal{H}$ with its corresponding $C_j = \frac{|x_j|^2}{\frac{\epsilon}{k}\|x_{-k}\|_2^2}$.

Pick $j \in \mathcal{H}$. Let also $j_1, j_2, \ldots, j_H$, be numbers such that

$$j \in I_{1,j_1}, j \in I_{2,j_2}, \ldots, j \in I_{R,j_H}.$$

For any $t \in \{1, \ldots, H-1\}$, if $I_{t,j_t} \in T_t$, then $I_{t+1,j_{t+1}} \in T_{t+1}$ with probability $1 - C_j^{-R/6}$, by Lemma 10.2.2. Since $C_j \geq 2$, this allows us to take a union bound over all H levels and claim that with probablity $1 - HC_j^{-R/6}$, $j \in T_R$. For $j \in \mathcal{H}$ define random variable to δ_j to

be 1 if $j \notin T_H$.

$$\begin{aligned}
\mathbb{E}\left[\delta_j x_j^2\right] &\leq H \cdot C_j^{-R/6} x_j^2 \\
&\leq H \cdot C_j^{-R/6} C_j \frac{\epsilon}{k} \|x_{-k}\|_2^2 \\
&= H \cdot C_j^{-R/6+1} \frac{\epsilon}{k} \|x_{-k}\|_2^2 \\
&\leq \frac{\epsilon}{80k} \|x_{-k}\|_2^2,
\end{aligned}$$

where the first step follows by definition of δ_j, the second step follows by the fact that $j \in \mathcal{H}$, and the last step follows by Lemma 10.2.4. Since $|\mathcal{H}| \leq k$, we have that

$$\mathbb{E}\left[\sum_{j \in \mathcal{H}} \delta_j x_j^2\right] \leq |\mathcal{H}| \cdot \frac{\epsilon}{80k} \|x_{-k}\|_2^2 \leq \frac{\epsilon}{80} \|x_{-k}\|_2^2.$$

Then applying Markov's inequality, we have

$$\Pr\left[\sum_{j \in \mathcal{H}} \delta_j x_j^2 > \frac{\epsilon}{2} \|x_{-k}\|_2^2\right] \leq \frac{1}{40}.$$

We condition on the event $\sum_{j \in \mathcal{H}} \delta_j x_j^2 \leq \frac{\epsilon}{2} \|x_{-k}\|_2^2$. Setting $T' = \mathcal{H} \cap T_H$ we observe that

$$\begin{aligned}
\|x - x_{T'}\|_2^2 &= \sum_{j \in \mathcal{H} \cap H(x,k)} \delta_j x_j^2 + \|x_{H(x,k) \setminus \mathcal{H}}\|_2^2 + \|x_{[n] \setminus H(x,k)}\|_2^2 \\
&\leq \frac{\epsilon}{2} \|x_{-k}\|_2^2 + k \cdot \frac{2\epsilon}{k} \|x_{-k}\|_2^2 + \|x_{-k}\|_2^2 \\
&\leq (1 + 3\epsilon) \|x_{-k}\|_2^2.
\end{aligned}$$

where the second step follows by the bound on $\sum_{j \in T} \delta_j x_j^2$ and the fact that every $j \notin T$ satisfies $|x_j|^2 \leq (2\epsilon/k) \|x_{-k}\|_2^2$.

Rescaling for ϵ we get the desired result. □

10.2.5 Bounding the number of measurements

In this subsection, we prove that

Claim 10.2.7 (#measurements)**.** *The number of measurements is* $O(\epsilon^{-1}k \cdot \log(\epsilon n/k))$.

Proof. Recall the definition of τ and q,

$$\tau = k/\epsilon, \quad q = n/\tau.$$

We thus have the following bound on the number of measurements:

$$B \cdot H \cdot R = C_B(k/\epsilon) \cdot C_H \frac{\log(\epsilon n/k)}{\log\log(\epsilon n/k)} \cdot C_R \log\log(\epsilon n/k) = O\left((k/\epsilon)\log(\epsilon n/k)\right).$$

□

10.3 The Pruning Linear Sketch

The goal of this section is to prove Theorem 10.3.1.

Theorem 10.3.1 (Restatement of Lemma 10.1.5)**.** *Let $C_L, \alpha, \beta > 1$ be three fixed constants. There exists a randomized construction of a matrix $\Phi \in \mathbb{R}^{m \times n}$, with $m = O((k/\epsilon) \cdot \log(1/\epsilon))$, with column sparsity $O(\log(1/\epsilon))$ such that the following holds :*
Suppose that one is given a set $L \subseteq [n]$ such that

$$|L| = C_L \cdot k/\epsilon, \qquad \exists T \subset L, |T| \leq k : \|x - x_T\|_2 \leq (1+\epsilon)\|x_{-k}\|_2.$$

Then procedure Prune *(Algorithm 10.2) can find a set S of size $\beta \cdot k$ in time $O(m)$, such that*

$$\|x - x_S\|_2 \leq (1 + \alpha \cdot \epsilon)\|x_{-k}\|_2$$

holds with probability 9/10.

In Section 10.3.1, we provide some basic definitions and description of our algorithm. We analyze the coordinates from several perspectives in Section 10.3.2. We prove the correctness of our algorithm in Section 10.3.3 and analyze time, number of measurements column sparsity, success probability of algorithm in Section 10.3.4.

10.3.1 Design of the sketching matrix, and helpful definitions

Definition 10.3.1 (sketching matrix Φ)**.** Let $C_R, C_B > 1$ be absolute constants. Let $R = C_R \log(1/\epsilon)$. Let $B = C_B k/\epsilon$. For $r \in [R]$, we pick 2-wise independent hash function $h_r : [n] \to [B]$, as well as normal random variables $\{g_{i,r}\}_{i \in [n], r \in [R]}$ and take measurements

$$y_{r,b} = \sum_{i \in h_r^{-1}(b)} x_i g_{i,r}.$$

Notation	Choice	Statement	Parameter
C_R	$10^4 + 500C_L$	Definition 10.3.1	R
C_B	5×10^5	Definition 10.3.1	B
C_g	$4/5$	Fact 10.3.2	Gaussian variable
C_L	10^4	Theorem 10.3.1	L
α	5	Theorem 10.3.1	Blow up on ϵ
β	100	Theorem 10.3.1	Blow up on k

Table 10.3: Summary of constants in Section 10.3, the column "Parameter" indicates which parameter is depending on that constant. Note that set L is the input of the algorithm in Section 10.3 and the output of the algorithm in Section 10.2.

Given the set L, for every $i \in L$ we calculate

$$z_i = \underset{r \in [R]}{\text{median}} |y_{r,h_r(i)}|,$$

and keep the indices i with the βk largest z_i values to form a set S of indices, for some absolute constant β sufficiently large. We describe this pruning step in Algorithm 10.2. For the analysis, we define the threshold

$$\tau = \|x_{-k}\|_2/\sqrt{k}. \tag{10.3}$$

We will need the following standard fact about the Gaussian distribution. Then we proceed with a series of definitions and lemmata.

Fact 10.3.2 (property of Gaussian)**.** *Suppose $x \sim \mathcal{N}(0, \sigma^2)$ is a Gaussian random variable. For any $t \in (0, \sigma]$ we have*

$$\Pr[x \geq t] \in \left[\frac{1}{2}(1 - \frac{4}{5}\frac{t}{\sigma}), \frac{1}{2}(1 - \frac{2}{3}\frac{t}{\sigma})\right].$$

Similarly, if $x \sim \mathcal{N}(\mu, \sigma^2)$, for any $t \in (0, \sigma]$, we have

$$\Pr[|x| \geq t] \in \left[1 - \frac{4}{5}\frac{t}{\sigma}, 1 - \frac{2}{3}\frac{t}{\sigma}\right].$$

Algorithm 10.2 The Prune Procedure

procedure PRUNE(x, n, k, ϵ, L) ▷ Theorem 10.3.1

  $B \leftarrow C_B k/\epsilon$
  for $r = 1 \to R$ **do**
    Sample $h_r : [n] \to [B] \sim$ 2-wise independent family
    for $i = 1 \to n$ **do**
      Sample $g_{i,r} \sim \mathcal{N}(0, 1)$
    end for
  end for
  for $r = 1 \to R$ **do**
    for $b = 1 \to B$ **do**
      $y_{r,b} \leftarrow \sum_{i \in h_r^{-1}(b)} x_i g_{i,r}$
    end for
  end for
  for $i \in L$ **do**
    $z_i \leftarrow \text{median}_{r \in [R]} |y_{r,h_r(i)}|$
  end for
  $S \leftarrow \{i \in L : z_i$ is in the top βk largest coordinates in vector $z\}$
  return S
end procedure

The form we will need is the following:

$$\Pr_{g \sim \mathcal{N}(0,1)}[|g| \leq t] \leq \frac{4}{5}t.$$

Thought the analysis, for convenience we will set $C_g = 4/5$. Another form we will need is:

$$\Pr_{g \sim \mathcal{N}(0,1)}\left[|g| \in \left[\frac{1}{3C_g}, 2\right]\right] \geq 0.63$$

Proof. The first form is true by simple calculation. The second form is holding due to

numerical values of cdf for normal distribution,

$$\Pr\left[|g_{i,r}| \in \left[\frac{1}{3C_g}, 2\right]\right] = 2(f(2) - f(1/3C_g)) = 2(f(2) - f(5/12)) \geq 2(0.977 - 0.662) = 0.63,$$

where $f(x) = \int_{-\infty}^{x} \frac{e^{-x^2/2}}{\sqrt{2\pi}} dx$ is the cdf of normal distribution. □

Stochastic dominance is a partial order between random variables and it is a classical concept in decision theory and decision analysis [HR69, Baw75]. We give the simplest definition below and it is sufficient for our application.

Definition 10.3.2 (stochastic domination of Gaussian random variables)**.** Let $\sigma_1 < \sigma_2$ and random variables $X \sim \mathcal{N}(0, \sigma_1^2), Y \sim \mathcal{N}(0, \sigma_2^2)$. Then we say that $|Y|$ stochastically dominates $|X|$, and it holds that

$$\Pr\left[|Y| \geq \lambda\right] \geq \Pr\left[|X| \geq \lambda\right], \quad \forall \lambda \geq 0.$$

We formally define the set L as follows:

Definition 10.3.3 (set L, input of the algorithm)**.** Let $C_L > 1$ be a fixed constant, and let set $L \subseteq [n]$ be defined as:

$$|L| = C_L \cdot k/\epsilon, \qquad \exists T \subset |T| \leq k : \|x - x_T\|_2 \leq (1+\epsilon)\|x_{-k}\|_2.$$

We provide a definition called "badly-estimated coordinate",

Definition 10.3.4 (badly-estimated coordinate)**.** We will say a coordinate $i \in [n]$ is badly-estimated if

$$z_i \notin \left[\frac{1}{3C_g}|x_i| - \frac{1}{100}\frac{\sqrt{\epsilon}}{\sqrt{k}}\|x_{-k}\|_2, 2|x_i| + \frac{1}{100}\frac{\sqrt{\epsilon}}{\sqrt{k}}\|x_{-k}\|_2\right],$$

Then, we can define "badly-estimated set",

Definition 10.3.5 (badly-estimated set $\mathcal{B}$)**.** Let set L be defined as Definition 10.3.3. We say $\mathcal{B} \subseteq L$ is a badly-estimated set if for all $i \in \mathcal{B}$, z_i is a badly estimated coordinate (see Definition 10.3.4).

We define a set of large coordinates in head,

Definition 10.3.6 (large coordinates in head)**.** Let τ be defined in (10.3). Let L be defined in Definition 10.3.3. Let C_g be the constant from Fact 10.3.2. Define set

$$\mathcal{M} = \{i \in L \cap H(x,k) : |x_i| \geq 3C_g\tau\},$$

which contains the head coordinates of x that are in L and are larger in magnitude than $3C_g\tau$.

10.3.2 Analyzing head and badly-estimated coordinates

Lemma 10.3.3 (expected error from coordinates above τ)**.** *We have that*

$$\mathbb{E}\left[\sum_{i\in\mathcal{M}} x_i^2 \cdot \mathbb{1}_{z_i<\tau}\right] \leq \frac{\epsilon}{100}\|x_{-k}\|_2^2.$$

Proof. Fix $i \in \mathcal{M}$. Observe that for $r \in [R]$

$$|y'_{r,h_r(i)}| \sim \|x_{h_r^{-1}(i)}\|_2 |\mathcal{N}(0,1)|.$$

Since

$$\|x_{h_r^{-1}(i)}\|_2 \geq |x_i|$$

we have that the random variable $|y'_{r,h_r(i)}|$ stochastically dominates the random variable $|x_i| \cdot |\mathcal{N}(0,1)|$.

By Fact 10.3.2, we have that

$$\Pr\left[|y'_{r,h_r(i)}| \leq \tau\right] \leq C_g \frac{\tau}{|x_i|}.$$

Because of the $R = C_R \log(1/\epsilon)$ repetitions, a standard argument gives that

$$\Pr\left[\mathbb{1}_{z_i<\tau} = 1\right] \leq \left(C_g \frac{\tau}{|x_i|}\right)^{C' \log(1/\epsilon)},$$

for some absolute constant $C' > C_R/3$.

We now bound

$$\begin{aligned}
\mathbb{E}\left[\sum_{i\in\mathcal{M}} x_i^2 \cdot \mathbb{1}_{z_i<\tau}\right] &\leq \sum_{i\in\mathcal{M}} x_i^2 \left(C_g \frac{\tau}{|x_i|}\right)^{C' \log(1/\epsilon)} \\
&= \sum_{i\in\mathcal{M}} C_g^2 \tau^2 \left(C_g \frac{\tau}{|x_i|}\right)^{C' \log(1/\epsilon)-2} \\
&\leq k \cdot \tau^2 \cdot \frac{\epsilon}{100} \\
&= \frac{\epsilon}{100} \|x_{-k}\|_2^2,
\end{aligned}$$

where the first step follows by the bound on $\mathbb{E}\left[\mathbb{1}_{z_i<\tau}\right] = \Pr\left[\mathbb{1}_{z_i<\tau} = 1\right]$, and the third step by choosing by choosing $C_R > 1$ to be some sufficiently large constant and the facts $C' > C_R/3$ and $(C_g\tau)/|x_i| \leq 1/3$.

□

Lemma 10.3.4 (probability of a fixed coordinate is badly-estimated)**.** *A coordinate i is badly-estimated (as in Definition 10.3.4) probability at most*

$$\frac{\epsilon^3}{100^2 C_L}.$$

Proof. Fix r and set set $b = h_r(i)$. Recall the definition of $y_{r,b} = \sum_{i \in h_r^{-1}(b)} x_i g_{i,r}$ in Definition 10.3.1. We have that

$$\left| |g_{i,r}x_i| - \left| \sum_{j \in h_r^{-1}(b) \setminus \{i\}} g_{j,r}x_j \right| \right| \leq |y_{r,b}| \leq |g_{i,r}x_i| + \left| \sum_{j \in h_r^{-1}(b) \setminus \{i\}} g_{j,r}x_j \right|,$$

Now, $|g_{i,r}x_i|$ will be at in $[(1/3C_g)|x_i|, 2|x_i|]$ with probability at least 0.63 (due to Fact 10.3.2).

Moreover, for any $j \in H(x,k) \setminus \{i\}$, $h_r(j) \neq b$ with probability $1 - 1/B = 1 - \epsilon/(C_B k) \geq 1 - 1/(C_B k)$. By a union bound, we get with probability at least $1 - 1/C_B$, for all $j \in H(x,k) \setminus \{i\}$, $h_r(j) \neq b$. Conditioning on this event, we have,

$$\mathbb{E}\left[\left(\sum_{j \in h_r^{-1}(b) \setminus \{i\}} g_{j,r}x_j \right)^2 \right] = \frac{\epsilon}{C_B k} \|x_{-k}\|_2^2.$$

We then apply Markov's inequality to get that with probability at least $1 - 10^4/C_B$,

$$\left(\sum_{j \in h_r^{-1}(b) \setminus \{i\}} g_{j,r}x_j \right)^2 \leq \frac{\epsilon}{10^4 k} \|x_{-k}\|_2^2.$$

Therefore, by a union bound,

$$\begin{aligned} \Pr\left[|y_{r,b}| \in \left[\frac{1}{3C_g}|x_i| - \frac{1}{100}\frac{\sqrt{\epsilon}}{\sqrt{k}}, 2|x_i| + \frac{1}{100}\frac{\sqrt{\epsilon}}{\sqrt{k}} \right] \right] &\geq 0.63 - \frac{1}{C_B} - \frac{10^4}{C_B} \\ &\geq 0.6, \end{aligned}$$

where the last step follows by $C_B \geq 5 \times 10^5$.

Note that z_i is obtained by taking median of R copies of i.i.d. $|y_{r,b}|$. For each $r \in [R]$, we define $Z_r = 1$ if $|y_{r,b}|$ falls into that region, and 0 otherwise. We have $\mathbb{E}[\sum_{r=1}^{R} Z_r] \geq 0.6R$. Using Chernoff bound, we have

$$\begin{aligned}\Pr\left[\sum_{r=1}^{R} Z_r < 0.9 \cdot 0.6R\right] &\leq \Pr\left[\sum_{r=1}^{R} Z_r < 0.9\,\mathbb{E}[\sum_{r=1}^{R} Z_r]\right] \\ &\leq e^{-\frac{1}{3}0.1^2\,\mathbb{E}[\sum_{r=1}^{R} Z_r]} \\ &\leq e^{-\frac{1}{3}0.1^2 \cdot 0.6R}\end{aligned}$$

Thus,

$$\begin{aligned}\Pr\left[z_i \notin \left[\frac{1}{3C_g}|x_i| - \frac{1}{100}\frac{\sqrt{\epsilon}}{\sqrt{k}}, 2|x_i| + \frac{1}{100}\frac{\sqrt{\epsilon}}{\sqrt{k}}\right]\right] &\leq e^{-\frac{1}{3}0.1^2 \cdot 0.6R} \\ &\leq 2^{-0.002R} \\ &= 2^{-0.002C_R \log(1/\epsilon)} \\ &\leq 2^{-0.002(10000+500C_L)\log(1/\epsilon)} \\ &\leq \frac{\epsilon^3}{100^2 C_L},\end{aligned}$$

where the third step follows from choice of C_R.

□

10.3.3 Guarantees of the algorithm

We now proceed with the proof of Theorem 10.3.1.

Proof. By Lemma 10.3.3 and an application of Markov's inequality we have that

$$\sum_{i \in \mathcal{M}} x_i^2 \cdot \mathbb{1}_{z_i < \tau} \leq \epsilon \|x_{-k}\|_2^2,$$

with probability 99/100. Let this event be $\mathcal{E}_1$.

Moreover, by Lemma 10.3.4,

$$\mathbb{E}[|\mathcal{B}|] \leq \frac{\epsilon^3 |L|}{100^2 C_L},$$

so, by Markov's inequality, we have

$$\Pr\left[|\mathcal{B}| \leq \frac{\epsilon^2 |L|}{100 C_L}\right] \geq 1 - \epsilon/100 \geq 99/100$$

Let this event be $\mathcal{E}_2$.

By taking a union bound, $\mathcal{E}_1$ and $\mathcal{E}_2$ both hold with probability 98/100. Plugging size of $|L|$ ($\leq C_L \cdot k/\epsilon$) into equation of event $\mathcal{E}_2$, we get

$$|\mathcal{B}| \leq \frac{\epsilon^2 |L|}{100 C_L} \leq \frac{\epsilon k}{100}. \tag{10.4}$$

It means there are at most $\epsilon k/100$ coordinates that badly-estimated.

We remind that our goal is to bound

$$\begin{aligned}
\|x - x_S\|_2^2 &= \|x_{\bar{S}}\|_2^2 \\
&= \|x_{\bar{S} \cap \mathcal{M}}\|_2^2 + \|x_{\bar{S} \setminus \mathcal{M}}\|_2^2 \\
&= \|x_{\bar{S} \cap \mathcal{M}}\|_2^2 + \|x_{(\bar{S} \setminus \mathcal{M}) \cap \mathcal{B}}\|_2^2 + \|x_{(\bar{S} \setminus \mathcal{M}) \setminus \mathcal{B}}\|_2^2
\end{aligned}$$

1. Bounding $\|x_{\mathcal{M} \cap \bar{S}}\|_2^2$. Consider the set

$$I = \{i \in L \setminus \mathcal{M} : |x_i| \geq \tau/3\},$$

which contains the coordinates in L with magnitude in the range $[\frac{1}{3}\tau, 3C_g\tau)$. By the definition of τ, clearly, $|I| \leq 3k + k = 4k$, because we can have at most k such elements in $H(x, k)$,

and at most $3k$ such elements in the tail $[n] \setminus H(x,k)$. Since the number of badly estimated coordinates is at most $\epsilon k/100$ and the size of S is βk for sufficiently large β, we can have at most $4k + \epsilon k/100 < \beta k$ coordinates $i \in L$ which are not in $\mathcal{M}$ and are larger than τ. This means that all coordinates in $\mathcal{M}$ with estimate $z_i \geq \tau$ will belong to S. This implies that

$$\mathcal{M} \cap \bar{S} = \{i \in \mathcal{M} : z_i < \tau\},$$

and hence

$$\|x_{\mathcal{M}\cap\bar{S}}\|_2^2 = \sum_{i\in\mathcal{M}} x_i^2 \cdot \mathbb{1}_{z_i<\tau} \leq \epsilon \|x_{-k}\|_2^2,$$

since we conditioned on event $\mathcal{E}_1$.

2. Bounding $\|x_{(\bar{S}\setminus\mathcal{M})\cap\mathcal{B}}\|_2^2$. For every $i \in (\bar{S} \setminus \mathcal{M}) \cap \mathcal{B})$ we have the trivial bound $|x_i| \leq \tau$. Since $(\bar{S} \setminus \mathcal{M}) \cap \mathcal{B}) \subseteq \mathcal{B}$, because the event $\mathcal{E}_2$ we get that

$$\|x_{(\bar{S}\setminus\mathcal{M})\cap\mathcal{B}}\|_2^2 \leq |\mathcal{B}| \cdot \tau^2 \leq \frac{\epsilon k}{100} \cdot \frac{\|x_{-k}\|_2^2}{k} = \frac{\epsilon}{100}\|x_{-k}\|_2^2,$$

where the second step follows from (10.4) and (10.3).

3. Bounding $\|x_{(\bar{S}\setminus\mathcal{M})\setminus\mathcal{B}}\|_2^2$. Observe that set $(\bar{S} \setminus \mathcal{M}) \setminus \mathcal{B}$ consists of well-estimated coordinates that are less than τ in magnitude, and their estimates do not belong to the largest βk estimates. For convenience, set $Q = (\bar{S} \setminus \mathcal{M}) \setminus \mathcal{B}$, then it is obvious that $Q = \overline{S}\setminus(\mathcal{M} \cup \mathcal{B})$.

We define three sets H_1, H_2, H_3 as follows,

$$H_1 = Q \cap T, \quad H_2 = Q \cap \bar{T}, \quad \text{and} \quad H_3 = (\overline{T}\setminus(\mathcal{M} \cup \mathcal{B}))\setminus\overline{S}.$$

Using the definition of Q, we can rewrite H_1, H_2, and H_3 as follows

$$\begin{aligned}
H_1 &= (\overline{S}\backslash(\mathcal{M}\cup\mathcal{B}))\cap T = \overline{S}\cap\overline{\mathcal{M}\cup\mathcal{B}}\cap T,\\
H_2 &= (\overline{S}\backslash(\mathcal{M}\cup\mathcal{B}))\cap \overline{T} = \overline{S}\cap\overline{\mathcal{M}\cup\mathcal{B}}\cap \overline{T},\\
H_3 &= (\overline{T}\backslash(\mathcal{M}\cup\mathcal{B}))\backslash\overline{S} = S\cap\overline{\mathcal{M}\cup\mathcal{B}}\cap \overline{T}.
\end{aligned}$$

We can show that

$$\begin{aligned}
H_2\cap H_3 &= (\overline{S}\cap\overline{\mathcal{M}\cup\mathcal{B}}\cap\overline{T})\cup(S\cap\overline{\mathcal{M}\cup\mathcal{B}}\cap\overline{T})\\
&= \emptyset, \qquad (10.5)
\end{aligned}$$

and

$$\begin{aligned}
H_2\cup H_3 &= (\overline{S}\cap\overline{\mathcal{M}\cup\mathcal{B}}\cap\overline{T})\cap(S\cap\overline{\mathcal{M}\cup\mathcal{B}}\cap\overline{T})\\
&= \overline{\mathcal{M}\cup\mathcal{B}}\cap\overline{T}\\
&= \overline{T}\backslash(\mathcal{M}\cup\mathcal{B}). \qquad (10.6)
\end{aligned}$$

Then,

$$\begin{aligned}
\|x_Q\|_2^2 &= \|x_{H_1}\|_2^2 + \|x_{H_2}\|_2^2\\
&= \|x_{H_1}\|_2^2 + (\|x_{\bar{T}\backslash(\mathcal{M}\cup\mathcal{B})}\|_2^2 - \|x_{H_3}\|_2^2)\\
&\leq \|x_{H_1}\|_2^2 + \|x_{\overline{T}}\|_2^2 - \|x_{H_3}\|_2^2\\
&\leq \|x_{H_1}\|_2^2 + (1+\epsilon)\|x_{-k}\|_2^2 - \|x_{H_3}\|_2^2,
\end{aligned}$$

where first step follows from $H_1\cap H_2=\emptyset$ and $H_1\cup H_2 = Q$, the second step follows from Eq. (10.5) and (10.6), the third step follows from $\|x_{\bar{T}\backslash(\mathcal{M}\cup\mathcal{B})}\|_2^2 \leq \|x_{\overline{T}}\|_2^2$ and the last step follows from $\|x_{\overline{T}}\|_2^2 \leq (1+\epsilon)\|x_{-k}\|_2^2$.

We define d, E, a, b as follows

$$d = |H_1|, \qquad E = \frac{1}{4}\sqrt{\epsilon/k}\|x_{-k}\|_2, \qquad a = \max_{i\in H_1}|x_i|, \qquad b = \min_{i\in H_3}|x_i|. \tag{10.7}$$

Let i^* and j^* be defined as follows:

$$i^* = \arg\max_{i\in H_1}|x_i|, \quad \text{and} \quad j^* = \arg\min_{j\in H_3}|x_j|. \tag{10.8}$$

Recall the definitions of H_1 and H_3, we know H_3 is a subset of S and H_1 is a subset of $\overline{S}$. Since the set S contains the largest βk coordinates, thus we have

$$z_j \geq z_i, \forall i \in H_1, j \in H_3.$$

It further implies $z_{j^*} \geq z_{i^*}$.

By Definition 10.3.4, we have

$$z_{i^*} \geq \frac{1}{3C_g}|x_{i^*}| - \frac{1}{100}\frac{\sqrt{\epsilon}}{\sqrt{k}}\|x_{-k}\|_2, \tag{10.9}$$

and

$$z_{j^*} \leq 2|x_{j^*}| + \frac{1}{100}\frac{\sqrt{\epsilon}}{\sqrt{k}}\|x_{-k}\|_2. \tag{10.10}$$

Then, we can show that $a \leq 6C_g b + E$ in the following sense:

$$\begin{aligned}
a &= |x_{i^*}| && \text{by def. of } i^*, a, (10.8), (10.7)\\
&\leq 3C_g z_{i^*} + \frac{3C_g}{100}\sqrt{\epsilon/k}\|x_{-k}\|_2 && \text{by (10.9)}\\
&\leq 3C_g z_{j^*} + \frac{3C_g}{200}\sqrt{\epsilon/k}\|x_{-k}\|_2 && \text{by } z_{i^*} \leq z_{j^*}\\
&\leq 6C_g|x_{j^*}| + \frac{6C_g}{200}\sqrt{\epsilon/k}\|x_{-k}\|_2 && \text{by (10.10)}\\
&= 6C_g b + \frac{6C_g}{200}\sqrt{\epsilon/k}\|x_{-k}\|_2 && \text{by def. of } j^*, b, (10.8), (10.7)\\
&\leq 6C_g b + E && \text{by def. of } E, (10.7)
\end{aligned}$$

Note that $H_3 = (\bar{T} \setminus (\mathcal{M} \cup \mathcal{B})) \setminus \overline{S} = S \setminus (T \cup \mathcal{M} \cup \mathcal{B})$. Therefore,

$$\begin{aligned} |H_3| &\geq |S| - |T| - |\mathcal{M}| - |\mathcal{B}| \\ &\geq \beta k - k - k - k \\ &= (\beta - 3)k. \end{aligned}$$

Finally, we can have

$$\begin{aligned} \|x_{H_1}\|_2^2 - \|x_{H_3}\|_2^2 &\leq da^2 - (\beta - 3)kb^2 \\ &\leq d(6C_g b + E)^2 - (\beta - 3)kb^2 && \text{by } a \leq 6C_g b + E \\ &= (36C_g^2 d - (\beta - 3)k)b^2 + 12C_g bdE + dE^2 \\ &\leq (36C_g^2 k - (\beta - 3)k)b^2 + 12C_g bkE + kE^2 && \text{by } d \leq k \\ &\leq (36C_g^2 k - (\beta - 5C_g^2)k)b^2 + 12C_g bkE + kE^2 && \text{by } C_g \geq 4/5 \\ &\leq -36kC_g^2 b^2 + 12C_g bkE + kE^2 && \text{by } \beta \geq 77C_g^2 \\ &= -k(6C_g b - E)^2 + 2kE^2 \\ &\leq 2kE^2 \\ &\leq \epsilon \|x_{-k}\|_2^2. \end{aligned}$$

where the last step follows from definition of E.

Thus, we have

$$\|x_Q\|_2^2 \leq (1 + 2\epsilon)\|x_{-k}\|_2^2.$$

Putting it all together. We have

$$\begin{aligned}\|x - x_S\|_2^2 &= \|x_{\overline{S}\cap\mathcal{M}}\|_2^2 + \|x_{(\overline{S}\setminus\mathcal{M})\cap\mathcal{B}}\|_2^2 + \|x_{(\overline{S}\setminus\mathcal{M})\setminus\mathcal{B}}\|_2^2 \\ &\leq \epsilon\|x_{-k}\|_2^2 + \frac{\epsilon}{100}\|x_{-k}\|_2^2 + (1+2\epsilon)\|x_{-k}\|_2^2 \\ &\leq (1+4\epsilon)\|x_{-k}\|_2^2\end{aligned}$$

Finally, we can conclude $\alpha = 5$ and $\beta = 100$.

□

10.3.4 Time, measurements, column sparsity, and probability

In this section, we will bound the decoding time, the number of measurements, column sparsity and success probability of algorithm.

Decoding time. For each $i \in L$, we compute z_i to be the median of R values. For this part, we spend $O(|L| \cdot R) = O((k/\epsilon) \cdot \log(1/\epsilon))$ time. Moreover, calculating the top βk estimates in L only takes $O(|L|)$ time. Therefore, the decoding time is $O((k/\epsilon) \cdot \log(1/\epsilon))$.

The number of measurements. The number of measurements is the bucket size B times the number of repetitions R, which is $O(BR) = O((k/\epsilon) \cdot \log(1/\epsilon))$.

Column sparsity. Each $i \in [n]$ goes to one bucket for each hash function, and we repeat R times, so the column sparsity is $O(R) = O(\log(1/\epsilon))$.

Success probability. By analysis in Section 10.3.3, the success probability is at least 0.98.

10.4 Tail Estimation

In Section 10.4.1, we present a standard result on random walks. In Section 10.4.2, we present some results on p-stable distribution. In what follows we asssume that $0 < p \leq 2$. We show an algorithm for ℓ_p tail estimation in Section 10.4.3.

10.4.1 Random walks

Theorem 10.4.1. *We consider the following random walk. We go right if $B_i = 1$ and we go left if $B_i = 0$. The probability of $B_i = 1$ is at least $9/10$ and the probability of $B_i = 0$ is at most $1/10$. With at least some constant probability bounded away from $\frac{1}{2}$, for all the possible length of the random walk, it will never return to the origin.*

This is a standard claim, that can be proved in numerous ways, such as martingales etc. For the completeness, we still provide a folklore proof here.

Proof. Let $p > 1/2$ be the probability of stepping to the right, and let $q = 1 - p$. For integer $m \geq 1$, let P_m be the probability of first hitting 0 in exactly m steps. It is obvious that $P_m = 0$ if n is even, and $P_1 = q$. In order to hit 0 for the first time on the third step you must Right-Left-Left, so $P_3 = pq^2$. To hit 0 for the first time in exactly $2k + 1$ steps, you must go right k times and left $k + 1$ times, your last step must be to the left, and through the first $2k$ steps you must always have made at least many right steps as left steps. It is well known that the number o such path is C_k, which is the k-th Catalan number. Thus,

$$P_{2k+1} = C_k q^k q^{k+1} = C_k \cdot q(pq)^k = \frac{q(pq)^k}{k+1}\binom{2k}{k},$$

since

$$C_k = \frac{1}{k+1}\binom{2k}{k}$$

By [Wil05], the generating function for the Catalan numbers is

$$c(x) = \sum_{k\geq 0} C_k x^k = \frac{1-\sqrt{1-4x}}{2x},$$

so the probability that the random walk will hit 0 is

$$\begin{aligned}
\sum_{k\geq 0} P_{2k+1} &= q\sum_{k\geq 0} C_k (pq)^k \\
&= q \cdot c(pq) \\
&= q \cdot \frac{1-\sqrt{1-4pq}}{2pq} && \text{by definition of } c(x) \\
&= \frac{1-\sqrt{1-4q(1-q)}}{2p} \\
&= \frac{1-\sqrt{1-4q+4q^2}}{2p} \\
&= \frac{1-(1-2q)}{2p} \\
&= q/p \\
&\leq 1/9.
\end{aligned}$$

Thus, we complete the proof. □

10.4.2 p-stable distributions

We first provide the definition of p-stable distribution. For the more details, we refer the readers to [Ind06].

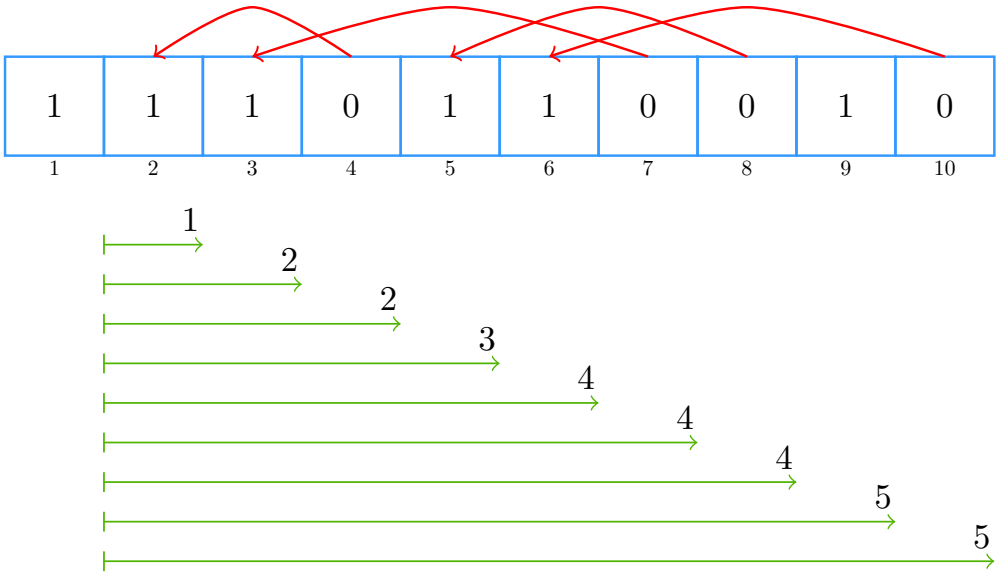

Figure 10.1: This is a visualization of part of the proof in Claim 10.4.7. We consider an example where there are $l = 10$ blocks, $B_1 = 1$, $B_2 = 1$, $B_1 = 1$, $B_3 = 0$, $B_4 = 0$, $B_5 = 1$, $B_6 = 1$, $B_7 = 0$, $B_8 = 0$, $B_9 = 1$ and $B_{10} = 0$. Recall the two important conditions in the proof of Claim 10.4.7, the first one is $B_1 = 1$ and the second one is, for all $j \in [l], \sum_{j'=2}^{j} B_{j'} > (j-1)/2$. The number on the green arrow is $\sum_{j'=2}^{j} B_{j'}$. It is to see that the example we provided here is satisfying those two conditions. Recall the definition of set S_1 and S_0. Here $S_1 = \{2, 3, 5, 6, 9\}$ and $S_0 = \{4, 7, 8, 10\}$. Then $S_1' = \{2, 3, 5, 6\}$. The mapping π satisfies that $\pi(4) = 2$, $\pi(7) = 3$, $\pi(8) = 5$ and $\pi(10) = 6$.

Definition 10.4.1 (p-stable distribution)**.** A distribution $\mathcal{D}$ over $\mathbb{R}$ is called p-stable, if there exists $p \geq 0$ such that for any n real numbers $a_1, a_2, \cdots, a_n$ and i.i.d. variables $x_1, x_2, \cdots, x_n$ from distribution $\mathcal{D}$, the random variable $\sum_{i=1}^{n} a_i x_i$ has the same distribution as the variable $\|a\|_p y$, where y is a random variable from distribution $\mathcal{D}$.

Theorem 10.4.2 ([Zol86])**.** *For any $p \in (0, 2]$, there exists a p-stable distribution.*

Gaussian distribution defined by the density function $f(x) = \frac{1}{\sqrt{2\pi}} e^{-x^2/2}$, is 2-stable. Cauchy distribution defined by density function $f(x) = \frac{1}{\pi} \frac{1}{1+x^2}$ is 1-stable. Let $\mathcal{D}_p$ denote the

p-stable distribution. For $p = 2$, $\mathcal{D}_p$ is $\mathcal{N}(0, 1)$ and for $p = 1$, $\mathcal{D}_p$ is $\mathcal{C}(0, 1)$.

10.4.3 ℓ_p-tail estimation algorithm

The goal of this Section is prove Lemma 10.4.3.

Algorithm 10.3 ℓ_p-tail Estimation Algorithm

procedure LpLpTailEstimation(x, k, p, C_0, δ) ▷ Lemma 10.4.3
▷ Requires $C_0 \geq 1000$
  $m \leftarrow O(\log(1/\delta))$
  Choose $g_{i,t}$ to be random variable that sampled i.i.d. from distribution $\mathcal{D}_p$, $\forall i, t \in [n] \times [m]$
  Choose $\delta_{i,t}$ to be Bernoulli random variable with $\mathbb{E}[\delta_{i,t}] = 1/(100k)$, $\forall i, t \in [n] \times [m]$
  ▷ Matrix A is implicitly constructed based on $g_{i,t}$ and $\delta_{i,t}$
  for $t \in [m]$ **do**
    $y_t \leftarrow \sum_{i=1}^{n} \delta_{i,t} \cdot g_{i,t} \cdot x_i$
  end for
  $V \leftarrow \text{median}_{t \in [m]} |y_t|^2$
  return V ▷ $\frac{1}{10k}\|x_{-C_0 k}\|_p^p \leq V \leq \frac{1}{k}\|x_{-k}\|_p^p$
end procedure

One can try to prove such a claim for $p = 2$ with random signs, instead of Gaussians, by applying the Paley-Zygmund inequality to obtain the lower bound. A straightforward calculation indicates that this approach does not give the desired result, hence we need a new argument to deal with the lower bound.

Lemma 10.4.3 (Restatement of Lemma 10.1.3)**.** *Let $C_0 \geq 1000$ denote some fixed constant. There is an oblivious construction of matrix $A \in \mathbb{R}^{m \times n}$ with $m = O(\log(1/\delta))$ along with a decoding procedure* LpLpTailEstimation(x, k, p, C_0, δ) *(Algorithm 10.3) such that, given Ax, it is possible to output a value V in time $O(m)$ such that*

$$\frac{1}{10k}\|x_{-C_0 k}\|_p^p \leq V \leq \frac{1}{k}\|x_{-k}\|_p^p,$$

holds with probability $1-\delta$.

Proof. Let $m = O(\log(1/\delta))$. For each $i \in [n], t \in [m]$, we use $g_{i,t}$ to denote a random variable that sample from distribution $\mathcal{D}_p$.

For each $i \in [n], t \in [m]$, we use $\delta_{i,t}$ to denote a Bernoulli random variable such that

$$\delta_{i,t} = \begin{cases} 1, & \text{with prob. } \frac{1}{100k}; \\ 0, & \text{otherwise.} \end{cases}$$

Then we have

$$\mathbb{E}[\delta_{i,t}] = \frac{1}{100k}.$$

For each $t \in [m]$, we define y_t as follows

$$y_t = \sum_{i=1}^{n} \delta_{i,t} g_{i,t} x_i. \tag{10.11}$$

For each $t \in [m]$, we define Δ_t as follows

$$\Delta_t = \left(\sum_{i=1}^{n} \delta_{i,t}^p x_i^p \right)^{1/p}. \tag{10.12}$$

Using Claim 10.4.4 and Claim 10.4.7

$$\Pr_{g,\delta} \left[|y_t| < \alpha \frac{1}{(2C_0 k)^{1/p}} \|x_{-C_0 k}\|_p \right] \leq 1/5.$$

Using Claim 10.4.5 and Claim 10.4.6

$$\Pr_{g,\delta} \left[|y_t| > \beta \frac{1}{k^{1/p}} \|x_{-k}\|_p \right] \leq 1/5.$$

Finally, we just take the median over m different independent repeats. Since $m = O(\log(1/\delta))$, thus, we can boost the failure probability to δ.

□

It is a standard fact, due to p-stability, that y_t follows the p-stable distribution : $\Delta_t \cdot \mathcal{D}_p$. Since p-stable distributions are continuous functions, we have the following two Claims:

Claim 10.4.4 (upper bound on $|y_t|$)**.** *Let y_t be defined in Eq. (10.11), let Δ_t be defined in Eq. (10.12). There is some sufficiently small constant $\alpha \in (0,1)$ such that*

$$\Pr_g[|y_t| < \alpha \cdot \Delta_t] \leq 1/10.$$

Claim 10.4.5 (lower bound on $|y_t|$)**.** *Let y_t be defined in Eq. (10.11), let Δ_t be defined in Eq. (10.12). There is some sufficiently large constant $\beta > 1$ such that*

$$\Pr_g[|y_t| > \beta \cdot \Delta_t] \leq 1/10.$$

It remains to prove Claim 10.4.6 and Claim 10.4.7.

Claim 10.4.6 (lower bound on Δ_t)**.** *Let Δ_t be defined in Eq. (10.12). Then we have*

$$\Pr_\delta \left[\Delta_t > \frac{1}{k^{1/p}} \|x_{-k}\|_p \right] \leq 1/10.$$

Proof. The proof mainly includes three steps,

First, for a fixed coordinate $i \in [n]$, with probability at most $1/(100k)$, it got sampled. Taking a union bound over all k largest coordinates. We can show that with probability at least $1 - 1/100$, none of k largest coordinates is sampled. Let ξ be that event.

Second, conditioning on event ξ, we can show that

$$\mathbb{E}[\Delta_t] \leq \frac{1}{(100k)^{1/p}} \|x_{-k}\|_p.$$

Third, applying Markov's inequality, we have

$$\Pr[\Delta_t \geq a] \leq \mathbb{E}[\Delta_t]/a.$$

Choosing $a = \frac{1}{k^{1/p}}\|x_{-k}\|_p$, we have

$$\Pr\left[\Delta_t \geq \frac{1}{k^{1/p}}\|x_{-k}\|_p\right] \leq 1/10.$$

□

Claim 10.4.7 (upper bound on Δ_t)**.** *Let Δ_t be defined in Eq. (10.12). For any $C_0 \geq 1000$, we have*

$$\Pr_{\delta}\left[\Delta_t < \frac{1}{(2C_0k)^{1/p}}\|x_{-C_0k}\|_p\right] \leq 1/10.$$

Proof. Without loss of generality, we can assume that all coordinates of x_i are sorted, i.e. $x_1 \geq x_2 \geq \cdots \geq x_n$. Then we split length n vector into l blocks where each block has length $s = C_0k$. Note that it is obvious $l \cdot s = n$.

For each $j \in [l]$, we use boolean variable B_j to denote that if at least one coordinate in j-th block has been sampled. For a fixed block $j \in [l]$, the probability of sampling at least one coordinate from that block is at least

$$1 - \left(1 - \frac{1}{100k}\right)^s = 1 - \left(1 - \frac{1}{100k}\right)^{C_0k} \geq 9/10.$$

Thus, we know $1 \geq \mathbb{E}[B_j] \geq 9/10$.

Warm-up. Note the probability is not allowed to take a union over all the blocks. However, if we conditioned on that each block has been sampled at least one coordinate,

then we have

$$\begin{aligned}\Delta_t^p &= \sum_{i=1}^{n} \delta_{i,t} x_i^p \\ &\geq \sum_{j=1}^{l-1} x_{js}^p \\ &\geq \sum_{j=1}^{l-1} \frac{1}{s} \left(x_{js+1}^p + x_{js+2}^p + \cdots + x_{js+s}^p \right) \\ &= \frac{1}{s} \|x_s\|_p^p.\end{aligned}$$

Fixed. For simplicity, for each $j \in [l]$, we use set T_j to denote $\{(j-1)s+1, (j-1)s+2, \cdots, (j-1)s+s\}$.

Using random walk Lemma 10.4.1, with probability at least 99/100, we have : for all $j \in \{2, \cdots, l\}$,

$$\sum_{j'=2}^{j} B_{j'} > (j-1)/2.$$

We know that with probability at least 99/100, $B_1 = 1$. Then with probability at least 99/100, we have

$$B_1 = 1, \text{ and } \sum_{j'=2}^{j} B_{j'} > (j-1)/2, \forall j \in [l].$$

We conditioned on the above event holds. Let set $S_1 \subset [n]$ denote the set of indices j such that $B_j = 1$, i.e.,

$$S_1 = \left\{ j \;\middle|\; B_j = 1, j \in [n] \backslash \{1\} \right\}.$$

Let set $S_0 \subset [n]$ denote the set of indices j such that $B_j = 0$, i.e.,

$$S_0 = \left\{ j \;\middle|\; B_j = 0, j \in [n] \backslash \{1\} \right\}.$$

Due to $\sum_{j'=2}^{j} B_{j'} > (j-1)/2, \forall j \in [l]$, then it is easy to see $S_1 > S_0$ and there exists a one-to-one mapping $\pi : S_0 \to S_1'$ where $S_1' \subseteq S_1$ such that for each coordinate $j \in S_0$, $\pi(j) < j$. Since we are the coordinates are being sorted already, thus

$$\begin{aligned} \sum_{j \in S_1} \|x_{T_j}\|_p^p &= \sum_{j \in S_1'} \|x_{T_j}\|_p^p \\ &= \sum_{j \in S_1'} \|x_{T_{\pi^{-1}(j)}}\|_p^p \\ &\geq \sum_{j \in S_0} \|x_{T_j}\|_p^p \end{aligned}$$

which implies that

$$\Delta_t^p = \sum_{i=1}^{n} \delta_i^p x_i^p = \sum_{j \in S_1} \|x_{T_j}\|_p^p \geq \frac{1}{2s} \|x_{-s}\|_p^p.$$

Thus, with probability at least $9/10$, we have

$$\Delta_t \geq \frac{1}{(2s)^{1/p}} \|x_{-s}\|_p.$$

□

10.5 Putting It All Together

Our full algorithm first applies interval forest sparse recovery algorithm in Algorithm 10.1 with precision parameter $\frac{\epsilon}{10}$ to obtain a set L of size $O(k/\epsilon)$. By Theorem 10.2.1, with probability $\frac{9}{10}$, L contains a subset T of size at most k so that $\|x-x_T\|_2 \leq (1+\frac{\epsilon}{10})\|x_{-k}\|_2$. Then the algorithm feeds L into the pruning procedure in Algorithm 10.2 also with precision parameter $\frac{\epsilon}{10}$ to get S. By Theorem 10.3.1, with probability $\frac{9}{10}$, $|S| = O(k)$ and $\|x - x_S\|_2 \leq (1+\frac{\epsilon}{2})\|x-x_{-k}\|_2$. Finally, the algorithm uses set query data structure in Lemma 10.1.6 to give $\widehat{x}_S$ as approximation to x_S. With probability at least $1-1/\operatorname{poly}(k)$, $\|\widehat{x}_S-x_S\|_2^2 \leq \frac{\epsilon}{2}\|x-x_S\|_2^2$. Therefore, $\|x-\widehat{x}_S\|_2^2 = \|x-x_S\|_2^2+\|x_S-\widehat{x}_S\|_2^2 \leq (1+\frac{\epsilon}{4})(1+\frac{\epsilon}{2})^2\|x-x_{-k}\|_2^2 \leq (1+\epsilon)^2\|x-x_{-k}\|_2^2$. By union bound, the overall failure probability is at most $1/4$.

Chapter 11

Continuous Fourier Transform I

In recent years, a number of works have studied methods for computing the Fourier transform in sublinear time if the output is sparse. Most of these have focused on the discrete setting, even though in many applications the input signal is continuous and naive discretization significantly worsens the sparsity level.

We present an algorithm for robustly computing sparse Fourier transforms in the continuous setting. Let $x(t) = x^*(t) + g(t)$, where x^* has a k-sparse Fourier transform and g is an arbitrary noise term. Given sample access to $x(t)$ for some duration T, we show how to find a k-Fourier-sparse reconstruction $x'(t)$ with

$$\frac{1}{T}\int_0^T |x'(t) - x(t)|^2 \mathrm{d}t \lesssim \frac{1}{T}\int_0^T |g(t)|^2 \mathrm{d}t.$$

The sample complexity is linear in k and logarithmic in the signal-to-noise ratio and the frequency resolution. Previous results with similar sample complexities could not tolerate an infinitesimal amount of i.i.d. Gaussian noise, and even algorithms with higher sample complexities increased the noise by a polynomial factor. We also give new results for how precisely the individual frequencies of x^* can be recovered.

11.1 Introduction

The Fourier transform is ubiquitous in digital signal processing of a diverse set of signals, including sound, image, and video. Much of this is enabled by the Fast Fourier Transform (FFT) [CT65], which computes the n-point discrete Fourier transform in $O(n \log n)$ time. But can we do better?

In many situations, much of the reason for using Fourier transforms is because the transformed signal is *sparse*—i.e., the energy is concentrated in a small set of k locations. In such situations, one could hope for a dependency that depends nearly linearly on k rather than n. Moreover, one may be able to find these frequencies while only sampling the signal for some period of time. This idea has led to a number of results on *sparse Fourier transforms*, including [GGI+02, GMS05, HIKP12a, IK14], that can achieve $O(k \log(n/k) \log n)$ running time and $O(k \log(n/k))$ sample complexity (although not quite both at the same time) in a robust setting.

These works apply to the discrete Fourier transform, but lots of signals including audio or radio originally come from a continuous domain. The standard way to convert a continuous Fourier transform into a discrete one is to apply a window function then subsample. Unfortunately, doing so "smears out" the frequencies, blowing up the sparsity. Thus, one can hope for significant efficiency gains by directly solving the sparse Fourier transform problem in the continuous setting. This has led researchers to adapt techniques from the discrete setting to the continuous both in theory [BCG+12, TBSR13, CF14, DB13] and in practice [SAH+13]. However, these results are not robust to noise: if the signal is sampled with a tiny amount of Gaussian noise or decays very slightly over time, no method has been known for computing a sparse Fourier transform in the continuous setting with sample

complexity linear in k and logarithmic in other factors. That is what we present in this paper.

Formally, a vector $x^*(t)$ has a k-sparse Fourier transform if it can be written as

$$x^*(t) = \sum_{i=1}^{k} v_i e^{2\pi \mathbf{i} f_i t}$$

for some *tones* $\{(v_i, f_i)\}$. We consider the problem where we can sample some signal

$$x(t) = x^*(t) + g(t)$$

at any t we choose in some interval $[0, T]$, where $x^*(t)$ has a k-sparse Fourier transform and $g(t)$ is arbitrary noise. As long as g is "small enough," one would like to recover a good approximation to x (or to x^*, or to $\{(v_i, f_i)\}$) using relatively few samples $t \in [0, T]$ and fast running time. Our algorithm achieves several results of this form, but a simple one is an ℓ_2/ℓ_2 guarantee: we reconstruct an $x'(t)$ with k-sparse Fourier transform such that

$$\frac{1}{T}\int_0^T |x'(t) - x(t)|^2 \mathrm{d}t \lesssim \frac{1}{T}\int_0^T |g(t)|^2 \mathrm{d}t$$

using a number of samples that is k times logarithmic factors[1]. To the best of our knowledge, this is the first algorithm achieving such a constant factor approximation with a sample complexity sublinear in T and the signal-to-noise ratio.

Our algorithm also gives fairly precise estimates of the individual tones (v_i, f_i) of the signal x^*. To demonstrate what factors are important, it is helpful to think about a concrete setting. Let us consider sound from a simplified model of a piano.

[1]We use $f \lesssim g$ to denote that $f \leq Cg$ for some universal constant C.

Thought experiment: piano tuning In a simplified model of a piano, we have keys corresponding to frequencies over some range $[-F, F]$. The noise $g(t)$ comes from ambient noise and the signals not being pure tones (because, for example, the notes might decay slowly over time). For concrete numbers, a modern piano has 88 keys spaced from about 27.5 Hz to $F = 4200$Hz. The space between keys ranges from a few Hz to a few hundred Hz, but most chords will have an $\eta = 30$Hz or more gap between the frequencies being played. One typically would like to tune the keys to within about $\pm\nu = 1$Hz. And piano music typically has k around 5.

Now, suppose you would like to build a piano tuner that can listen to a chord and tell you what notes are played and how they are tuned. For such a system, how long must we wait for the tuner to identify the frequencies? How many samples must the tuner take? And how robust is it to the noise?

If you have a constant signal-to-noise ratio, you need to sample for a time T of at least order $1/\nu = 1$ second in order to get 1Hz precision—frequencies within 1Hz of each other will behave very similarly over small fractions of a second, which noise can make indistinguishable. You also need at least $\Omega(k \log \frac{F}{k\nu}) \approx 50$ samples, because the support of the signal contains that many bits of information and you only get a constant number per measurement (at constant SNR). At higher signal-to-noise ratios ρ, these results extend to $\Omega(\frac{1}{\nu\rho})$ duration and $\Omega(k \log_\rho \frac{F}{k\nu})$ samples. But as the signal-to-noise ratio gets very high, there is another constraint on the duration: for $T < \frac{1}{\eta} \approx 33$ milliseconds the different frequencies start becoming hard to distinguish, which causes the robustness to degrade exponentially in k [Moi15] (though the lower bound there only directly applies to a somewhat restricted version of our setting).

This suggests the form of a result: with a duration $T > \frac{1}{\eta}$, one can hope to recover the frequencies to within $\frac{1}{\rho T}$ using $O(k \log_\rho \frac{FT}{k})$ samples. We give an algorithm that is within logarithmic factors of this ideal: with a duration $T > \frac{O(\log(k/\delta))}{\eta}$, we recover the frequencies to within $O(\frac{1}{\rho T})$ using $O(k \log_\rho(FT) \cdot \log(k/\delta) \log k)$ samples, where ρ and $1/\delta$ are (roughly speaking) the minimum and maximum signal-to-noise ratios that you can tolerate, respectively.

Instead of trying to tune the piano by recovering the frequencies precisely, one may simply wish to record the sound for future playback with relatively few samples. Our algorithm works for this as well: the combination $x'(t)$ of our recovered frequencies satisfies

$$\frac{1}{T}\int_0^T |x'(t) - x(t)|^2 \mathrm{d}t \lesssim \frac{1}{T}\int_0^T |g(t)|^2 \mathrm{d}t.$$

Let us now state our main theorems. The first shows how well we can estimate the frequencies f_i and their weights v_i; we refer to this (v_i, f_i) pair as a *tone*.

Theorem 11.1.1 (Tone estimation). Consider any signal $x(t) : [0, T] \to \mathbb{C}$ of the form

$$x(t) = x^*(t) + g(t),$$

for arbitrary "noise" $g(t)$ and an exactly k-sparse $x^* = \sum_{i \in [k]} v_i e^{2\pi \mathbf{i} f_i t}$ with frequencies $f_i \in [-F, F]$ and frequency separation $\eta = \min_{i \neq j} |f_i - f_j|$. For some parameter $\delta > 0$, define the "noise level"

$$\mathcal{N}^2 := \frac{1}{T}\int_0^T |g(t)|^2 \mathrm{d}t + \delta \sum_{i=1}^k |v_i|^2.$$

We give an algorithm that takes samples from $x(t)$ over any duration $T > O(\frac{\log(k/\delta)}{\eta})$ and returns a set of k tones $\{(v_i', f_i')\}$ that approximates x^* with error proportional to $\mathcal{N}$. In

particular, every large tone is recovered: for any v_i with $|v_i| \gtrsim \mathcal{N}$, we have for an appropriate permutation of the indices that

$$|f_i' - f_i| \lesssim \frac{\mathcal{N}}{T|v_i|} \qquad \text{and} \qquad |v_i' - v_i| \lesssim \mathcal{N}. \tag{11.1}$$

In fact, we satisfy a stronger guarantee that the *total* error is bounded:

$$\sum_{i=1}^{k} \frac{1}{T} \int_0^T |v_i' e^{2\pi \mathbf{i} f_i' t} - v_i e^{2\pi \mathbf{i} f_i t}|^2 \mathrm{d}t \lesssim \mathcal{N}^2. \tag{11.2}$$

The algorithm takes $O(k \log(FT) \log(\frac{k}{\delta}) \log(k))$ samples and $O(k \log(FT) \log(\frac{FT}{\delta}) \log(k))$ running time, and succeeds with probability at least $1 - 1/k^c$ for an arbitrarily large constant c.

We then show that the above approximation of the individual tones is good enough to estimate the overall signal $x(t)$ to within constant factors:

Theorem 11.1.2 (Signal estimation). In the same setting as Theorem 11.1.1, if the duration is slightly longer at $T > O(\frac{\log(1/\delta) + \log^2 k}{\eta})$, the reconstructed signal $x'(t) = \sum_{i=1}^{k} v_i' e^{2\pi \mathbf{i} f_i' t}$ achieves a constant factor approximation to the complete signal x:

$$\frac{1}{T} \int_0^T |x'(t) - x(t)|^2 \mathrm{d}t \lesssim \mathcal{N}^2. \tag{11.3}$$

The algorithm takes $O(k \log(FT) \log(\frac{k}{\delta}) \log(k))$ samples and $O(k \log(FT) \log(\frac{FT}{\delta}) \log(k))$ running time, and succeeds with probability at least $1 - 1/k^c$ for an arbitrarily large constant c.

The above theorems give three different error guarantees, which are all in terms of a "noise level" $\mathcal{N}^2$ that is the variance of the noise $g(t)$ plus δ times the energy of the signal. The algorithm depends logarithmically on δ, so one should think of $\mathcal{N}^2$ as being the variance of the noise, e.g. σ^2 if samples have error $N(0, \sigma^2)$.

Error guarantees. Our algorithm does a good job of estimating the signal, but how exactly should we quantify this? Because very few previous results have shown robust recovery in the continuous setting, there is no standard error measure to use. We therefore bound the error in three different ways: the maximum error in the estimation of any tone; the weighted total error in the estimation of all tones; and the difference between the reconstructed signal and the true signal over the sampled interval. The first measure has been studied before, while the other two are to the best of our knowledge new but useful to fully explain the robustness we achieve.

The error guarantee (11.1) says that we achieve good recovery of any tones with magnitude larger than $C\mathcal{N}$ for some constant C. Note that such a requirement is necessary: for tones with $|v_i| \leq \mathcal{N}$, one could have $g(t) = -v_i e^{2\pi \mathbf{i} f_i t}$, completely removing the tone (v_i, f_i) from the observed $x(t)$ and making it impossible to find. For the tones of sufficiently large magnitude, we find them to within $\frac{\mathcal{N}}{T|v_i|}$. This is always less than $1/T$, and converges to 0 as the noise level decreases. This is known as *superresolution*–one can achieve very high frequency resolution in sparse, nearly noiseless settings. Moreover, by Lemma 11.3.15 our "superresolution" precision $|f_i' - f_i| \lesssim \frac{\mathcal{N}}{T|v_i|}$ is optimal.

While the guarantee of (11.1) is simple and optimal given its form, it is somewhat unsatisfying. It shows that the maximum error over all k tones is $\mathcal{N}$, while one can hope to bound the *total* error over all k tones by $\mathcal{N}$. This is precisely what Equation (11.2) does. The guarantee (11.1) is the precision necessary to recover the tone to within $O(\mathcal{N})$ average error in time, that is (11.1) is equivalent to

$$\frac{1}{T}\int_0^T |v_i' e^{2\pi \mathbf{i} f_i' t} - v_i e^{2\pi \mathbf{i} f_i t}|^2 \mathrm{d}t \lesssim \mathcal{N}^2 \qquad \forall i \in [k].$$

In (11.2), we show that this bound holds even if we sum the left hand side over all $i \in [k]$, so the *average* error is a factor k better than would be implied by (11.1). It also means that the total mass of all tones that are not recovered to within $\pm 1/T$ is $O(\mathcal{N})$, not just that every tone larger than $O(\mathcal{N})$ is recovered to within $\pm 1/T$.

The stronger bound (11.2) can be converted to the guarantee (11.3), which is analogous to the ℓ_2/ℓ_2 recovery guarantee standard in compressive sensing. It bounds the error of our estimate in terms of the input noise, on average over the sampled duration. The standard form of the ℓ_2/ℓ_2 guarantee in the discrete sparse Fourier transform setting [GGI+02, GMS05, HIKP12a, IKP14, IK14] compares the energy in frequency domain rather than time domain. This cannot be achieved directly in the continuous setting, since frequencies infinitesimally close to each other are indistinguishable over a bounded time interval T. But if the signal is periodic with period T (the case where a discrete sparse Fourier transform applies directly), then (11.3) is equivalent to the standard guarantee by Parseval's identity. So (11.3) seems like the right generalization of ℓ_2/ℓ_2 recovery to our setting.

Other factors. Our algorithm succeeds with high probability in k, which could of course be amplified by repetition (but increasing the sample complexity and running time). Our running time, at $O(k \log(FT) \log(FT/\delta) \log k)$, is (after translating between the discrete and continuous setting) basically a $\log k$ factor larger than the fastest known algorithm for discrete sparse Fourier transforms ([HIKP12a]). But since that result only succeeds with constant probability, and repetition would also increase that by a $\log k$ factor, our running time is actually equivalent to the fastest known results that succeed with high probability in k.

Our sample complexity is $O(\log(k/\delta)\log k)$ worse than the presumptive optimal, which is known to be achievable in the discrete setting ([IK14]). However, the techniques that [IK14] uses to avoid the $\log(k/\delta)$ factor seem hard to adapt to the continuous setting without losing some of the robustness/precision guarantees.

Another useful property of our method, not explicitly stated in the theorem, is that the sampling method is relatively simple: it chooses $O(\log(FT)\log k)$ different random arithmetic sequences of points, where each sequence has $O(k\log(k/\delta))$ points spread out over a constant fraction of the time domain T. Thus one could implement this in hardware using a relatively small number of samplers, each of which performs regular sampling at a rate of $\frac{k\log(k/\delta)}{T}$. This is in contrast to the Nyquist rate for non-sparse signals of $2F$ — in the piano example, each sampler has a rate on the order of 50Hz rather than 8000Hz.

The superresolution frequency is optimal because two signals of magnitude v_i and frequency separation $\nu < 1/T$ will differ by $O(\nu^2T^2|v_i|^2)$ over the duration T, so for ν below our threshold the difference is just $\mathcal{N}^2$. Hence if the observed signal $x(t)$ looks identical to (v_i, f_i), it might actually be (v_i, f_i') with noise equaling the difference between the two.

The only previous result known in the form of (11.1) was [Moi15], which lost a $\text{poly}(k, \frac{\max|v_i|}{\min|v_i|}, \eta)$ factor in noise tolerance and also did not optimize for sample complexity.

11.1.1 Comparison to Naive Methods

This section compares our result to some naive ways one could try to solve this problem by applying algorithms not designed for a continuous, sparse Fourier transform setting. The next section will compare our result to algorithms that are designed for such a setting.

Nyquist Sampling. The traditional theory of band-limited signals from discrete samples says that, from samples taken at the Nyquist rate $2F$, one can reconstruct an F-band-limited signal exactly. The Whittaker-Shannon interpolation formula then says that

$$x^*(t) = \sum_{i=-\infty}^{\infty} x^*(2Fi)\,\mathrm{sinc}(2Ft - i) \tag{11.4}$$

where $\mathrm{sinc}(t)$ is the normalized sinc function $\frac{\sin(\pi t)}{\pi t}$. This is for the band-limited "pure" signal x^*, but one could then get a relationship for samples of the actual signal $x(t)$. This has no direct implications for learning the tones (e.g. our (11.1) or (11.2)), but for learning the signal (our (11.3)) there is also an issue. Even in the absence of noise and for $k = 1$, this method will have error polynomially rather than exponentially small in the number of samples.

That is, if there is no noise the method has zero error given infinitely many samples. But we only receive samples over the interval $[0, T]$, leading to error. Consider the trivial setting of $x(t) = 1$. The partial sum of (11.4) at a given t will be missing terms for $i > 2Ft$ and $i < 0$, which (for a random t in $[0, T/2]$) have magnitude at most $1/(Ft)$. The terms alternate in sign, so the sum has error approximately $1/(Ft)^2$. This means that the error over the first $1/F$ time is a constant, leading to average error of $\frac{1}{FT}$. This is with an algorithm that uses FT samples and time. By contrast, our algorithm in the noiseless setting has error exponentially small in the samples and running time.

Discrete Sparse Fourier Transforms. An option related to the previous would be to discretize very finely, then apply a discrete sparse Fourier transform algorithm to keep the sample complexity and runtime small. The trouble here is that sparse Fourier transforms

require sparsity, and this process decreases the sparsity. In particular, this process supposes that the signal is periodic with period T, so one can analyze this process as first converting the signal to one, equivalent over $[0, T]$, but with frequency spectrum only containing integer multiples of $1/T$. This is done by convolving each frequency f_i with a sinc function (corresponding to windowing to $[0, T]$) then restricting to multiples of $1/T$ (corresponding to aliasing). The result is that a one-sparse signal $e^{2\pi \mathbf{i} f_i t}$ is viewed as having Fourier spectrum

$$\widehat{x''}[j] = \operatorname{sinc}(f_i T - j)$$

for $j \in \mathbb{Z}$. When f_i is not a multiple of $1/T$, this means the signal is not a perfectly sparse signal. And this is true regardless of the discretization level, which only affects the subsequent error from aliasing $j \in \mathbb{Z}$ down to $\mathbb{Z}_n$. To have error proportional to $\delta \left\| \widehat{x}^* \right\|_2$, one would need to run such methods for a sparsity level of k/δ. Thus, as with Nyquist sampling, the sample and runtime will be polynomial, rather than logarithmic, in δ.

The above discussion refers to methods for learning the signal (our (11.3)). In terms of learning the tones, one could run the algorithm for sparsity $O(k)$ so that δ is a small constant, which would let one learn roughly where the peaks are and get most of the frequencies to the nearest $1/T$. This would give a similar bound to our (11.1), but without the superresolution effect as the noise becomes small. On the plus side, the duration could be just $O(1/\eta)$—which is sufficient for the different peaks to be distinguishable—rather than $O(\frac{\log k}{\eta})$ as our method would require, and the time and sample complexities could save a $\log k$ factor (if one did not want to recover *all* the tones, just most of them).

Essentially, this algorithm tries to round each frequency to the nearest multiple of $1/T$, which introduces noise that is a constant fraction of the signal. If the signal-to-noise

ratio is already low, this does not increase the noise level by that much so such an algorithm will work reasonably well. If the signal-to-noise ratio is fairly high, however, then the added noise leads to much worse performance. Getting a constant factor approximation to the whole signal is only nontrivial for high SNR, so such a method does badly in that setting. For approximating the tones, it is comparable to our method in the low SNR setting but does not improve much as SNR increases.

11.1.2 Previous Work In Similar Settings

There have been several works that recover continuous frequencies from samples in the time domain. Some of these are in our setting where the samples can be taken at arbitrary positions over $[0, T]$ and others are in the discrete-time (DTFT) setting where the samples must be taken at multiples of the Nyquist frequency $\frac{1}{2F}$.

The results of [TBSR13, CF14, YX15, DB13] show that a convex program can solve the problem in the DTFT setting using $O(k \log k \log(FT))$ samples if the duration is $T > O(\frac{1}{\eta})$, in the setting where $g(t) = 0$ and the coefficients of x^* have random phases. The sample complexity can be one log factor better than ours, which one would expect for the noiseless setting. None of these results show robustness to noise, and some additionally require a running time polynomial in FT rather than k.

The result of [BCG+12] is in a similar setting to our paper, using techniques of the same lineage. It achieves very similar sample complexity and running time to our algorithm, and a guarantee similar in spirit to (11.1) with some notion of robustness. However, the robustness is weaker than ours in significant ways. They consider the noise $g(t)$ in frequency space (i.e. $\widehat{g}(f)$), then require that $\widehat{g}(f)$ is zero at any frequency within η of the signal

frequencies f_i, and bound the error in terms of $\mathcal{N}' = \|\widehat{g}\|_1 / k$ instead of $\|g\|_2$. This fails to cover simple examples of noise, including i.i.d. Gaussian noise $g(t) \sim N(0, \sigma^2)$ and the noise one would get from slow decay of the signal over time (e.g. $x(t) = x^*(t)e^{-\frac{t}{100T}}$.). Both types of noise violate both assumptions on the noise: $\widehat{g}(f)$ will be nonzero arbitrarily close to each f_i and $\|\widehat{g}\|_1$ will be unbounded. Their result also requires a longer duration than our algorithm and has worse precision for any fixed duration.

The result of [Moi15] studies noise tolerance in the DTFT setting, ignoring sample complexity and running time. It shows that the matrix pencil method [HS90], using FT samples, achieves a guarantee of the form (11.1), except that the bounds are an additional $\text{poly}(FT, k, \delta)$ factor larger. Furthermore, it shows a sharp characterization of the minimal T for which this is possible by any algorithm: $T = (1 \pm o(1))\frac{2}{\eta}$ is necessary and sufficient. It is an interesting question whether the lower bound generalizes to our non-DTFT setting, where the samples are not necessarily taken from an even grid.

Lastly, [SAH+13] tries to apply sparse Fourier transforms to a domain with continuous signals. They first apply a discrete sparse Fourier transform then use hill-climbing to optimize their solution into a decent set of continuous frequencies. They have interesting empirical results but no theoretical ones.

11.2 Algorithm Overview

At a high level, our algorithm is an adaptation of the framework used by [HIKP12a] to the continuous setting. However, getting our result requires a number of subtle changes to the algorithm. This section will describe the most significant ones. We assume some familiarity with previous work in the area [GGI+02, CCF02, GMS05, GLPS10, HIKP12a].

First we describe a high-level overview of the structure. The algorithm proceeds in $\log k$ stages, where each stage attempts to recover each tone with a large constant probability (e.g. 9/10). In each stage, we choose a parameter $\sigma \approx \frac{T}{k \log(k/\delta)}$ that we think of as "hashing" the frequencies into random positions. For this σ, we will choose about $\log(FT)$ different random "start times" t_0 and sample an arithmetic sequence starting at t_0, i.e. observe

$$x(t_0), x(t_0 + \sigma), x(t_0 + 2\sigma), \ldots, x(t_0 + (k \log(k/\delta))\sigma)$$

We then scale these observations by a "window function," which has specific properties but among other things scales down the values near the ends of the sequence, giving a smoother transition between the time before and after we start/end sampling. We alias this down to $B = O(k)$ terms (i.e. add together terms $1, B+1, 2B+1, \ldots$ to get a B-dimensional vector) and take the B-dimensional DFT. This gives a set of B values $\widehat{u}_i$. The observation made in previous papers is that $\widehat{u}$ is effectively a *hashing* of the tones of $\widehat{x}$ into B buckets, where σ defines a permutation on the frequencies that affects whether two different tones land in the same bucket, and $\widehat{u}_j$ approximately equals the sum of all the tones that land in bucket j, each scaled by a phase shift depending on t_0.

Because of this phase shift, for each choice of t_0 the value of $\widehat{u}_j$ is effectively a sample from the Fourier transform of a signal that contains only the tones of $\widehat{x}^*$ that land in bucket

j, with zeros elsewhere. And since there are k tones and $O(k)$ buckets, most tones are alone in their bucket. Therefore this sampling strategy reduces the original problem of k-sparse recovery to one of 1-sparse recovery—we simply choose t_0 according to some strategy that lets us achieve 1-sparse recovery, and recover a tone for each bin.

One-sparse recovery. The algorithm for one-sparse recovery in [HIKP12a] is a good choice for adaptation to the continuous setting. It narrows down to the frequency in a locality-aware way, maintaining an interval of frequencies that decreases in size at each stage (in contrast to the method in [GMS05], which starts from the least significant bit rather than most significant bit).

If a frequency is perturbed slightly in time (e.g., by multiplying by a very slow decay over time) this will blur the frequency slightly into a narrow band. The one-sparse recovery algorithm of [HIKP12a] will proceed normally until it gets to the narrow scale, at which point it will behave semi-arbitrarily and return something near that band. This gives a desired level of robustness—the error in the recovered frequency will be proportional to the perturbation.

Still, to achieve our result we need a few changes to the one-sparse algorithm. One is related to the duration T: in the very last stage of the algorithm, when the interval is stretched at the maximal amount, we can only afford one "fold" rather than the typical $O(\log n)$. The only cost to this is in failure probability, and doing it for one stage is fine—but showing this requires a different proof. Another difference is that we need the final interval to have precision $\frac{1}{T\rho}$ if the signal-to-noise ratio is ρ—the previous analysis showed $\frac{1}{T\sqrt{\rho}}$ and needed to be told ρ, but (as we shall see) to achieve an ℓ_2/ℓ_2 guarantee we need the optimal

ρ-dependence and for the algorithm to be oblivious to the value of ρ. Doing so requires a modification to the algorithm and slightly more clever analysis.

k-sparse recovery. The changes to the k-sparse recovery structure are broader. First, to make the algorithm simpler we drop the [GLPS10]-style recursion with smaller k, and just repeat an $O(k)$-size hashing $O(\log k)$ times. This loses a $\log k$ factor in time and sample complexity, but because of the other changes it is not easy to avoid, and at the same time improves our success probability.

The most significant changes come because we can no longer measure the noise in frequency space or rely on the hash function to randomize the energy that collides with a given heavy hitter. Because we only look at a bounded time window T, Parseval's identity does not hold and the energy of the noise in frequency space may be unrelated to its observed energy. Moreover, if the noise consists of frequencies infinitesimally close to a true frequency, then because σ is bounded the true frequency will always hash to the same bin as the noise. These two issues are what drive the restrictions on noise in the previous work [BCG+12]—assuming the noise is bounded in ℓ_1 norm in frequency domain and is zero in a neighborhood of the true frequencies fixes both issues. But we want a guarantee in terms of the average ℓ_2 noise level $\mathcal{N}^2$ in time domain over the observed duration. If the noise level is $\mathcal{N}^2$, because we cannot hash the noise independently of the signal, we can only hope to guarantee reliable recovery of tones with magnitude larger than $\mathcal{N}^2$. This is in contrast to the $\mathcal{N}^2/k$ that is possible in the discrete setting, and would naively lose a factor of k in the ℓ_2/ℓ_2 approximation.

The insight here is that, even though the noise is not distributed randomly across bins, the total amount of noise is still bounded. If a heavy hitter of magnitude v^2 is not

recovered due to noise, that requires $\Omega(v^2)$ noise mass in the bin that is not in any other bin. Thus the total amount of signal mass not recovered due to noise is $O(\mathcal{N}^2)$, which allows for ℓ_2/ℓ_2 recovery.

This difference is why our algorithm only gets a constant factor approximation rather than the $1+\epsilon$ guarantee that hashing techniques for sparse recovery can achieve in other settings. These techniques hash into $B = O(k/\epsilon)$ bins so the average noise per bin is $O(\frac{\epsilon}{k}\mathcal{N}^2)$. In our setting, where the noise is not hashed independently of the signal, this would give no benefit.

Another difference arises in the choice of the parameter σ, which is the separation between samples in the arithmetic sequence used for a single hashing, and gives the permutation during hashing. In the discrete setting, one chooses σ uniformly over n, which in our setting would correspond to a scale of $\sigma \approx \frac{1}{\eta}$. Since the arithmetic sequences have $O(k\log(k/\delta))$ samples, the duration would then become at least $\frac{k\log(k/\delta)}{\eta}$ (which is why [BCG+12] has this duration). What we observe is that σ can actually be chosen at the scale of $\frac{1}{k\eta}$, giving the desired $O(\frac{\log(k/\delta)}{\eta})$ duration. This causes frequencies at the minimum separation η to always land in bins that are a constant separation apart. This is sufficient because we use [HIKP12a]-style window functions with strong isolation properties (and, in fact, [HIKP12a] could have chosen $\sigma \approx n/B$); it would be an issue if we were using the window functions of [GMS05, IK14] that have smaller supports but less isolation.

Getting an ℓ_2 bound Lastly, converting the guarantee (11.2) into (11.3) is a nontrivial task that is trivial in the discrete setting. In the discrete setting, it follows immediately from the different frequencies being orthogonal to each other. In our setting, we use that

the recovered frequencies should themselves have $\Omega(\eta)$ separation, and that well-separated frequencies are nearly orthogonal over long enough time scales $T \gg 1/\eta$.

This bears some similarity to issues that arise in sparse recovery with overcomplete dictionaries. It would be interesting to see whether further connections can be made between the problems.

11.3 Proof outline

In this section we present the key lemmas along the path to producing the algorithm. The full proof are presented later.

Notation. First we define the notation necessary to understand the lemmas. The full notation as used in the proofs appears in Section 11.4.

The algorithm proceeds in stages, each of which hashes the frequencies to B bins. The hash function depends on two parameters σ and b, and so we define it as $h_{\sigma,b}(f) : [-F, F] \to [B]$.

A tone with a given frequency f can have two "bad events" $E_{coll}(f)$ or $E_{off}(f)$ hold for a given hashing. These correspond to colliding with another frequency of x^* or landing within an α fraction of the edge, respectively; they each will occur with small constant probability.

For a given hashing, we will choose a number of different offsets a that let us perform recovery of the tones that have neither bad event in this stage.

We use $f \lesssim g$ to denote that there exists a constant C such that $f \leq Cg$, and $f \approx g$ to denote $f \lesssim g \lesssim f$.

Key Lemmas First, we need to be able to compare the distance between two pure tone signals in time domain to their differences in parameters. The relation is as follows:

Lemma 11.3.1. Let (v, f) and (v', f') denote any two tones, i.e., (magnitude, frequency)

pairs. Then for

$$\operatorname{dist}\left((v,f),(v',f')\right)^2 := \frac{1}{T}\int_0^T \left|ve^{2\pi ft\mathbf{i}} - v'e^{2\pi f't\mathbf{i}}\right|^2 \mathrm{d}t,$$

we have

$$\operatorname{dist}\left((v,f),(v',f')\right)^2 \eqsim (|v|^2+|v'|^2)\cdot\min(1,T^2|f-f'|^2) + |v-v'|^2,$$

and

$$\operatorname{dist}\left((v,f),(v',f')\right) \eqsim |v|\cdot\min(1,T|f-f'|) + |v-v'|.$$

The basic building block for our algorithm is a function HashToBins, which is very similar to one of the same name in [HIKP12a].

The key property of HashToBins is that, if neither "bad" event holds for a frequency f (i.e. it does not collide or land near the boundary of the bin), then for the bin $j = h_{\sigma,b}(f)$ we have that $|\widehat{u}_j| \approx |\widehat{x^*}(f)|$ with a phase depending on a.

How good is the approximation? In the discrete setting, one can show that each tone has error about $\mathcal{N}^2/B$ in expectation. Here, because the hash function cannot randomize the noise, we instead show that the total error over all tones is about $\mathcal{N}^2$:

Lemma 11.3.2. *Let $\sigma \in [\frac{1}{B\eta}, \frac{2}{B\eta}]$ uniformly at random, then $b \in [0, \frac{\lceil F/\eta\rceil}{\sigma B}]$, $a \in [0, \frac{cT}{\sigma}]$ be sampled uniformly at random for some constant $c > 0$. Let the other parameters be arbitrary in $\widehat{u} = \text{HashToBins}(x, P_{\sigma,a,b}, B, \delta, \alpha)$, and consider*

$$H = \{f \in \operatorname{supp}(\widehat{x}^*) \mid \textit{neither } E_{coll}(f) \textit{ nor } E_{off}(f) \textit{ holds}\}$$

and $I = [B] \setminus h_{\sigma,b}(\operatorname{supp}(\widehat{x}^*))$ to be the bins that have no frequencies hashed to them. Then

$$\mathop{\mathbb{E}}_{\sigma,b,a}\left[\sum_{f\in H}\left|\widehat{u}_{h_{\sigma,b}(f)} - \widehat{x^*}(f)e^{a\sigma 2\pi f\mathbf{i}}\right|^2 + \sum_{j\in I}\widehat{u}_j^2\right] \lesssim \mathcal{N}^2$$

We prove Lemma 11.3.2 by considering the cases of $x^* = 0$ and $g = 0$ separately; linearity then gives the result. Both follow from properties of our window functions.

Lemma 11.3.3. If $x^*(t) = 0, \forall t \in [0, T]$, then

$$\mathop{\mathbb{E}}_{\sigma,a,b}\left[\sum_{j=1}^{B} |\widehat{u}_j|^2\right] \lesssim \frac{1}{T}\int_0^T |g(t)|^2 \mathrm{d}t.$$

Lemma 11.3.4. If $g(t) = 0, \forall t \in [0, T]$. Let H denote a set of frequencies, $H = \{f \in \text{supp}(\widehat{x^*}) \mid \text{neither } E_{coll}(f) \text{ nor } E_{off}(f) \text{ holds}\}$. Then,

$$\mathop{\mathbb{E}}_{\sigma,a,b}\left[\sum_{f\in H} \left|\widehat{u}_{h_{\sigma,b}(f)} - \widehat{x^*}(f)e^{a\sigma 2\pi f \mathbf{i}}\right|^2\right] \leq \delta\|\widehat{x^*}\|_1^2.$$

Lemma 11.3.2 is essentially what we need for 1-sparse recovery. We first show a lemma about the inner call, which narrows the frequency from a range of size Δl to one of size $\frac{\Delta l}{\rho st}$ for some parameters ρst. This gives improved performance (superresolution) when the signal-to-noise ratio ρ within the bucket is high. The parameter s and t provide a tradeoff between success probability, performance, running time, and duration.

Lemma 11.3.5. *Consider any B, δ, α. Algorithm* HashToBins *takes $O(B\log(k/\delta))$ samples and runs in $O(\frac{B}{\alpha}\log(k/\delta) + B\log B)$ time.*

Lemma 11.3.6. Given σ and b, consider any frequency f for which neither $E_{coll}(f)$ nor $E_{off}(f)$ holds, and let $j = h_{\sigma,b}(f)$. Let $\mu^2(f) = \mathbb{E}_a[|\widehat{u}_j - \widehat{x^*}(f)e^{a\sigma 2\pi f\mathbf{i}}|^2]$ and $\rho^2 = |\widehat{x^*}(f)|^2/\mu^2(f)$. For sufficiently large ρ, and $\forall 0 < s < 1, t \geq 4$, consider any run of LocateInner with $f \in [l_j - \frac{\Delta l}{2}, l_j + \frac{\Delta l}{2}]$. It takes $O(R_{loc})$ random $(\gamma, \beta) \in [\frac{1}{2}, 1] \times [\frac{st}{4\sigma\Delta l}, \frac{st}{2\sigma\Delta l}]$ samples over duration $\beta\sigma = \Theta(\frac{st}{\Delta l})$, runs in $O(stR_{loc})$ time, to learn f within a region that has length $\Theta(\frac{\Delta l}{t})$ with failure probability at most $(\frac{4}{s\rho})^{R_{loc}} + t\cdot(60s)^{R_{loc}/2}$.

By repeating this inner loop, we can recover the tones in almost every bin that does not have the "bad" events happen, so we recover a large fraction of the heavy hitters in each stage.

Lemma 11.3.7. Algorithm LocateKSignal takes $O(k \log_C(FT) \log(k/\delta))$ samples over $O(\frac{\log(k/\delta)}{\eta})$ duration, runs in $O(k \log_C(FT) \log(FT/\delta))$ time, and outputs a set $L \subset [-F, F]$ of $O(k)$ frequencies with minimum separation $\Omega(\eta)$.

Given σ and b, consider any frequency f for which neither of $E_{coll}(f)$ or $E_{off}(f)$ hold. Let $j = h_{\sigma,b}(f)$, $\mu^2(f) = \mathbb{E}_a[|\widehat{u}_j - \widehat{x^*}(f)e^{a\sigma 2\pi f \mathbf{i}}|^2]$, and $\rho^2 = |\widehat{x^*}(f)|^2/\mu^2(f)$. If $\rho > C$, then with an arbitrarily large constant probability there exists an $f' \in L$ with

$$|f - f'| \lesssim \frac{1}{T\rho}.$$

Combining this with estimation of the magnitudes of recovered frequencies, we can show that the total error over all bins without "bad" events—that is, bins with either one well placed frequency or zero frequencies—is small. At this point we give no guarantee for the (relatively few) bins with bad events; the recovered values there may be arbitrarily large.

Lemma 11.3.8. Algorithm OneStage takes $O(k \log_C(FT) \log(k/\delta))$ samples over $O(\frac{\log(k/\delta)}{\eta})$ duration, runs in $O(k(\log_C(FT) \log(FT/\delta)))$ time, and outputs a set of $\{(v_i', f_i')\}$ of size $O(k)$ with $\min_{i \neq j} |f_i' - f_j'| \gtrsim \eta$. Moreover, one can imagine a subset $S \subseteq [k]$ of "successful" recoveries, where $\Pr[i \in S] \geq \frac{9}{10}$ $\forall i \in [k]$ and for which there exists an injective function $\pi : [k] \to [O(k)]$ so that

$$\mathop{\mathbb{E}}_{\sigma,b}\left[\sum_{i \in S} \frac{1}{T} \int_0^T \left| v_i' e^{2\pi f_i' t \mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t \mathbf{i}} \right|^2 \mathrm{d}t\right] \lesssim C^2 \mathcal{N}^2.$$

with $1 - 1/k^c$ probability for an arbitrarily large constant c.

We can repeat the procedure for $O(\log k)$ stages and merge the results, getting a list of $O(k)$ tones that includes k tones that match up well to the true tones. However, we give no guarantee for the rest of the recovered tones at this point—as far as the analysis is concerned, mistakes from bins with collisions may cause arbitrarily large spurious tones.

Lemma 11.3.9. Repeating algorithm OneStage $O(\log k)$ times, MergedStages returns a set $\{(v_i', f_i')\}$ of size $O(k)$ with $\min_{i \neq j} |f_i' - f_j'| \gtrsim \eta$ that can be indexed by π such that

$$\sum_{i=1}^{k} \frac{1}{T} \int_0^T \left| v_i' e^{2\pi f_i' t \mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t \mathbf{i}} \right|^2 \mathrm{d}t \lesssim C^2 \mathcal{N}^2.$$

with probability $1 - 1/k^c$ for an arbitrarily large constant c.

To address the issue of spurious tones, we run the above algorithm twice and only take the tones that are recovered in both stages. We show that the resulting $O(k)$ tones are together a good approximation to the vector.

Lemma 11.3.10. If we run MergedStages twice and take the tones $\{(v_i', f_i')\}$ from the first result that have f_i' within $c\eta$ for small c of some frequency in the second result, we get a set of $k'' = O(k)$ tones that can be indexed by some permutation π such that

$$\sum_{i=1}^{k} \frac{1}{T} \int_0^T \left| v_i' e^{2\pi f_i' t \mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t \mathbf{i}} \right|^2 \mathrm{d}t + \sum_{i=k+1}^{k''} |v_i'|^2 \lesssim C^2 \mathcal{N}^2. \tag{11.5}$$

Simply picking out the largest k recovered tones then gives the result (11.2).

Theorem 11.3.11. Algorithm ContinuousFourierSparseRecovery returns a set $\{(v_i', f_i')\}$ of size k with $\min_{i \neq j} |f_i' - f_j'| \gtrsim \eta$ for which

$$\sum_{i=1}^{k} \frac{1}{T} \int_0^T \left| v_i' e^{2\pi f_i' t \mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t \mathbf{i}} \right|^2 \mathrm{d}t \lesssim C^2 \mathcal{N}^2$$

with probability $1 - 1/k^c$ for an arbitrarily large constant c.

By only considering the term in the sum corresponding to tone i and applying Lemma 11.3.1, we get result (11.1):

Corollary 11.3.12. *With probability $1 - 1/k^c$ for an arbitrarily large constant c, we recover a set of tones $\{(v_i', f_i')\}$ such that, for any v_i with $|v_i| \gtrsim \mathcal{N}$, we have for an appropriate permutation of the indices that*

$$|f_i' - f_i| \lesssim \frac{\mathcal{N}}{T|v_i|} \qquad \text{and} \qquad |v_i' - v_i| \lesssim \mathcal{N}. \tag{11.6}$$

We then show that (11.2) implies (11.3) for sufficiently long durations T. A long duration helps because it decreases the correlation between η-separated frequencies.

Lemma 11.3.13. Let $\{(v_i, f_i)\}$ and $\{(v_i', f_i')\}$ be two sets of k tones for which $\min_{i \neq j} |f_i - f_j| \geq \eta$ and $\min_{i \neq j} |f_i' - f_j'| \gtrsim \eta$ for some $\eta > 0$. Suppose that $T > O(\frac{\log^2 k}{\eta})$. Then these sets can be indexed such that

$$\frac{1}{T} \int_0^T \left| \sum_{i=1}^{k} (v_i' e^{2\pi \mathbf{i} f_i' t} - v_i e^{2\pi \mathbf{i} f_i t}) \right|^2 \mathrm{d}t \lesssim \sum_{i=1}^{k} \frac{1}{T} \int_0^T \left| v_i' e^{2\pi \mathbf{i} f_i' t} - v_i e^{2\pi \mathbf{i} f_i t} \right|^2 \mathrm{d}t. \tag{11.7}$$

Combining Theorem 11.3.11 and Lemma 11.3.13 immediately implies

Theorem 11.3.14. *Suppose we sample for a duration $T > O(\frac{\log(1/\delta) + \log^2 k}{\eta})$. Then the reconstructed signal $x'(t) = \sum_{i=1}^{k} v_i' e^{2\pi \mathbf{i} f_i' t}$ achieves a constant factor approximation to the complete signal x:*

$$\frac{1}{T} \int_0^T |x'(t) - x(t)|^2 \mathrm{d}t \lesssim C^2 \mathcal{N}^2. \tag{11.8}$$

The algorithm takes $O(k \log \frac{F}{\eta} \log(\frac{k}{\delta}) \log(k))$ samples, runs in $O(k \log \frac{F}{\eta} \log(\frac{FT}{\delta}) \log(k))$ time, and succeeds with probability at least $1 - 1/k^c$ for an arbitrarily large constant c.

That finishes the proof of our main theorem. We also show that our "superresolution" precision from (11.1) is optimal, which is a simple corollary of Lemma 11.3.1.

Lemma 11.3.15. There exists a constant $c > 0$ such that, for a given sample duration T, one cannot recover the frequency f to within

$$c\frac{\mathcal{N}}{T|\widehat{x}^*(f)|}$$

with $3/4$ probability, for all $\delta > 0$, even if $k = 1$.

11.4 Notation and Definitions: Permutation, Hashing, Filters

This section gives definitions about the permutation, hashing, and filters that are used throughout the proofs. Let $[n]$ denote the set $\{1, 2, \cdots, n-1, n\}$. $\mathbb{R}$ denotes the real numbers, $\mathbb{Z}$ denotes the integer numbers and $\mathbb{C}$ denotes the complex numbers. The convolution of two continuous functions f and g is written as $f * g$,

$$(f * g)(t) := \int_{-\infty}^{+\infty} f(\tau) g(t-\tau) \mathrm{d}\tau$$

and the discrete convolution of f and g is given by,

$$(f * g)[n] := \sum_{m=-\infty}^{+\infty} f[m] g[n-m]$$

Let $\mathbf{i}$ denote $\sqrt{-1}$, and $e^{\mathbf{i}\theta} = \cos(\theta) + \mathbf{i}\sin(\theta)$. For any complex number $z \in \mathbb{C}$, we have $z = a + \mathbf{i}b$, where $a, b \in \mathbb{R}$. Define $\overline{z} = a - \mathbf{i}b$, $|z|^2 = z\overline{z} = a^2 + b^2$ and let $\phi(z)$ be the phase of z. Let $\mathrm{supp}(f)$ denote the support of function/vector f, and $\|f\|_0 = |\mathrm{supp}(f)|$. For any $p \in [1, \infty]$, the ℓ_p norm of a vector of x is $\|x\|_p = (\sum_i |x_i|^p)^{\frac{1}{p}}$, defined to be $\max_i |x_i|$ for $p = \infty$. Let k denote the sparsity of frequency domain. All the frequencies $\{f_1, f_2, \cdots, f_k\}$ are from $[-F, F]$. Let $B = O(k)$ denote the number of hash bins in our algorithm.

We translate the "permutation" $P_{\sigma,a,b}$ of [HIKP12a] from the DFT setting to the DTFT setting.

Definition 11.4.1. $(P_{\sigma,a,b}x^*)(t) = x^*(\sigma(t-a))e^{-2\pi\mathbf{i}\sigma bt}$.

Lemma 11.4.1. $\widehat{P_{\sigma,a,b}x^*}(\sigma(f-b)) = e^{-2\pi f\sigma a\mathbf{i}}\widehat{x}^*(f)$

Proof. The time domain representation of the given Fourier definition would be

$$\begin{aligned} x'(t) &= \sum_{f \in \text{supp}(\widehat{x}^*)} e^{-2\pi \mathbf{i} \sigma a f} \widehat{x}^*(f) e^{2\pi \mathbf{i} \sigma (f-b)t} \\ &= \sum_{f \in \text{supp}(\widehat{x}^*)} e^{-2\pi \mathbf{i} \sigma b t} \widehat{x}^*(f) e^{2\pi \mathbf{i} \sigma (t-a) f} \\ &= e^{-2\pi \mathbf{i} \sigma b t} x^*(\sigma(t-a)) \end{aligned}$$

which matches, so the formula is right. □

We also extend the flat window function for the DFT setting [HIKP12a], [HIKP12b] to the DTFT setting:

Definition 11.4.2. Let $M = O(B \log \frac{k}{\delta})$. We say that $(G, \widehat{G'}) = (G_{B,\delta,\alpha}, \widehat{G'}_{B,\delta,\alpha}) \in \mathbb{R}^M \times \mathbb{R}^{[-F,F]}$ is a flat window function with parameters $B \geq 1$, $\delta > 0$, and $\alpha > 0$. For simplicity, let's say B is a function of α. Define $|\text{supp}(G)| = M$ and $\widehat{G'}$ satisfies

- $G_i = \frac{\sin(i\frac{1}{B})}{i} \cdot e^{-\frac{i^2}{2\sigma^2}}$, where $\sigma = \Theta(B\sqrt{\log(k/\delta)})$.
- $\widehat{G}(f) = \sum_{i=1}^{M} G_i e^{f \cdot \frac{i}{M} 2\pi \mathbf{i}}$.
- $\text{supp}(\widehat{G'}) \subset [-\frac{2\pi}{2B}, \frac{2\pi}{2B}]$.
- $\widehat{G'}(f) = 1$ for all $f \in [-\frac{(1-\alpha)2\pi}{2B}, \frac{(1-\alpha)2\pi}{2B}]$.
- $\widehat{G'}(f) = 0$ for all $|f| \geq \frac{2\pi}{2B}$.
- $\widehat{G'}(f) \in [0,1]$ for all f.
- $\|\widehat{G'} - \widehat{G}\|_\infty^2 < \delta/k$.

Claim 11.4.2. $\sum_{i=1}^{M} G_i^2 \eqsim \frac{1}{B}$, *where* $M = O(B \log k/\delta)$.

Proof. By definition of G_i, we have

$$\sum_{i=1}^{M} G_i^2 = 2 \sum_{i=1}^{M/2} \frac{\sin^2(i\frac{1}{B})}{(i)^2} (e^{-\frac{(i)^2}{2\sigma^2}})^2.$$

There exists some constant $c \in [0, 2\pi)$, such that $\frac{\sin(i/B)}{i} \eqsim \frac{1}{B}$ if $i/B < c\pi$.

$$\begin{aligned}
\sum_{i=1}^{M} G_i^2 &= 2 \sum_{i=1}^{\lfloor Bc\pi \rfloor} \frac{\sin^2(i\frac{1}{B})}{(i)^2} (e^{-\frac{(i)^2}{2\sigma^2}})^2 + 2 \sum_{i=\lceil Bc\pi \rceil}^{M/2} \frac{\sin^2(i\frac{1}{B})}{(i)^2} (e^{-\frac{(i)^2}{2\sigma^2}})^2 \\
&\leq 2 \sum_{i=1}^{\lfloor Bc\pi \rfloor} \frac{\sin^2(i\frac{1}{B})}{(i)^2} \cdot 1 + 2 \sum_{i=\lceil Bc\pi \rceil}^{M/2} \frac{\sin^2(i\frac{1}{B})}{(i)^2} \cdot 1 \\
&\lesssim \sum_{i=1}^{\lfloor Bc\pi \rfloor} \frac{1}{B^2} + \sum_{i=\lceil Bc\pi \rceil}^{M/2} \frac{1}{i^2} \\
&\lesssim \frac{1}{B}.
\end{aligned}$$

Thus, we show an upper bound. It remains to prove the lower bound.

$$\begin{aligned}
\sum_{i=1}^{M} G_i^2 &\geq 2 \sum_{i=1}^{\lfloor Bc\pi \rfloor} \frac{\sin^2(i\frac{1}{B})}{(i)^2} (e^{-\frac{(i)^2}{2\sigma^2}})^2 \\
&\geq 2 \sum_{i=1}^{\lfloor Bc\pi \rfloor} \frac{\sin^2(i\frac{1}{B})}{(i)^2} (e^{-\frac{(Bc\pi)^2}{2\sigma^2}})^2 \\
&\gtrsim 2 \sum_{i=1}^{\lfloor Bc\pi \rfloor} \frac{1}{B^2} (e^{-\frac{(Bc\pi)^2}{2\sigma^2}})^2 \\
&\gtrsim \frac{1}{B} (e^{-\frac{(Bc\pi)^2}{2\sigma^2}})^2 \\
&\gtrsim \frac{1}{B} (e^{-c_0})^2.
\end{aligned}$$

The last inequality follows by there exists some universal constant $c_0 > 0$ such that $-\frac{1}{\log(k/\delta)} \gtrsim -c_0$. Thus, we show $\sum_{i=1}^{M} G_i^2 \gtrsim \frac{1}{B}$. □

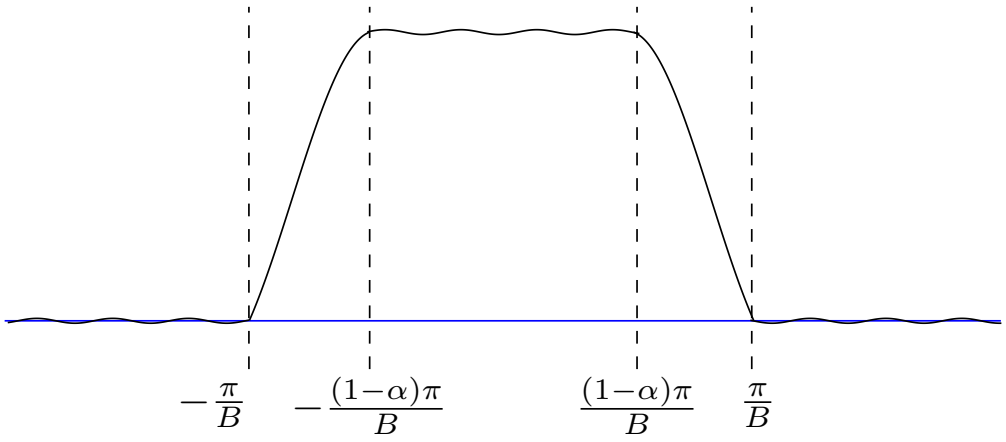

Figure 11.1: Filter $\widehat{G'}(f)$

To analyze the details of our algorithm, we explain some lower-level definitions and claims first. Here we give the definition of three notations that related to hash function.

Definition 11.4.3. $\pi_{\sigma,b}(f) = 2\pi\sigma(f - b) \pmod{2\pi}$. We maps frequency to a circle $[0, 2\pi)$, since our observation of sample is the phase of some complex number, which also belongs to $[0, 2\pi)$.

Definition 11.4.4. $h_{\sigma,b}(f) = \text{round}(\pi_{\sigma,b}(f) \cdot \frac{B}{2\pi})$. $h_{\sigma,b}(f)$ is a "hash function" that hashes frequency f into one of the B bins. The motivation is, it is very likely that each bin only has 1 heavy hitters if we choose large enough B. Then, for each bin, we can run a 1-sparse algorithm to recover the frequency.

Definition 11.4.5. $o_{\sigma,b}(f) = \pi_{\sigma,b}(f) - \frac{2\pi}{B} \cdot h_{\sigma,b}(f)$. Offset $o_{\sigma,b}(f)$ denotes the distance from $\pi_{\sigma,b}(f)$ to the center of the corresponding bin that frequency f was hashed into.

Then we define some events that might happen after applying hash function to the entire frequency domain.

Definition 11.4.6. "Collision" event $E_{coll}(f)$: holds iff $h_{\sigma,b}(f) \in h_{\sigma,b}(\mathrm{supp}(\widehat{x^*})\backslash\{f\})$. The "collision" event happening means there exists some other frequency f' such that both f and f' are hashed into the same bin. Once two frequencies are colliding in one bin, the algorithm will not be able to recover them.

Definition 11.4.7. "Large offset" event $E_{off}(f)$: holds iff $|o_{\sigma,b}(f)| \geq (1-\alpha)\frac{2\pi}{2B}$. The event holds if frequency f is not within factor $1-\alpha$ of the radius close to the center of that hash bin. It causes the frequency to be in the intermediate regime of filter and not recoverable, see Figure 11.1.

Definition 11.4.8. We sample σ uniformly at random from $[\frac{1}{B\eta}, \frac{2}{B\eta}]$. Conditioning on σ is chosen first, we sample b uniformly at random from $[0, \frac{\lceil F/\eta \rceil}{B\sigma}]$. Then we sample γ uniformly at random from $[\frac{1}{2}, 1]$ and β uniformly at random from $[\widehat{\beta}, 2\widehat{\beta}]$, where $\widehat{\beta}$ is dynamically changing during our algorithm(The details of setting $\widehat{\beta}$ are explained in Lemma 11.3.6). For $P_{\sigma,\gamma,b}$ and $P_{\sigma,\gamma+\beta,b}$, we take the following two sets of samples over time domain,

$$x(\sigma(1-\gamma)), x(\sigma(2-\gamma)), x(\sigma(3-\gamma)), \cdots, x(\sigma(B\log(k/\delta)-\gamma))$$
$$x(\sigma(1-\gamma-\beta)), x(\sigma(2-\gamma-\beta)), x(\sigma(3-\gamma-\beta)), \cdots, x(\sigma(B\log(k/\delta)-\gamma-\beta))$$

Conditioning on drawing σ, b from some distribution, we are able to show that the probability of "Collision" and "Large offset" event holding are small.

Lemma 11.4.3. *For any $\widetilde{T}$, and $0 \leq \widetilde{\epsilon}, \widetilde{\delta} \leq \widetilde{T}$, if we sample $\widetilde{\sigma}$ uniformly at random from $[A, 2A]$, then*

$$\frac{2\widetilde{\epsilon}}{\widetilde{T}} - \frac{2\widetilde{\epsilon}}{A} \leq \Pr\left[\widetilde{\sigma} \pmod{\widetilde{T}} \in [\widetilde{\delta}-\widetilde{\epsilon}, \widetilde{\delta}+\widetilde{\epsilon}\,]\right] \leq \frac{2\widetilde{\epsilon}}{\widetilde{T}} + \frac{4\widetilde{\epsilon}}{A}. \tag{11.9}$$

Proof. Since we sample $\widetilde{\sigma}$ uniformly at random from $[A, 2A]$, let I denote a set of candidate integers, then the smallest one is $\lfloor A \rfloor$ and the largest one is $\lceil 2A \rceil$. Thus, the original probability equation is equivalent to

$$\Pr\left[\widetilde{\sigma} \in [s \cdot \widetilde{T} + \widetilde{\delta} - \widetilde{\epsilon}, s \cdot \widetilde{T} + \widetilde{\delta} + \widetilde{\epsilon}\,] \; \exists s \in I\right], \tag{11.10}$$

where $I = \{\lfloor A/\widetilde{T} \rfloor, \cdots, \lceil 2A/\widetilde{T} \rceil\}$.

Consider any $s \in I$, the probability of $\widetilde{\sigma}$ belonging to the interval $[s\cdot\widetilde{T}+\widetilde{\delta}-\widetilde{\epsilon}, s\cdot\widetilde{T}+\widetilde{\delta}+\widetilde{\epsilon}]$ is

$$\Pr\left[\widetilde{\sigma} \in [s \cdot \widetilde{T} + \widetilde{\delta} - \widetilde{\epsilon}, s \cdot \widetilde{T} + \widetilde{\delta} + \widetilde{\epsilon}\,]\right] = \frac{2\widetilde{\epsilon}}{A}.$$

Taking the summation over all $s \in I$, we obtain

$$\begin{aligned}
& \Pr\left[\widetilde{\sigma} \in [s \cdot \widetilde{T} + \widetilde{\delta} - \widetilde{\epsilon}, s \cdot \widetilde{T} + \widetilde{\delta} + \widetilde{\epsilon}\,] \; \exists s \in I\right] \\
= & \sum_{s \in I} \Pr\left[\widetilde{\sigma} \in [s \cdot \widetilde{T} + \widetilde{\delta} - \widetilde{\epsilon}, s \cdot \widetilde{T} + \widetilde{\delta} + \widetilde{\epsilon}\,]\right] \\
= & \sum_{s \in I} \frac{2\widetilde{\epsilon}}{A} \\
= & \frac{2\widetilde{\epsilon}|I|}{A}.
\end{aligned}$$

It remains to bound $\frac{2\widetilde{\epsilon}|I|}{A}$. Since $|I| = \lceil 2A/\widetilde{T} \rceil - \lfloor A/\widetilde{T} \rfloor + 1$, then we have an upper bound for I,

$$|I| \leq A/\widetilde{T} + 2.$$

On the other side, we have an lower bound,

$$|I| \geq A/\widetilde{T} - 1.$$

Plugging upper bound of I into $\frac{2\widetilde{\epsilon}|I|}{A}$,

$$\frac{2\widetilde{\epsilon}|I|}{A} \leq \frac{2\widetilde{\epsilon}}{A}(A/\widetilde{T}+2) = \frac{2\widetilde{\epsilon}}{\widetilde{T}} + \frac{4\widetilde{\epsilon}}{A}.$$

Using the lower bound of $|I|$, we have

$$\frac{2\widetilde{\epsilon}|I|}{A} \geq \frac{2\widetilde{\epsilon}}{A}(A/\widetilde{T}-1) = \frac{2\widetilde{\epsilon}}{\widetilde{T}} - \frac{2\widetilde{\epsilon}}{A}.$$

Thus, we complete the proof. □

The following corollary will be used many times in this paper. The proof directly follows by Lemma 11.4.3.

Corollary 11.4.4. *For any $\widetilde{T}$, Δf, and $0 \leq \widetilde{\epsilon}, \widetilde{\delta} \leq \widetilde{T}$, if we sample $\widetilde{\sigma}$ uniformly at random from $[A, 2A]$, then*

$$\frac{2\widetilde{\epsilon}}{\widetilde{T}} - \frac{2\widetilde{\epsilon}}{A\Delta f} \leq \Pr\left[\widetilde{\sigma}\Delta f \pmod{\widetilde{T}} \in [\widetilde{\delta}-\widetilde{\epsilon}, \widetilde{\delta}+\widetilde{\epsilon}\,]\right] \leq \frac{2\widetilde{\epsilon}}{\widetilde{T}} + \frac{4\widetilde{\epsilon}}{A\Delta f}. \tag{11.11}$$

Proof. Since $\widetilde{\sigma}$ is sampled uniformly at random from $[A, 2A]$, then $\widetilde{\sigma}\Delta f$ is sampled uniformly at random from $[A\Delta f, 2A\Delta f]$. Now applying Lemma 11.4.3 by only replacing $A\Delta f$ by A. □

Claim 11.4.5. *Let σ be sampled uniformly at random from $[\frac{1}{B\eta}, \frac{2}{B\eta}]$ and $\min_{i\neq j}|f_i - f_j| > \eta$. $\forall i, j \in [k]$, if $i \neq j$, then $\Pr[h_{\sigma,b}(f_i) = h_{\sigma,b}(f_j)] \lesssim \frac{1}{B}$.*

Proof. To simplify the proof, define $\Delta f = |f_i - f_j|$. We consider two cases: (I) $\eta \leq |f_i - f_j| < \frac{(B-1)\eta}{2}$, (II) $\frac{(B-1)\eta}{2} \leq |f_i - f_j|$.

(I) If $\Delta f = \eta$, then $2\pi\sigma\Delta f$ is at least $\frac{2\pi}{\eta B} \cdot \eta = \frac{2\pi}{B}$, which means two frequencies have to go to different bins after hashing. If $\Delta f = \frac{(B-1)\eta}{2}$, then $2\pi\sigma\Delta f$ is at most $\frac{4\pi}{B\eta} \cdot \frac{(B-1)\eta}{2} =$

$(1-1/B)2\pi$. In order to make two frequencies collide, $2\pi\sigma\Delta f$ should belong to $[(1-1/B)2\pi, (1+1/B)2\pi)$. Since for any $\Delta f \in [\eta, \frac{(B-1)\eta}{2})$, we have $2\pi\sigma\Delta f \in [\frac{1}{B}2\pi, (1-1/B)2\pi)$, which does not intersect interval $[(1-1/B)2\pi, (1+1/B)2\pi)$. Thus,

$$\Pr_{\sigma,b}[h_{\sigma,b}(f_i) = h_{\sigma,b}(f_j)] = 0.$$

(II) We apply Corollary 11.4.4 by setting $\widetilde{T} = 2\pi$, $\widetilde{\sigma} = 2\pi\sigma$, $\widetilde{\delta} = 0$, $\widetilde{\epsilon} = \frac{2\pi}{2B}$, $A = 2\pi\frac{1}{B\eta}$. Then we have

$$\Pr_{\sigma,b}[h_{\sigma,b}(f_i) = h_{\sigma,b}(f_j)] = \Pr_{\sigma,b}\left[2\pi\sigma\Delta f \in \left[s\cdot 2\pi - \frac{2\pi}{2B}, s\cdot 2\pi + \frac{2\pi}{2B}\right] \exists\ s\ \in\ I\right] \quad (11.12)$$

where

$$I = \left\{\lfloor \frac{1}{B\eta}\Delta f\rfloor, \cdots, \lceil \frac{2}{B\eta}\Delta f\rceil\right\}.$$

By upper bound of Corollary 11.4.4, Equation (11.12) is at most

$$\frac{1}{\frac{2\pi}{B\eta}\Delta f}\cdot\frac{2\pi}{B}\cdot(\frac{1}{B\eta}\Delta f + 2) = \frac{1}{B} + \frac{2\eta}{\Delta f} \le \frac{1}{B} + \frac{4}{B-1} \lesssim \frac{1}{B},$$

where the first inequality follows by $\frac{(B-1)\eta}{2} \le |f_i - f_j|$ which is the assumption of part (II).

□

Claim 11.4.6. $\forall f, \forall\ 0<\alpha<1$, $\Pr_{\sigma,b}\left[|o_{\sigma,b}(f)| \le (1-\alpha)\frac{2\pi}{2B}\right] \ge 1 - O(\alpha)$.

Proof. Since we draw σ uniformly at random from $[\frac{1}{B\eta}, \frac{2}{B\eta}]$, then $2\pi\sigma(f-b) \in [\frac{2\pi}{B\eta}(f-b), \frac{4\pi}{B\eta}(f-b)]$ uniformly at random. The probability is equal to

$$\Pr_{\sigma,b}\left[2\pi\sigma(f-b) \in \left[s\cdot\frac{2\pi}{B} - (1-\alpha)\frac{2\pi}{2B}, s\cdot\frac{2\pi}{B} + (1-\alpha)\frac{2\pi}{2B}\right]\ \exists s\in I\right],$$

where

$$I = \left\{ \lfloor \frac{2\pi}{B\eta}(f-b)\frac{B}{2\pi} - \frac{1-\alpha}{2} \rfloor, \cdots, \lceil \frac{4\pi}{B\eta}(f-b)\frac{B}{2\pi} + \frac{1-\alpha}{2} \rceil \right\}.$$

We apply Corollary 11.4.4 by setting $\widetilde{T} = \frac{2\pi}{B}$, $\widetilde{\sigma} = 2\pi\sigma$, $\widetilde{\delta} = 0$, $\widetilde{\epsilon} = (1-\alpha)\frac{2\pi}{2B}$, $A = 2\pi\frac{1}{B\eta}$, $\Delta f = |f-b|$.

By lower bound of Corollary 11.4.4, we have

$$\Pr\left[|o_{\sigma,b}(f)| \leq (1-\alpha)\frac{2\pi}{2B}\right] \geq (1-\alpha) - (1-\alpha)\cdot\frac{\eta}{|f-b|}.$$

Since $\alpha \cdot \frac{\eta}{|f-b|} > 0$, then

$$\Pr\left[|o_{\sigma,b}(f)| \leq (1-\alpha)\frac{2\pi}{2B}\right] \geq (1-\alpha) - \frac{\eta}{|f-b|}.$$

Recall that we sample σ uniformly at random from $[\frac{1}{B\eta}, \frac{2}{B\eta}]$ and sample b uniformly at random from $[0, \frac{\lceil F/\eta \rceil}{B\sigma}]$. Since $f \in [-F, F]$ and b is uniformly chosen from range $(0, \frac{\lceil F/\eta \rceil}{B\sigma}]$, thus for any $C > 0$, $\Pr_b[|f-b| \leq C\eta] \lesssim \frac{C\eta}{F}$. Replacing C by $1/\alpha$, we have $\Pr[\frac{\eta}{|f-b|} \leq \alpha] \geq 1 - \Theta(\frac{\eta}{\alpha F})$. Compared to $\frac{\eta}{F}$, α is just a constant. Thus, we finish the proof.

□

11.5 Proofs of basic hashing-related lemmas

Lemma 11.3.1. Let (v, f) and (v', f') denote any two tones, i.e., (magnitude, frequency) pairs. Then for

$$\operatorname{dist}\left((v,f),(v',f')\right)^2 := \frac{1}{T}\int_0^T \left|ve^{2\pi ft\mathbf{i}} - v'e^{2\pi f't\mathbf{i}}\right|^2 \mathrm{d}t,$$

we have

$$\operatorname{dist}\left((v,f),(v',f')\right)^2 \eqsim (|v|^2 + |v'|^2)\cdot\min(1, T^2|f-f'|^2) + |v-v'|^2,$$

and

$$\operatorname{dist}\left((v,f),(v',f')\right) \eqsim |v|\cdot\min(1, T|f-f'|) + |v-v'|.$$

Proof. Define $\nu = |f - f'|$. First, let's show the first upper bound. We have that

$$\begin{aligned}
\text{LHS} &= \frac{1}{T}\int_0^T \left|ve^{2\pi ft\mathbf{i}} - v'e^{2\pi f't\mathbf{i}}\right|^2 \mathrm{d}t \\
&\le 2\cdot\frac{1}{T}\int_0^T \left|ve^{2\pi ft\mathbf{i}} - ve^{2\pi f't\mathbf{i}}\right|^2 + \left|ve^{2\pi f't\mathbf{i}} - v'e^{2\pi f't\mathbf{i}}\right|^2 \mathrm{d}t \\
&= 2|v|^2\cdot\frac{1}{T}\int_0^T \left|e^{2\pi\nu t\mathbf{i}} - 1\right|^2 \mathrm{d}t + 2|v-v'|^2 \\
&\le 2|v|^2\cdot\frac{1}{T}\int_0^T \min(2, 2\pi\nu t)^2 \mathrm{d}t + 2|v-v'|^2 \\
&\le 2|v|^2\cdot\min(4, \frac{4\pi^2}{3}\nu^2T^2) + 2|v-v'|^2,
\end{aligned}$$

as desired.

Now consider the lower bound. First we show this in the setting where $|v| = |v'|$.

Suppose $v' = ve^{-\theta \mathbf{i}}$. Then we want to bound

$$\begin{aligned}\text{LHS} &= \frac{1}{T}\int_0^T \left|ve^{2\pi f t\mathbf{i}} - ve^{(2\pi f' t-\theta)\mathbf{i}}\right|^2 \mathrm{d}t \\ &= |v|^2 \frac{1}{T}\int_0^T \left|e^{(2\pi\nu t+\theta)\mathbf{i}} - 1\right|^2 \mathrm{d}t,\end{aligned}$$

as being at least $\Omega(|v|^2(\min(1, \nu^2T^2) + \theta^2))$. In the case that $\nu T < 1/10$, then

$$\left|e^{(2\pi\nu t+\theta)\mathbf{i}} - 1\right| \gtrsim |2\pi\nu t + \theta|,$$

and

$$\mathop{\mathbb{E}}_{t}[(2\pi\nu t + \theta)^2] \geq (\theta - \frac{2\pi\nu T}{2})^2 + \mathbb{E}[(2\pi\nu(t - T/2))^2] \gtrsim \nu^2T^2 + (\theta - \frac{2\pi\nu T}{2})^2 \gtrsim \nu^2T^2 + \theta^2.$$

On the other hand, if $\nu T > 1/10$, then $2\pi\nu t - \theta$ is $\Omega(1)$ for at least a constant fraction of the t, giving that

$$\left|e^{(2\pi\nu t+\theta)\mathbf{i}} - 1\right| \gtrsim 1.$$

Hence the lower bound holds whenever $|v| = |v'|$.

Finally, consider the lower bound for $|v| \neq |v'|$. Without loss of generality assume $|v'| \geq |v|$, and define $v^* = \frac{|v|}{|v'|}v''$. For any two angles θ, θ' we have that

$$|ve^{\theta\mathbf{i}} - v'e^{\theta'\mathbf{i}}|^2 \geq |ve^{\theta\mathbf{i}} - v^*e^{\theta'\mathbf{i}}|^2 + |v^* - v'|^2,$$

because the angle $\angle vv^*v'$ is obtuse. Therefore

$$\begin{aligned}\text{LHS} &\geq \frac{1}{T}\int_0^T \left|ve^{2\pi f t\mathbf{i}} - v^*e^{2\pi f' t\mathbf{i}}\right|^2 + |v^* - v'|^2 \mathrm{d}t \\ &\gtrsim |v|^2 \min(1, \nu^2T^2) + |v - v^*|^2 + |v^* - v'|^2 \\ &\gtrsim |v|^2 \min(1, \nu^2T^2) + |v - v'|^2.\end{aligned}$$

Now, if $|v'|^2 \leq 2|v|^2$, this gives the desired bound. But otherwise, it also gives the desired bound because $|v - v'|^2 \gtrsim |v'|^2$. So we get the bound in all settings.

The second equation follows from the first, using that $(a+b)^2 \eqsim a^2 + b^2$ for positive a, b to show

$$\operatorname{dist}((v,f),(v',f')) \eqsim (|v| + |v'|) \cdot \min(1, T|f - f'|) + |v - v'|.$$

We can then replace $|v| + |v'|$ with $|v|$ because either they are equivalent up to constants or $|v - v'|$ is within a constant factor of $|v| + |v'|$. □

Lemma 11.3.3. If $x^*(t) = 0, \forall t \in [0, T]$, then

$$\mathop{\mathbb{E}}_{\sigma,a,b}\left[\sum_{j=1}^{B} |\widehat{u}_j|^2\right] \lesssim \frac{1}{T}\int_0^T |g(t)|^2 \mathrm{d}t.$$

Proof. Since $\widehat{u}_j = \mathrm{FFT}(u_j)$, then $\sum_{j=1}^{B} |\widehat{u}_j|^2 = B\sum_{j=1}^{B} |u_j|^2$. Recall that $(P_{\sigma,a,b}x)(t) = x(\sigma(t-a))e^{2\pi\sigma bt\mathbf{i}}$, $u_j = \sum_{i=1}^{\log(k/\delta)} y_{j+Bi}$ and $y_j = G_j \cdot (P_{\sigma,a,b}g)_j = G_j \cdot g(\sigma(j-a))e^{2\pi\mathbf{i}\sigma bj}$. Then

$$\begin{aligned}
\mathop{\mathbb{E}}_{\sigma,a,b}\left[\sum_{j=1}^{B} |u_j|^2\right] &= \mathop{\mathbb{E}}_{\sigma,a,b}\left[\sum_{j=1}^{B}\left|\sum_{i=1}^{\log(k/\delta)} y_{j+Bi}\right|^2\right] \\
&= \mathop{\mathbb{E}}_{\sigma,a}\left[\sum_{j=1}^{B}\mathop{\mathbb{E}}_{b}\left|\sum_{i=1}^{\log(k/\delta)} y_{j+Bi}\right|^2\right] \\
&= \mathop{\mathbb{E}}_{\sigma,a}\left[\sum_{j=1}^{B}\mathop{\mathbb{E}}_{b}\left[\left(\sum_{i=1}^{\log(k/\delta)} y_{j+Bi}\right)\left(\sum_{i'=1}^{\log(k/\delta)} \overline{y_{j+Bi'}}\right)\right]\right] \\
&= \mathop{\mathbb{E}}_{\sigma,a}\left[\sum_{j=1}^{B}\mathop{\mathbb{E}}_{b}\left[\sum_{i=1}^{\log(k/\delta)} y_{j+Bi}\overline{y_{j+Bi}} + \sum_{i\neq i'}^{\log(k/\delta)} y_{j+Bi}\overline{y_{j+Bi'}}\right]\right].
\end{aligned}$$

For any $(i,j) \in [\log(k/\delta)] \times [B]$, let $S_{i,j} = G_{j+Bi} g(\sigma(j+Bi-a)) = y_{j+Bi} e^{-2\pi \mathbf{i} \sigma b(j+Bi)}$, then

$$\mathop{\mathbb{E}}_{\sigma,a,b}\left[\sum_{j=1}^{B} |u_j|^2\right] = \mathop{\mathbb{E}}_{\sigma,a}\left[\sum_{j=1}^{B} \mathop{\mathbb{E}}_{b}\left[\underbrace{\sum_{i=1}^{\log(k/\delta)} |S_{i,j}|^2}_{C_1} + \underbrace{\sum_{i\neq i'}^{\log(k/\delta)} S_{i,j}\overline{S_{i',j}} e^{2\pi \mathbf{i}\sigma b B(i-i')}}_{C_2}\right]\right].$$

Consider the expectation of C_2:

$$\begin{aligned}
\mathop{\mathbb{E}}_{b}[C_2] &= \mathop{\mathbb{E}}_{b}\left[\sum_{i\neq i'}^{\log(k/\delta)} S_{i,j}\overline{S_{i',j}} e^{2\pi \mathbf{i}\sigma b B(i-i')}\right] \\
&= \sum_{i\neq i'}^{\log(k/\delta)} S_{i,j}\overline{S_{i',j}} \mathop{\mathbb{E}}_{b}\left[e^{2\pi \mathbf{i}\sigma b B(i-i')}\right] \\
&= 0 \qquad \text{by Definition 11.4.8} \qquad (11.13)
\end{aligned}$$

Note that term C_1 is independent of b which means $\mathop{\mathbb{E}}_{b} C_1 = C_1$. Thus, we can remove the expectation over b. Then,

$$\begin{aligned}
\mathop{\mathbb{E}}_{\sigma,a,b}\left[\sum_{j=1}^{B} |u_j|^2\right] &= \mathop{\mathbb{E}}_{\sigma,a}\left[\sum_{j=1}^{B}\sum_{i=1}^{\log(k/\delta)} |G_{j+Bi}|^2 \cdot |g(\sigma(j+Bi-a))|^2\right] \\
&= \mathop{\mathbb{E}}_{\sigma,a}\left[\sum_{i=1}^{B\log(k/\delta)} |G_i|^2 \cdot |g(\sigma(i-a))|^2\right].
\end{aligned}$$

Now, the idea is to replace the expectation term $\mathbb{E}_a$ by an integral term $\int_{a\in A}(\star)\mathrm{d}a$. Then, replace it by another integral term $\int_0^T(\star)\mathrm{d}t$. Let A denote a set of intervals that we will sample a from. It is easy to verify that $|A| \lesssim T/\sigma$, since $(\sigma(i-a))$ is sampled from $[0,T]$. If we choose T to be a constant factor larger than $\sigma|\operatorname{supp}(G)|$, then we also have $|A| \gtrsim T/\sigma$.

$$\begin{aligned}
\mathop{\mathbb{E}}_{\sigma}\left[\mathop{\mathbb{E}}_{a}\left[\sum_{i=1}^{B\log(k/\delta)}|G_i|^2\cdot|g(\sigma(i-a))|^2\right]\right] &= \mathop{\mathbb{E}}_{\sigma}\left[\frac{1}{|A|}\int_{a\in A}\sum_{i=1}^{B\log(k/\delta)}|G_i|^2\cdot|g(\sigma(i-a))|^2\mathrm{d}a\right] \\
&= \mathop{\mathbb{E}}_{\sigma}\left[\sum_{i=1}^{B\log(k/\delta)}|G_i|^2\cdot\frac{1}{|A|}\int_{a\in A}|g(\sigma(i-a))|^2\mathrm{d}a\right] \\
&= \mathop{\mathbb{E}}_{\sigma}\left[\sum_{i=1}^{B\log(k/\delta)}|G_i|^2\cdot\frac{1}{\sigma|A|}\int_{a\in A}|g(\sigma(i-a))|^2\mathrm{d}\sigma a\right] \\
&\lesssim \mathop{\mathbb{E}}_{\sigma}\left[\|G\|_2^2\cdot\frac{1}{T}\int_0^T|g(t)|^2\mathrm{d}t\right].
\end{aligned}$$

By Claim 11.4.2, we know that $\|G\|_2^2 \eqsim \frac{1}{B}$. Combining $\sum_{j=1}^{B}|\widehat{u}_j|^2 = B\sum_{j=1}^{B}|u_j|^2$ and $\|G\|_2^2 \eqsim \frac{1}{B}$ gives the desired result. □

Lemma 11.3.4. If $g(t) = 0, \forall t \in [0,T]$. Let H denote a set of frequencies, $H = \{f \in \mathrm{supp}(\widehat{x}^*) \mid \text{neither } E_{coll}(f) \text{ nor } E_{off}(f) \text{ holds}\}$. Then,

$$\mathop{\mathbb{E}}_{\sigma,a,b}\left[\sum_{f\in H}\left|\widehat{u}_{h_{\sigma,b}(f)} - \widehat{x^*}(f)e^{a\sigma 2\pi f\mathbf{i}}\right|^2\right] \le \delta\|\widehat{x^*}\|_1^2.$$

Proof. For simplicity, let $G = G_{B,\delta,\alpha}$ and $\widehat{G'} = \widehat{G'}_{B,\delta,\alpha}$. we have

$$\begin{aligned}
\widehat{y} &= G\widehat{\cdot P_{\sigma,a,b}x} \\
&= \widehat{G} * \widehat{P_{\sigma,a,b}x} \\
&= \widehat{G'} * \widehat{P_{\sigma,a,b}x} + (\widehat{G} - \widehat{G'}) * \widehat{P_{\sigma,a,b}x}.
\end{aligned}$$

The ℓ_∞ norm of second term can be bounded :

$$\|(\widehat{G} - \widehat{G'}) * \widehat{P_{\sigma,a,b}x}\|_\infty \le \|\widehat{G} - \widehat{G'}\|_\infty\|\widehat{P_{\sigma,a,b}x}\|_1 \le \sqrt{\delta/k}\|\widehat{x^*}\|_1.$$

Thus, consider the jth term of $\widehat{u}$,

$$\begin{aligned}
\widehat{u}_j &= \widehat{y}_{jF/B} \\
&= \sum_{|l|<F/(2B)} \widehat{G'}_{-l}(\widehat{P_{\sigma,a,b}x})_{jF/B+l} \pm \sqrt{\delta/k}\|\widehat{x^*}\|_1 \\
&= \sum_{|\pi_{\sigma,b}(f)-jF/B|<F/(2B)} \widehat{G'}_{jF/B-\pi_{\sigma,b}(f)}\widehat{P_{\sigma,a,b}x}_{\pi_{\sigma,b}(f)} \pm \sqrt{\delta/k}\|\widehat{x^*}\|_1 \\
&= \sum_{h_{\sigma,b}(f)=j} \widehat{G'}_{-o_{\sigma,b}(f)}\widehat{x^*}(f)e^{2\pi f\sigma a\mathbf{i}} \pm \sqrt{\delta/k}\|\widehat{x^*}\|_1.
\end{aligned}$$

If neither $E_{coll}(f)$ nor $E_{off}(f)$ happens, then we know that frequency f is the only heavy hitter hashed into bin j and $\widehat{G'}_{-o_{\sigma,b}(f)} = 1$ for frequency f. Thus,

$$\mathop{\mathbb{E}}_{\sigma,a,b}\left[\left|\widehat{u}_{h_{\sigma,b}(f)} - \widehat{x^*}(f)e^{a\sigma 2\pi f\mathbf{i}}\right|^2\right] \leq \delta/k\|\widehat{x^*}\|_1^2.$$

Since the above equation holds for all $f \in H$, we get

$$\sum_{f\in H}\mathop{\mathbb{E}}_{\sigma,a,b}\left[\left|\widehat{u}_{h_{\sigma,b}(f)} - \widehat{x^*}(f)e^{a\sigma 2\pi f\mathbf{i}}\right|^2\right] \leq k\delta/k\|\widehat{x^*}\|_1^2 = \delta\|\widehat{x^*}\|_1^2.$$

□

11.6 Proofs for one stage of recovery

Binary search of one-sparse algorithm We first explain a simple, clean, but not optimal one-sparse algorithm, then we try to optimize the algorithm step by step. Let "heavy" frequency $f \in [-F, F]$, we can split the frequency interval into two regions: left region $[-F, 0)$ and right region $[0, F]$. We can observe $\theta \equiv 2\pi\beta f \pmod{2\pi}$ by checking the phase difference between using $P_{1,a,b}$ and $P_{1,a+\beta,b}$, where β is uniformly at random sampled from some suitable range $[\widehat{\beta}, 2\widehat{\beta}]$. For each observation θ, we can guess m different possibilities for f, say $\theta_1, \theta_2, \cdots, \theta_m$, if θ_i belong to the left region, we add a vote to that, otherwise we add a vote to the right region. After taking enough samples, we choose the region that has the largest vote. This decision will let us narrow down the searching range of the true frequency by half with some good probability. Suppose we decide to choose the right region $[0, F]$, then we can just repeat the above binary search over $[0, F]$ again to get into a region that has size $F/2$. Repeating it D times, we can learn the frequency with a region that has size at most $2F/2^D$. But the binary search is not the best approach, actually, we can do much better with using t-ary search.

k-sparse To locate those k heavy signals in the frequency domain, we need to consider the "bins" computed by HashToBins with $P_{\sigma,a,b}$. One of the main difference from previous work [HIKP12a] is, instead of permuting the discrete coordinates according to $P_{\sigma,a,b}$ and partitioning the coordinates into $B = O(k)$ bins, we permute the continuous frequency domain and partition the frequency domain into $B = O(k)$ bins. With a large constant probability, we can obtain for each heavy signal f that neither E_{coll} nor E_{off} happens. After splitting those k frequencies into different bins, then we can run the one-sparse algorithm

for all the bins simultaneously.

t-ary search To argue the final succeed probability of our algorithm, we need to take the union bound for each array/region in each round and also take the union bound over each round. There are several benefits of changing binary search to t-ary search, (1) to reach the same accuracy, the number of rounds D for t-ary search is smaller than the number of rounds for binary search; (2) our searching procedure is a "noisy" searching problem, for the noiseless version of the searching problem, we do not need to take care of the union bound argument. Having a parameter for the number of arrays/regions is important to optimize the entire procedure.

Recall the traditional binary search problem(noiseless version), given a list of sorted numbers $a[1, 2 \cdots, n]$ in increasing order. We want to determine if some number x belongs to $a[1, 2, \cdots, n]$. When we compare some $a[i]$ with x, we will know the true answer.

But the noisy binary search problem is slightly harder. $a[1, 2, \cdots, n]$ is still a list of sorted numbers in increasing order, we want to determine if some number x belongs to $a[1, 2, \cdots, n]$. But when we compare the $a[i]$ with x, we will know the true answer with $9/10$ probability, and get the false answer with $1/10$ probability. In this case, we can not finish the task by following the procedure of traditional binary search algorithm, e.g. making the decision by just comparing $a[i]$ with x once. The reason is after taking the union bound of $\log n$ rounds, the failure probability can be arbitrarily large. One idea to fix this issue is independently comparing $a[i]$ with x multiple times, e.g. $\log \log n$ times. Then we can amplify the succeed probability of each round from $9/10$ to $1 - \frac{1}{\text{poly}(\log n)}$, after taking the union bound over $\log n$ rounds, we still have $1 - \frac{1}{\text{poly}(\log n)}$ succeed probability.

Our problem is still more complicated than the above noisy binary search problem. In each round of algorithm LocateInner, we do a t-array search by splitting the candidate frequency region(that has length Δl) into t consecutive regions, $Q_1, Q_2, \cdots, Q_t$, each of them has the equal size $\frac{\Delta l}{t}$. By using the hash values of $P_{\sigma,a,b}$ and $P_{\sigma,a+\beta,b}$ (Line 26-27 in Algorithm 11.2), we can have an observation over $[0, 2\pi)$. For each such observation over $[0, 2\pi)$, it was in fact scaled by $2\pi\sigma\beta$ and rounded over $[0, 2\pi)$. Thus the corresponding frequency location of this observation might belong to $m = \Theta(\sigma\beta\Delta l)$ different possible regions. Since we do not know which one, we just add a vote to all of the possible regions. To understand t-ary search, let's consider this example. Suppose we split the frequency into 20 regions, the true frequency belongs to region 9 and each observation is correct with probability 4/5. For each observation, we will add a vote to a batch of roughly evenly spaced regions.

1. For the observation 1, we add a vote to region $1, 5, 9, 13, 17$.
2. For the observation 2, we add a vote to region $3, 9, 15$.
3. For the observation 3, we add a vote to region $2, 9, 16$.
4. For the observation 4, we add a vote to region $4, 9, 14, 19$.
5. For the observation 5, we add a vote to region $2, 6, 10, 14, 20$.

where the first four observations are the correct observations and the last one is wrong. Then the true region will have more than half of the $R_{loc} = 5$ votes with some good probability.

Details of adding vote In previous description, to let people have a better understanding of t-ary search, we simplify the step of adding vote. In fact, adding a vote to each of the m

candidate region is not enough. The right thing to do is, not only adding a vote to those m regions, but also adding a vote to a constant number c_n of neighbors of each possible region (e.g. two neighbors nearby that region, line 33 in Algorithm 11.2). The reason for doing this is, if the frequency f is located very close to the boundary of two regions, then neither of them will get more than $R_{loc}/2$ votes. After we already have R_{loc} independent observations, we just choose any region that contains more than $R_{loc}/2$ votes and enlarge it by the same constant factor c_n to be the next candidate frequency region for t-array search, and plugging the new parameters into algorithm LocateInner and running it again.

The slightly different last round Recall that, in the previous description of each round of t-ary search, we're able to decrease the searching range of frequency geometrically. To achieve this progress, we have to increase the sample duration of β is geometrically. At some point, the sample duration will reach T. Suppose the sample duration of β is geometrically increasing during the first $D-1$ rounds (Line 13-15 in Algorithm 11.2) and it becomes T after $D-1$ rounds. If we want to use the same duration T to perform one more round again, can we get some benefit for learning the frequency by doing some tricks? (1) Suppose in all the first $D-1$ rounds, we use $R_{loc}(D-1)$ samples. Then we can use $R_{loc}(D-1)$ for the last round, since it does not increase the sample complexity. This way allows us to learn frequency within $\frac{1}{CT}$. But can we do better than that? (2) Using more samples is a nice observation, another right thing to do is changing the algorithm from reporting region to reporting frequency. In the previous $D-1$ rounds, as the description of t-ary search, we just report the region that has more than $R_{loc}/2$ votes. But, we can take the median over all the values that were assigned to any region that has votes more than $R_{loc}/2$. This way

can actually allow us to learn frequency location more accurately ($\approx \frac{1}{\rho T}$) without increasing the resolution for β! Another question people might ask is, if we take median in the last round, why not just do it in every round? The answer is, in the first $D-1$ rounds, our goal is just narrowing down the search range of frequency location and we do not need to report a frequency location. Another reason is reporting a candidate region needs less samples and has higher succeed probability, but taking the median is more expensive than reporting a candidate region. We cannot pay for taking the median in every round.

To prove main Lemma 11.3.6 for one stage recovery, we introduce Lemma 11.6.1. Before explaining the proof, we give some definitions. Consider a frequency f, and define $j = h_{\sigma,b}(f)$ to be the bin that frequency f was hashed into. Define $\theta = f - b \pmod F$. Define

$$\widehat{u} = \textsc{HashToBins}(x, P_{\sigma,\gamma,b}, B, \delta, \alpha) \quad \text{and} \quad \widehat{u}' = \textsc{HashToBins}(x, P_{\sigma,\gamma+\beta,b}, B, \delta, \alpha).$$

Note that "bin" and "region" are representing different things in this paper. "bin" is related to hash function $h_{\sigma,b}(f)$. "region" is only used in the algorithm of one stage recovery in this section. Define "true" region to be the region that contains frequency f. Define "wrong" region to be the region that is not within a constant number c_n of neighbors of the "true" region. Part (I) of Lemma 11.6.1 shows that for each observation generated by a batch of samples drawn from time domain, the counter $v_{j,q'}$ corresponding to the true region will increase by one, with some "good" probability. On the other side, Part (II) of Lemma 11.6.1 shows that the counter $v_{j,q}$ corresponding to wrong region will not increase by one, with some "good" probability. Note that, [HIKP12a] proved the case when $c_n = 6$ under discrete setting, we translate it into continuous setting, here.

Lemma 11.6.1. *Given σ and b. Assume $f \in \text{region}(j, q')$ and $\mathop{\mathbb{E}}_{\gamma}[\left|\widehat{u}_j - e^{2\pi\gamma\sigma\theta\mathbf{i}}\widehat{x}(\theta)\right|^2] \leq \frac{1}{\rho^2}|\widehat{x}(\theta)|^2$. $\forall 0 < s < 1$, for each two samples $(\gamma, 0)$ and (γ, β), where γ is sampled from $[\frac{1}{2}, 1]$ uniformly at random and β is sampled from $[\frac{st}{4\sigma\Delta l}, \frac{st}{2\sigma\Delta l}]$ uniformly at random, we have*

(I) for the q', with probability at least $1 - (\frac{2}{\rho s})^2$, $v_{j,q'}$ will increase by one.

(II) for any q such that $|q - q'| > 3$, with probability at least $1 - 15s$, $v_{j,q}$ will not increase.

Proof. Part (I) of Lemma 11.6.1. We have,

$$\mathop{\mathbb{E}}_{\gamma}[\left|\widehat{u}_j - e^{2\pi\gamma\sigma\theta\mathbf{i}}\widehat{x}(\theta)\right|^2] \leq \frac{1}{\rho^2}|\widehat{x}(\theta)|^2.$$

By Chebyshev's Inequality, we have $\forall\ g > 0$, with probability $1 - g$ we have

$$\left|\widehat{u}_j - e^{2\pi\gamma\sigma\theta\mathbf{i}}\widehat{x}(\theta)\right| \leq \frac{1}{\rho}\sqrt{\frac{1}{g}}\,|\widehat{x}(\theta)|$$
$$\|\phi(\widehat{u}_j) - (\phi(\widehat{x}(\theta)) - 2\pi\gamma\sigma\theta)\|_{\bigcirc} \leq \sin^{-1}(\frac{1}{\rho}\sqrt{\frac{1}{g}}),$$

where $\|x - y\|_{\bigcirc} = \min_{z\in\mathbb{Z}}|x - y + 2\pi z|$ denote the "circular distance" between x and y. Similarly, replacing γ by $\gamma + \beta$, with probability $1 - g$, we also have that

$$\|\phi(\widehat{u}'_j) - (\phi(\widehat{x}(\theta)) - 2\pi(\gamma + \beta)\sigma\theta)\|_{\bigcirc} \leq \sin^{-1}(\frac{1}{\rho}\sqrt{\frac{1}{g}}).$$

Define $c_j = \phi(\widehat{u}_j/\widehat{u}'_j)$. Combining the above two results, with probability $1 - 2g$ we have

$$\begin{aligned}
\|c_j - 2\pi\beta\sigma\theta\|_{\bigcirc} &= \|\phi(\widehat{u}_j) - \phi(\widehat{u}'_j) - 2\pi\beta\sigma\theta\|_{\bigcirc} \\
&= \|(\phi(\widehat{u}_j) - (\phi(\widehat{x}(\theta)) - 2\pi\gamma\sigma\theta))) - (\phi(\widehat{u}'_j) - (\phi(\widehat{x}(\theta)) - 2\pi(\gamma + \beta)\sigma\theta)))\|_{\bigcirc} \\
&\leq \|\phi(\widehat{u}_j) - (\phi(\widehat{x}(\theta)) - 2\pi\gamma\sigma\theta)\|_{\bigcirc} + \|\phi(\widehat{u}'_j) - (\phi(\widehat{x}(\theta)) - 2\pi(\gamma + \beta)\sigma\theta)\|_{\bigcirc} \\
&\leq 2\sin^{-1}(\frac{1}{\rho}\sqrt{\frac{1}{g}}).
\end{aligned}$$

Here, we want to set $g = (\frac{4}{s\pi\rho})^2$, thus, with probability at least $1 - (\frac{2}{s\rho})^2$

$$\|c_j - 2\pi\beta\sigma\theta\|_{\bigcirc} < s\pi/2. \tag{11.14}$$

The above equation shows that c_j is a good estimate for $2\pi\beta\sigma\theta$ with good probability. We will now show that this means the true region $Q_{q'}$ gets a vote with large probability.

For each q' with $f \in [l_j - \frac{\Delta l}{2} + \frac{q'-1}{t}\Delta l, l_j - \frac{\Delta l}{2} + \frac{q'}{t}\Delta l] \subset [-F, F]$, we have that $m_{j,q'} = l_j - \frac{\Delta l}{2} + \frac{q'-0.5}{t}\Delta l$ and $\theta_{j,q'} = m_{j,q'} - b \pmod F$ satisfies

$$|f - m_{j,q'}| \leq \frac{\Delta l}{2t} \text{ and } |\theta - \theta_{j,q'}| \leq \frac{\Delta l}{2t}.$$

Since we sample β uniformly at random from $[\frac{st}{4\sigma\Delta l}, \frac{st}{2\sigma\Delta l}]$, then $\beta \leq \frac{st}{2\sigma\Delta l}$, which implies that $2\pi\beta\sigma\frac{\Delta l}{2t} \leq \frac{s\pi}{2}$. Thus, we can show the observation c_j is close to the true region in the following sense,

$$\begin{aligned}
&\|c_j - 2\pi\beta\sigma\theta_{j,q'}\|_{\bigcirc} \\
\leq &\|c_j - 2\pi\beta\sigma\theta\|_{\bigcirc} + \|2\pi\beta\sigma\theta - 2\pi\beta\sigma\theta_{j,q'}\|_{\bigcirc} \text{ by triangle inequality} \\
< &\frac{s\pi}{2} + 2\pi\|\beta\sigma\theta - \beta\sigma\theta_{j,q'}\|_{\bigcirc} \text{ by Equation (11.14)} \\
\leq &\frac{s\pi}{2} + 2\pi\beta\sigma\frac{\Delta l}{2t} \\
= &\frac{s\pi}{2} + \frac{s\pi}{2} \\
\leq &s\pi.
\end{aligned}$$

Thus, $v_{j,q'}$ will increase in each round with probability at least $1 - (\frac{2}{\rho s})^2$. □

Proof. Part (II) of Lemma 11.6.1.

Consider q with $|q - q'| > 3$. Then $|f - m_{j,q}| \geq \frac{7\Delta l}{2t}$, and (assuming $\beta \geq \frac{st}{4\sigma\Delta l}$) we have

$$2\pi\beta\sigma|f - m_{j,q}| \geq 2\pi\frac{st}{4\sigma\Delta l}\sigma|f - m_{j,q}| = \frac{s\pi t}{2\Delta l}|f - m_{j,q}| \geq \frac{7s\pi}{4} > \frac{3s\pi}{2}. \tag{11.15}$$

There are two cases: $|f - m_{j,q}| \leq \frac{\Delta l}{st}$ and $|f - m_{j,q}| > \frac{\Delta l}{st}$.

First, if $|f - m_{j,q}| \leq \frac{\Delta l}{st}$. In this case, from the definition of β it follows that

$$2\pi\beta\sigma|f - m_{j,q}| \leq \frac{s\pi t}{\sigma\Delta l}\sigma|f - m_{j,q}| \leq \pi. \tag{11.16}$$

Combining equations (11.15) and (11.16) implies that

$$\Pr[2\pi\beta\sigma(f - m_{j,q}) \mod 2\pi \in [-\frac{3s}{4}2\pi, \frac{3s}{4}2\pi]] = 0.$$

Second, if $|f - m_{j,q}| > \frac{\Delta l}{st}$. We show this claim is true: $\Pr[2\pi\beta\sigma(f - m_{j,q}) \pmod{2\pi} \in [-\frac{3s}{4}2\pi, \frac{3s}{4}2\pi]] \lesssim s$. To prove it, we apply Corollary 11.4.4 by setting $\widetilde{T} = 2\pi$, $\widetilde{\sigma} = 2\pi\sigma\beta$, $\widetilde{\delta} = 0$, $\widetilde{\epsilon} = \frac{3s}{4}2\pi$, $A = 2\pi\sigma\widehat{\beta}$, $\Delta f = |f - m_{j,q}|$. By upper bound of Corollary 11.4.4, the probability is at most

$$\frac{2\widetilde{\epsilon}}{\widetilde{T}} + \frac{4\widetilde{\epsilon}}{A\Delta f} = \frac{3s}{2} + \frac{3s}{\sigma\widehat{\beta}\Delta f} \leq \frac{3s}{2} + \frac{3s}{\sigma\frac{st}{4\sigma\Delta l}\frac{\Delta l}{st}} < 15s.$$

Then in either case, with probability at least $1 - 15s$, we have

$$\|2\pi\beta\sigma m_{j,q} - 2\pi\beta\sigma f\|_{\bigcirc} > \frac{3s}{4}2\pi.$$

which implies that $v_{j,q}$ will not increase. □

Lemma 11.3.6. Given σ and b, consider any frequency f for which neither $E_{coll}(f)$ nor $E_{off}(f)$ holds, and let $j = h_{\sigma,b}(f)$. Let $\mu^2(f) = \mathbb{E}_a[|\widehat{u}_j - \widehat{x^*}(f)e^{a\sigma 2\pi f\mathbf{i}}|^2]$ and $\rho^2 = |\widehat{x^*}(f)|^2/\mu^2(f)$. For sufficiently large ρ, and $\forall 0 < s < 1, t \geq 4$, consider any run of LocateInner with $f \in [l_j - \frac{\Delta l}{2}, l_j + \frac{\Delta l}{2}]$. It takes $O(R_{loc})$ random $(\gamma, \beta) \in [\frac{1}{2}, 1] \times [\frac{st}{4\sigma\Delta l}, \frac{st}{2\sigma\Delta l}]$ samples over duration $\beta\sigma = \Theta(\frac{st}{\Delta l})$, runs in $O(stR_{loc})$ time, to learn f within a region that has length $\Theta(\frac{\Delta l}{t})$ with failure probability at most $(\frac{4}{s\rho})^{R_{loc}} + t \cdot (60s)^{R_{loc}/2}$.

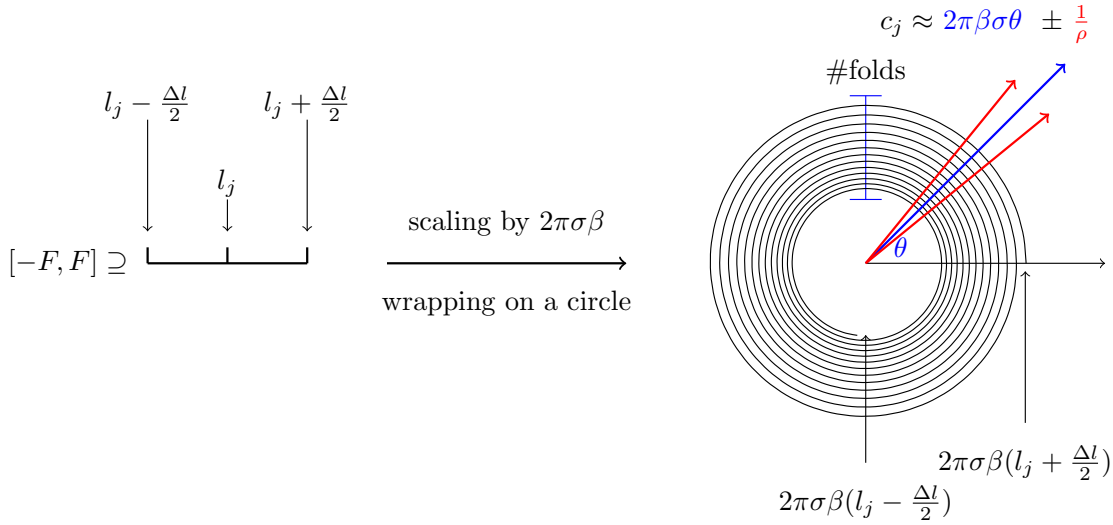

Figure 11.2: For an arbitrary frequency interval $[l_j - \frac{\Delta l}{2}, l_j + \frac{\Delta l}{2}]$, we scale it by $2\pi\sigma\beta$ to get a longer interval $[2\pi\sigma\beta(l_j + \frac{\Delta l}{2}), 2\pi\sigma\beta(l_j - \frac{\Delta l}{2})]$. Then, we wrap the longer interval on a circle $[0, 2\pi)$. The number of folds after wrapping is $\lceil \sigma\beta\Delta l \rceil$. For any random sample, the observation c_j is close to the true answer within $1/\rho$ with some "good" probability.

Proof. Let t denote the number of regions, and $[l_j - \frac{\Delta l}{2}, l_j + \frac{\Delta l}{2}]$ be the interval that contains frequency f. Let Q_q denote a region that is $[l_j - \frac{\Delta l}{2} + (q-1)\frac{\Delta l}{t}, l_j - \frac{\Delta l}{2} + q\frac{\Delta l}{t}]$. Let $\theta = f - b \pmod F$. Recall that we sample σ uniformly at random from $[\frac{1}{B\eta}, \frac{2}{B\eta}]$. Then we sample γ uniformly at random from $[\frac{1}{2}, 1]$ and sample β uniformly at random from $[\frac{st}{4\sigma\Delta l}, \frac{st}{2\sigma\Delta l}]$. Define $c_j = \phi(\widehat{u}_j/\widehat{u}'_j)$. Let m denote the number of folds, which is equal to $\lceil \sigma\beta\Delta l \rceil$. Let $v_{j,q}$ denote the vote of region(j, q).

We hope to show that in any round r, each observed c_j is close to $2\pi\sigma\beta\theta$ with good probability. On the other hand, for each observed c_j, we need to assign it to some regions and increase the vote of the corresponding region. The straightforward way is just checking all possible t regions, which takes $O(t)$ time. In fact, there are only $\Theta(m)$ regions close enough to the observation c_j, where $m = \Theta(\frac{2\pi\sigma\beta\Delta l}{2\pi}) = \Theta(st)$. The reason is $2\pi\sigma\beta$ will scale

the original length Δl interval to a new interval that has length $2\pi\sigma\beta\Delta l$. This new interval can only wrap around circle $[0, 2\pi)$ at most $\lceil \sigma\beta\Delta l \rceil$ times. The running time is $O(stR_{loc})$, since we take R_{loc} independent observations.

For each observed c_j: Part (I) of Lemma 11.6.1 says, we assign it to the true region with some good probability; Part (II) of Lemma 11.6.1 says, we do not assign it to the wrong region with some good probability. Thus taking R_{loc} independent c_j, we can analyze the failure probability of this algorithm based on these three cases.

(I) What's the probability of true fold fails?

$$
\begin{aligned}
& \Pr[\text{True fold fails}] \\
= \; & \Pr[\text{True region fails} \geq R_{loc}/2 \text{ times}] \\
\leq \; & 2 \cdot \binom{R_{loc}}{R_{loc}/2} \cdot (\Pr[\text{True region fails once}])^{R_{loc}/2} \\
\leq \; & 2 \cdot \binom{R_{loc}}{R_{loc}/2} \cdot (\frac{2}{s\rho})^{2R_{loc}/2} \quad \text{by Lemma 11.6.1} \\
\leq \; & (\frac{4}{s\rho})^{R_{loc}}.
\end{aligned}
$$

(II) What if the region that is "near"(within c_n neighbors) true region becomes true?

Any of those region gets a vote only if true region also gets a vote. Since our algorithm choosing any region that has more than $R_{loc}/2$ votes and enlarging the region size by containing c_n nearby neighbors of that chosen region, then the new larger region must contain the "real" true region.

(III) What if the region that is "far away"(not within c_n neighbors) from true region becomes true?

By Part (II) of Lemma 11.6.1, the probability of one such wrong region gets a vote is at most $15s$. Thus, one of the wrong region gets more than $R_{loc}/2$ votes is at most $(60s)^{R_{loc}/2}$. By taking the union bound over all t regions, we have the probability of existing one wrong region getting more than $R_{loc}/2$ vote is at most $t \cdot (60s)^{R_{loc}/2}$.

Thus, if we first find any region Q_q that has more than $R_{loc}/2$ votes, and report a slightly larger region $[l_j - \frac{\Delta l}{2} + (q-1)\frac{\Delta l}{t} - \frac{c_n}{2}\frac{\Delta l}{t}, l_j - \frac{\Delta l}{2} + q\frac{\Delta l}{t} + \frac{c_n}{2}\frac{\Delta l}{t}]$, it is very likely this large region contains the frequency f. Finally, the failure probability of this algorithm is at most $\Theta((\frac{4}{s\rho})^{R_{loc}} + t \cdot (60s)^{R_{loc}/2})$. □

Lemma 11.6.2. *Taking the median of values belong to any region getting at least* $\frac{1}{2}R_{loc}$ *votes, then we can learn frequency* f *within* $\Theta(\frac{\Delta l}{\rho s t})$ *with probability* $1 - \exp(-\Omega(R_{loc}))$.

Proof. Let region(j, q') be the region that getting at least $\frac{1}{2}R_{loc}$ votes. Let $R = |\text{region}(j, q')|$ denote the number of observations/votes assigned to region(j, q'). Since this region getting at least $\frac{1}{2}R_{loc}$ votes, then $\frac{1}{2}R_{loc} \leq R \leq R_{loc}$. Using Equation (11.14) in Lemma 11.6.1, $\forall g > 0$, we have

$$\|c_j - 2\pi\beta\sigma\theta\|_{\bigcirc} \leq 2 \cdot \sin^{-1}\left(\frac{1}{\rho}\sqrt{\frac{1}{g}}\right),$$

holds with probability $1 - 2g$. Choosing $g = \Theta(1)$, we have with constant success probability $p > \frac{1}{2}$,

$$\|c_j - 2\pi\beta\sigma\theta\|_{\bigcirc} \lesssim \frac{1}{\rho},$$

holds.

Taking the median over all the observations that belong to region(j, q') gives

$$
\begin{aligned}
&\Pr\left[\left|\underset{r\in\text{region}(j,q')}{\text{median}} c_j^r - 2\pi\beta^r\sigma\theta\right| \gtrsim \frac{1}{\rho}\right] \\
&< \sum_{i=R/2}^{R_{loc}} \binom{R_{loc}}{i}(1-p)^i p^{R_{loc}-i} \\
&= \sum_{i=R_{loc}/2}^{R_{loc}} \binom{R_{loc}}{i}(1-p)^i p^{R_{loc}-i} + \sum_{i=R/2}^{R_{loc}/2} \binom{R_{loc}}{i}(1-p)^i p^{R_{loc}-i} \\
&< \sum_{i=R_{loc}/2}^{R_{loc}} \binom{R_{loc}}{R_{loc}/2}(1-p)^i + \sum_{i=R/2}^{R_{loc}/2} \binom{R_{loc}}{R_{loc}/2}(1-p)^i \\
&< 2\binom{R_{loc}}{R_{loc}/2}(1-p)^{R/2} \\
&\leq 2(2e)^{R_{loc}/2}(1-p)^{R_{loc}/4} \\
&\leq e^{-cR_{loc}}, \qquad (11.17)
\end{aligned}
$$

where the the second inequality follows by $\binom{R}{i} \leq \binom{R}{R/2}$ and $p^{R_{loc}-i} < 1$, $\forall i$; the fourth inequality follows by $\binom{n}{k} \leq (ne/k)^k$; the last inequality follows by choosing some p such that $\frac{1}{2}\log_{2e}\frac{1}{1-p} - 1 > 2c$ where $c > 0$ is some constant. Equation (11.17) implies that

$$
\Pr\left(\left|\underset{r\in\text{region}(j,q')}{\text{median}} \theta^r - \theta\right| < \frac{1}{\rho 2\pi\sigma\widehat{\beta}}\right) > 1 - \exp(-\Omega(R_{loc})),
$$

where $\forall r \in [R_{loc}]$, β^r is sampled uniformly at random from $[\widehat{\beta}, 2\widehat{\beta}] = [\frac{st}{4\sigma\Delta l}, \frac{st}{2\sigma\Delta l}]$. Thus, we can learn f within $\Theta(\frac{1}{\rho 2\pi\sigma\widehat{\beta}}) = \Theta(\frac{\Delta l}{\rho st})$.

□

Lemma 11.3.7. Algorithm LocateKSignal takes $O(k\log_C(FT)\log(k/\delta))$ samples over $O(\frac{\log(k/\delta)}{\eta})$ duration, runs in $O(k\log_C(FT)\log(FT/\delta))$ time, and outputs a set $L \subset [-F, F]$ of $O(k)$ frequencies with minimum separation $\Omega(\eta)$.

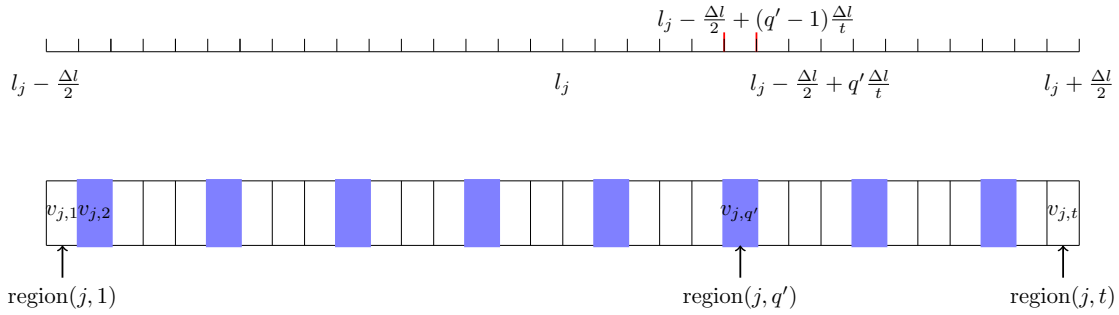

Figure 11.3: The number of "blue" regions is equal to the number of folds m. The number of total regions is t. For each observed c_j, instead of checking all the t regions, we only assign vote to the these "blue" regions. Since only these m "blue" regions can be the candidate region that contains frequency f.

Given σ and b, consider any frequency f for which neither of $E_{coll}(f)$ or $E_{off}(f)$ hold. Let $j = h_{\sigma,b}(f)$, $\mu^2(f) = \mathbb{E}_a[|\widehat{u}_j - \widehat{x^*}(f)e^{a\sigma 2\pi f \mathbf{i}}|^2]$, and $\rho^2 = |\widehat{x^*}(f)|^2/\mu^2(f)$. If $\rho > C$, then with an arbitrarily large constant probability there exists an $f' \in L$ with

$$|f - f'| \lesssim \frac{1}{T\rho}.$$

Proof. Algorithm LocateKSignal rerun procedure LocateInner D times. For the first $D-1$ rounds, the sampling range for β is increased by t every time. For the last round, the sampling range for β is not increasing any more. On the other hand, the sampling range for β for $D-1$ round and the last round are the same.

Recall that, we sample σ uniformly at random from $[\frac{1}{B\eta}, \frac{2}{B\eta}]$. Then we sample γ uniformly at random from $[\frac{1}{2}, 1]$ and β uniformly at random from $[\frac{st}{4\sigma\Delta l}, \frac{st}{2\sigma\Delta l}]$. c_n is some constant for the number of neighbor regions nearby "true" region. In the first $D-1$ rounds, we set $s = 1/\sqrt{C}$, $\Delta l = F/(t')_0^{i-1}, \forall i \in [D-1]$, $t \approx \log(FT)$, and $t' = \frac{t}{c_n+1}$. For the last round, we set $s \approx 1/C$, $\Delta l \approx st/T$ and $t \approx \log(FT)/s$. C is known as "approximation" factor.

Finally, we need to choose depth $D = \log_{t'}(FT/st) \approx \log_{t'}(FT)$ and set $R_{loc} = O(\log_C(tC))$ for all the rounds. Define $DR = \sum_{i=1}^{D} R_{loc}^i$, which is $(D-1)R_{loc} + R_{loc}^D = O(\log_C(FT))$.

After setting all the parameters for the first $D-1$ rounds and the last round, we explain some intuitions and motivations for setting the last round in a different way of the first $D-1$ rounds. For the first $D-1$ rounds, it is not acceptable to have constant failure probability for each round, since we need to take the union bound over $D-1$ rounds. But, for the last round, it is acceptable to allow just constant failure probability, since it is just a single round. That's the reason for setting C in a different way.

We have the following reason for choosing the number of regions($= t$) in the last round larger than that of first $D-1$ rounds. For the first $D-1$ rounds, we do not need to learn frequency within $\approx \frac{1}{T\rho}$. It is enough to know which region does frequency belong to, although the diameter of the region is large at the beginning. The algorithm is making progress round by round, since the diameter of each region is geometrically decreasing while $\widehat{\beta}$ is geometrically increasing. For the last round, by Lemma 11.6.2, we can learn f within $\Theta(\frac{\Delta l}{\rho st})$. Since after the last round, we hope to learn frequency within $\frac{1}{T\rho}$, thus we need to choose some s, t and Δl such that $\frac{1}{T} \approx \frac{\Delta l}{st}$. To get more accuracy result in the last round, we'd like to choose a larger t. But there is no reason to increase $\widehat{\beta}$ again, since the $\widehat{\beta}$ of the $(D-1)$th rounds can tolerance the t we choose at the last round.

To show the constant succeed probability of this Lemma, we separately consider about the failure probability of the first $D-1$ rounds and the last round. By the union bound,

the probability of existing one of the first $D-1$ rounds is failing is,

$$\begin{aligned}
& (D-1)\left((\frac{4}{s\rho})^{R_{loc}}+t\cdot(60s)^{R_{loc}/2}\right)\\
\leq\ & D\left((\frac{4}{s\rho})^{R_{loc}}+t\cdot(60s)^{R_{loc}/2}\right)\\
\leq\ & D\left((\frac{4}{sC})^{R_{loc}}+t\cdot(60s)^{R_{loc}/2}\right) \text{ by } \rho>C>1\\
=\ & D\left((\frac{4}{\sqrt{C}})^{R_{loc}}+t\cdot(\frac{60}{\sqrt{C}})^{R_{loc}/2}\right) \text{ by setting } s\approx 1/\sqrt{C}\\
\leq\ & D\cdot\frac{1}{(Ct)^c} \text{ by setting } R_{loc}=O(\log_C(tC)),
\end{aligned}$$

where c is some arbitrarily large constant. Using $t>D$, we can show that failure happening in any of the first $D-1$ rounds is small. Then, we still need to show that the probability of the last round is failing is also small,

$$\begin{aligned}
& (\frac{4}{s\rho})^{R_{loc}}+t\cdot(60s)^{R_{loc}/2}+e^{-\Theta(R_{loc})}\\
\leq\ & (\Theta(\frac{C}{\rho}))^{R_{loc}}+t\cdot(\Theta(\frac{1}{C}))^{R_{loc}/2}+e^{-\Theta(R_{loc})} \text{ by setting } s\approx 1/C\\
\leq\ & \frac{1}{c_1}+\frac{1}{(tC)^{c_2}}+e^{-\Theta(R_{loc})} \text{ by setting } R_{loc}=O(\log_C(tC))\\
\leq\ & \frac{1}{c_1}+\frac{1}{(tC)^{c_2}}+\frac{1}{c_3},
\end{aligned}$$

where in the first line, the first two terms are from Lemma 11.3.6 and the third term comes from Lemma 11.6.2; in the last line c_1, c_2 and c_3 are some arbitrarily large constants.

The expected running time includes the following part: Running HashtoBins algorithm $O(DR)$ times, each run takes $O(\frac{B}{\alpha}\log\frac{k}{\delta}+B\log B)$. Updating the counter v, which

takes $O(DR \cdot Bt)$ time. The total running time should be

$$\begin{aligned} & O(DR(\frac{B}{\alpha}\log\frac{k}{\delta} + B\log B) + (DR_{loc}Bt)) \\ = \; & O(DRB\log(k/\delta \cdot B \cdot FT)) \\ = \; & O(B\log_C(FT)\log(\frac{k}{\delta}BFT)) \\ = \; & O(B\log_C(FT)\log(FT/\delta)) \quad \text{by } FT \gg F\frac{1}{\eta} \gg k. \end{aligned}$$

The total number of samples is

$$O\left(DR \cdot B\log(\frac{k}{\delta})\right) = O(B\log_C(FT)\log(k/\delta)).$$

The sample duration of Algorithm LocateKSignal is $O(\frac{\log\frac{k}{\delta}}{\eta})$.

In conclusion, we can show that for frequency where neither E_{coll} nor E_{off} holds, we recover an f' with $|f - f'| \lesssim \frac{1}{T\rho}$ as long as $\rho > C$, with an arbitrarily large constant probability. □

Lemma 11.3.8. Algorithm OneStage takes $O(k\log_C(FT)\log(k/\delta))$ samples over $O(\frac{\log(k/\delta)}{\eta})$ duration, runs in $O(k(\log_C(FT)\log(FT/\delta)))$ time, and outputs a set of $\{(v_i', f_i')\}$ of size $O(k)$ with $\min_{i\neq j}|f_i' - f_j'| \gtrsim \eta$. Moreover, one can imagine a subset $S \subseteq [k]$ of "successful" recoveries, where $\Pr[i \in S] \geq \frac{9}{10}$ $\forall i \in [k]$ and for which there exists an injective function $\pi : [k] \to [O(k)]$ so that

$$\mathop{\mathbb{E}}_{\sigma,b}\left[\sum_{i\in S}\frac{1}{T}\int_0^T \left|v_i' e^{2\pi f_i' t\mathbf{i}} - v_{\pi(i)}e^{2\pi f_{\pi(i)}t\mathbf{i}}\right|^2 \mathrm{d}t\right] \lesssim C^2\mathcal{N}^2.$$

with $1 - 1/k^c$ probability for an arbitrarily large constant c.

Proof. Let H denote the set of frequencies f for which neither $E_{coll}(f)$ nor $E_{off}(f)$ holds. For each such f, let $v = \widehat{x^*}(f)$ and denote

$$\mu^2(f) = \mathop{\mathbb{E}}_{a}[|\widehat{u}_j - ve^{a\sigma 2\pi f\mathbf{i}}|^2] \tag{11.18}$$

and $\rho^2(f) = |v|^2/\mu^2(f)$, as in Lemma 11.3.7. We have that, if $\rho^2(f) > C^2$, then with an arbitrarily large constant probability one of the recovered $f' \in L$ has $|f' - f| \lesssim \frac{1}{T\rho}$. If this happens, then OneStage will estimate v using $v' = \widehat{u}_j e^{-a\sigma 2\pi f'\mathbf{i}}$. By triangle inequality,

$$|v' - v|^2 \lesssim |v|^2|e^{a2\pi\sigma(f'-f)\mathbf{i}} - 1|^2 + |\widehat{u}_j - ve^{a\sigma 2\pi f\mathbf{i}}|^2. \tag{11.19}$$

Since $a\sigma \leq T$ and $|f' - f| \lesssim \frac{1}{T\rho}$, then the first term of RHS of Equation (11.19) have

$$|v|^2|e^{a2\pi\sigma(f'-f)\mathbf{i}} - 1|^2 \lesssim |v|^2|a\sigma(f' - f)|^2.$$

For the second term of RHS of Equation (11.19). Using Equation (11.18), we have

$$|\widehat{u}_j - ve^{a\sigma 2\pi f\mathbf{i}}|^2 \lesssim \mu^2(f),$$

with arbitrarily large constant probability. Combining the bounds for those two terms gives

$$|v' - v|^2 \lesssim |v|^2|a\sigma(f' - f)|^2 + \mu^2(f),$$

with arbitrarily large constant probability. Since $a\sigma \leq T$, the first term is $|v|^2/\rho^2 = \mu^2$, for

$$|v' - v|^2 \lesssim \mu^2(f).$$

On the other hand, if $\rho^2(f) < C^2$, then $|v| = \rho(f)\mu(f) \lesssim C\mu(f)$ so regardless of the frequency f' recovered, the estimate v' will have

$$|v' - v|^2 \lesssim C^2\mu^2(f).$$

with arbitrarily large constant probability.

Combining with Lemma 11.3.1, we get for any $f \in H$ that the recovered f', v' will have

$$\frac{1}{T}\int_0^T \left|v'e^{2\pi f' t\mathbf{i}} - ve^{2\pi f t\mathbf{i}}\right|^2 \mathrm{d}t \lesssim C^2\mu^2(f).$$

with arbitrarily large constant probability. Let $S \subset H$ be the set of frequencies for which this happens. We can choose our permutation π to match frequencies in S to their nearest approximation. By Lemma 11.3.2, this means that

$$\mathop{\mathbb{E}}_{\sigma,b}\left[\sum_{i\in S}\frac{1}{T}\int_0^T \left|v_i'e^{2\pi f_i' t\mathbf{i}} - v_{\pi(i)}e^{2\pi f_{\pi(i)} t\mathbf{i}}\right|^2 \mathrm{d}t\right] \lesssim C^2\mathcal{N}^2.$$

as desired. □

11.7 Proofs for combining multiple stages

We first prove that the median of a bunch of estimates of a frequency has small error if most of the estimates have small error.

Lemma 11.7.1. *Let (v_i, f_i) be a set of tones for $i \in S$. Define v' and f' to be the (coordinate-wise) median of the (v_i, f_i). Then for any (v^*, f^*) we have*

$$\frac{1}{T}\int_0^T \left|v^* e^{2\pi f^* t\mathbf{i}} - v' e^{2\pi f' t\mathbf{i}}\right|^2 \, \mathrm{d}t \lesssim \operatorname*{median}_i \frac{1}{T}\int_0^T \left|v^* e^{2\pi f^* t\mathbf{i}} - v_i e^{2\pi f_i t\mathbf{i}}\right|^2 \mathrm{d}t.$$

Proof. By Lemma 11.3.1 we have that

$$\frac{1}{T}\int_0^T \left|v^* e^{2\pi f^* t\mathbf{i}} - v' e^{2\pi f' t\mathbf{i}}\right|^2 \, \mathrm{d}t \eqsim |v^*|^2 \min(1, T^2|f^* - f'|^2) + |v^* - v'|^2.$$

Using that v' is taken as a two dimensional median, it suffices to show: if $x^{(1)}, x^{(2)}, \ldots \in \mathbb{R}^3$ then $x' = \operatorname*{median}_i x^{(i)}$ has

$$\|x'\|_2^2 \lesssim \operatorname*{median}_i \left\|x^{(i)}\right\|_2^2. \tag{11.20}$$

This follows because in each of the three coordinates j, we have

$$(x'_j)^2 = (\operatorname*{median}_i x_j^{(i)})^2 \le \operatorname*{median}_i (x_j^{(i)})^2 \le \operatorname*{median}_i \left\|x^{(i)}\right\|_2^2.$$

so summing over the three coordinates gives (11.20), as desired.

Therefore, for two dimensional median and one dimension median, we have

$$|v^* - v'|^2 \lesssim \operatorname*{median}_i |v^* - v_i|^2 \tag{11.21}$$

and

$$|f^* - f'|^2 \lesssim \operatorname*{median}_i |f^* - f_i|^2.$$

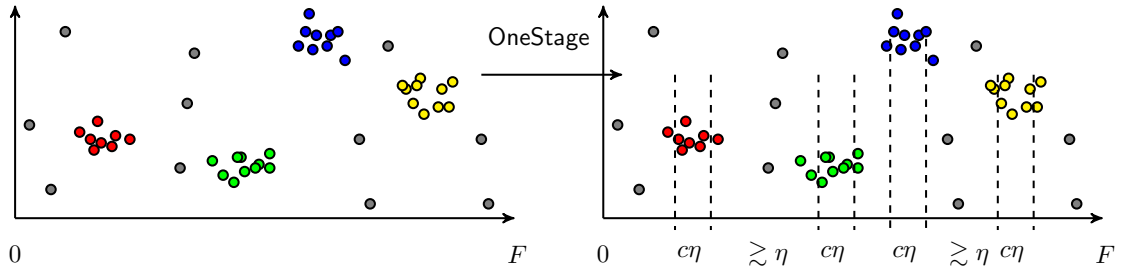

Figure 11.4: We demonstrate the algorithm for merging various stages($R = O(\log k)$) on 2-dimensional data. Note that the true data should be 3-dimensional, since for each tone (v_i, f_i), $v_i \in \mathbb{C}$ and $f_i \in \mathbb{R}$. The x-axis represents the frequency and the y-axis represents the real part of magnitude.

Moreover,

$$\begin{aligned} |v^*|^2 \cdot \min(1, T^2|f^* - f'|^2) &\lesssim |v^*|^2 \cdot \min(1, T^2 \operatorname*{median}_i |f^* - f_i|^2) \\ &= |v^*|^2 \cdot \min(1, \operatorname*{median}_i T^2|f^* - f_i|^2) \\ &= |v^*|^2 \cdot \operatorname*{median}_i \min(1, T^2|f^* - f_i|^2) \end{aligned} \tag{11.22}$$

Combining Equation (11.21) and (11.22), we have

$$\begin{aligned} & |v^* - v'|^2 + |v^*|^2 \cdot \min(1, T^2|f^* - f'|^2) \\ \lesssim\ & \operatorname*{median}_i |v^* - v_i|^2 + \operatorname*{median}_i |v^*|^2 \cdot \min(1, T^2|f^* - f_i|^2) \\ =\ & \operatorname*{median}_i |v^* - v_i|^2 + |v^*|^2 \cdot \min(1, T^2|f^* - f_i|^2). \end{aligned}$$

Thus, we complete the proof. □

Lemma 11.3.9. Repeating algorithm OneStage $O(\log k)$ times, MergedStages returns a set $\{(v'_i, f'_i)\}$ of size $O(k)$ with $\min_{i \neq j} |f'_i - f'_j| \gtrsim \eta$ that can be indexed by π such that

$$\sum_{i=1}^{k} \frac{1}{T} \int_0^T \left| v'_i e^{2\pi f'_i t \mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t \mathbf{i}} \right|^2 \mathrm{d}t \lesssim C^2 \mathcal{N}^2.$$

with probability $1 - 1/k^c$ for an arbitrarily large constant c.

Proof. Our only goal here is to recover the actual tones well, not to worry about spurious tones.

Suppose the number of stages we perform is $R = O(\log k)$. The algorithm for merging the various stages is to scan over a $c\eta$ size region for small c, and take the median (in both frequency and magnitude) over $3c\eta$ region around that $c\eta$ if there are at least $\frac{6}{10}R$ results in that $c\eta$ region. If so, the algorithm will jump to the first right point that is at least η far away from current region and look for the next $c\eta$ region. Because the minimum separation between frequencies for a given stage is $\Omega(\eta)$, this will have minimum separation η in the output, and because there are $O(k)$ tones output at each stage so will this method. What remains is to show that the total error is small.

We say a stage is "good" if the term inside the expectation of Lemma 11.3.8 is less than 10 times its expectation, as happens with 9/10 probability:

$$\Pr\left[\sum_{i\in S}\frac{1}{T}\int_0^T \left|v_i' e^{2\pi f_i' t\mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t\mathbf{i}}\right|^2 \mathrm{d}t \le 10 \mathop{\mathbb{E}}_{\sigma,b}\left[\sum_{i\in S}\frac{1}{T}\int_0^T \left|v_i' e^{2\pi f_i' t\mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t\mathbf{i}}\right|^2 \mathrm{d}t\right]\right] \ge 9/10.$$

We say a frequency f_i is "successful" in a given stage if the stage is good and i lies in S for that stage. Therefore a frequency is successful in each stage with at least 8/10 probability. For sufficiently large $R = O(\log k)$, this will cause all k frequencies to be successful more than $\frac{7}{10}R$ times with high probability. Suppose this happens.

Let $\mu^2(f_i)$ denote the error of (v_i, f_i). By Lemma 11.3.8, the total error over all good stages and every successful recovery of a tone in a good stage is $O(C^2\mathcal{N}^2R)$. We define $\mu^2(f)$ to be the $6/10R$ worst amount of error in the recovery of f over all stages. Because there are $R/10$ worse successful recoveries for each f, we have that $\sum_i \mu^2(f_i) \lesssim C^2\mathcal{N}^2$.

We will match each f_i with a recovered frequency f'_i with cost at most $\mu^2(f_i)$. If $\mu^2(f_i) \gtrsim |v_i|^2$, then we can set an arbitrary f'_i with $v'_i = 0$. Otherwise, more that $\frac{6}{10}R$ successful recoveries of f_i also yield f' that are within $O(\frac{1}{T}) \ll c\eta$ of f_i. Thus the algorithm for merging tones will find enough tones to report something. What it reports will be the median of at most R values, 6/10 of which have less error than $\mu^2(f)$. Therefore by Lemma 11.7.1 the reported frequency and magnitude will have error $O(\mu^2(f))$. This suffices to get the result. □

Lemma 11.3.10. If we run MERGEDSTAGES twice and take the tones $\{(v'_i, f'_i)\}$ from the first result that have f'_i within $c\eta$ for small c of some frequency in the second result, we get a set of $k'' = O(k)$ tones that can be indexed by some permutation π such that

$$\sum_{i=1}^{k} \frac{1}{T} \int_0^T \left| v'_i e^{2\pi f'_i t \mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t \mathbf{i}} \right|^2 \mathrm{d}t + \sum_{i=k+1}^{k''} |v'_i|^2 \lesssim C^2 \mathcal{N}^2. \tag{11.5}$$

Proof. By Lemma 11.3.9 and Lemma 11.3.1, the first run gives us a set of $k' = O(k)$ pairs $\{(v'_i, f'_i)\}$ such that they may be indexed by using permutation π such that the first k are a good approximation to $\{(v_i, f_i)\}$ in the sense that

$$\sum_{i=1}^{k} (|v_{\pi(i)}|^2 + |v'_i|^2) \cdot \min(1, T^2 |f_{\pi(i)} - f'_i|^2) + |v_{\pi(i)} - v'_i|^2 \lesssim C^2 \mathcal{N}^2.$$

We may as well index to match tones to their nearest match in frequency (because the separation for both f'_i and f_i is at least $\Omega(\eta) > 1/T$). That is, we may index such that $|f'_j - f_i| \gtrsim \eta$ for any $j \neq i$.

Now, for indices where $|f'_i - f_{\pi(i)}| > 1/T$, one would do better by setting the corresponding v_i to zero. In particular, suppose you knew the true frequencies $f_{\pi(i)}$ and only took

the (v_i', f_i') where f_i' is close to $f_{\pi(i)}$. That is, there exists some permutation π, for the subset $S \subseteq [k]$ containing $\{i : |f_{\pi(i)} - f_i'| \leq c/T\}$ for any $c \gtrsim 1$, we have

$$\sum_{i \in S}((|v_{\pi(i)}|^2 + |v_i'|^2) \cdot \min(1, T^2|f_{\pi(i)} - f_i'|^2) + |v_{\pi(i)} - v_i'|^2) + \sum_{i \in [k] \setminus S} (|v_{\pi(i)}|^2 + |v_i'|^2) \lesssim C^2\mathcal{N}^2. \tag{11.23}$$

The problem is that we do not know the set S, so we can not throw out the other frequencies. However, we can fake it by running the algorithm again on the signal. In particular, we apply Lemma 11.3.9 again to sparse recovery of the signal defined by

$$\{(v_i, f_i) \mid i \in [k]\} \cup \{(0, f_i') \mid i \in \{k+1, \ldots, k'\}\}.$$

That is, we pretend the "signal" has terms at the other f_i' for $k < i \leq k'$, but with magnitude zero. This is an identical signal in time domain, so it's really just an analytical tool; for the analysis, it has $k' = O(k)$ sparsity and $\Omega(\eta)$ separation, so Lemma 11.3.9 applies again and gets a set of $k'' = O(k)$ pairs $\{(v_j'', f_j'')\}$ such that, for the subset $S^* \subset [k']$ containing the indices i where $|f_j'' - f_i'| \leq c/T$ for some $j \in [k'']$. In other words, there exists some permutation τ such that for the subset $S^* \subset [k']$ containing $\{i : |f''_{\tau(i)} - f_i'| \leq c/T\}$. We have

by analogy to (11.23) that

$$\begin{aligned}
C^2\mathcal{N}^2 \gtrsim & \sum_{i\in S^*\cap[k]} ((|v_{\pi(i)}|^2+|v''_{\tau(i)}|^2)\cdot\min(1,T^2|f_{\pi(i)}-f''_{\tau(i)}|^2)+|v_{\pi(i)}-v''_{\tau(i)}|^2)\\
+ & \sum_{i\in S^*\setminus[k]} ((|0|^2+|v''_{\tau(i)}|^2)\cdot\min(1,T^2|f'_i-f''_{\tau(i)}|^2)+|v''_{\tau(i)}-0|^2)\\
+ & \sum_{i\in[k]\setminus S^*} (|v_{\pi(i)}|^2+|v''_{\tau(i)}|^2)+\sum_{i\in[k']\setminus S^*\setminus[k]} (|v''_{\tau(i)}|^2)\\
\gtrsim & \sum_{i\in S^*\cap[k]} ((|v_{\pi(i)}|^2+|v''_{\tau(i)}|^2)\cdot\min(1,T^2|f_{\pi(i)}-f''_{\tau(i)}|^2)+|v_{\pi(i)}-v''_{\tau(i)}|^2)\\
+ & \sum_{i\in S^*\setminus[k]} |v''_{\tau(i)}|^2+\sum_{i\in[k]\setminus S^*} |v_{\pi(i)}|^2,
\end{aligned}$$

where π and τ are two permutations and $|S^*|=k^*=O(k)$. This last term is precisely the desired total error for the set of tones $\{(v''_{\tau(i)},f''_{\tau(i)}):i\in S^*\}$, giving the result.

□

To prove Theorem 11.3.11, we still need the following "local" Lemma.

Lemma 11.7.2. *For any three tones $(v_{\pi(i)},f_{\pi(i)})$, (v_i^*,f_i^*) and (v'_i,f'_i), if $|v'_i|\geq|v_i^*|$ then,*

$$\begin{aligned}
& (|v'_i|^2+|v_{\pi(i)}|^2)\cdot\min(1,T^2|f'_i-f_{\pi(i)}|^2)+|v'_i-v_{\pi(i)}|^2\\
\lesssim\ & (|v_i^*|^2+|v_{\pi(i)}|^2)\cdot\min(1,T^2|f_i^*-f_{\pi(i)}|^2)+|v_i^*-v_{\pi(i)}|^2+|v'_i|^2.
\end{aligned}$$

Proof. First, we can show an upper bound for LHS. Using inequality $\min(1,T^2|f'_i-f_{\pi(i)}|^2)\leq 1$,

$$\text{LHS}\leq|v'_i|^2+|v_{\pi(i)}|^2+|v'_i-v_{\pi(i)}|^2.$$

By triangle inequality,

$$|v_i' - v_{\pi(i)}|^2 \leq 2|v_i'|^2 + 2|v_{\pi(i)}|^2.$$

Thus, we obtain,

$$\text{LHS} \lesssim |v_i'|^2 + |v_{\pi(i)}|^2.$$

Second, we can show a lower bound for RHS. Since first term of RHS is nonnegative, then

$$\text{RHS} \geq |v_i^* - v_{\pi(i)}|^2 + |v_i'|^2.$$

Using $|v_i'| \geq |v_i^*|$, we have

$$\text{RHS} \gtrsim |v_i'|^2 + 2|v_i^*|^2 + 2|v_i^* - v_{\pi(i)}|^2.$$

By triangle inequality,

$$2|v_i^*|^2 + 2|v_i^* - v_{\pi(i)}|^2 \geq |v_{\pi(i)}|^2.$$

Then, we prove the lower bound for RHS,

$$\text{RHS} \gtrsim |v_i'|^2 + |v_{\pi(i)}|^2.$$

Combining the lower bound of RHS and the upper bound of LHS completes the proof.

□

By plugging Lemma 11.3.1 into Lemma 11.7.2, we have

Corollary 11.7.3. *For any three tones $(v_{\pi(i)}, f_{\pi(i)})$, (v_i^*, f_i^*) and (v_i', f_i'), if $|v_i'| \geq |v_i^*|$, then*

$$\frac{1}{T}\int_0^T \left|v_i' e^{2\pi f_i' t\mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t\mathbf{i}}\right|^2 \mathrm{d}t \lesssim \frac{1}{T}\int_0^T \left|v_i^* e^{2\pi f_i^* t\mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t\mathbf{i}}\right|^2 \mathrm{d}t + |v_i'|^2.$$

We use Corollary 11.7.3 to present the proof of Theorem 11.3.11,

Theorem 11.3.11. Algorithm ContinuousFourierSparseRecovery returns a set $\{(v_i', f_i')\}$ of size k with $\min_{i \neq j} |f_i' - f_j'| \gtrsim \eta$ for which

$$\sum_{i=1}^{k} \frac{1}{T} \int_0^T \left| v_i' e^{2\pi f_i' t \mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t \mathbf{i}} \right|^2 \mathrm{d}t \lesssim C^2 \mathcal{N}^2$$

with probability $1 - 1/k^c$ for an arbitrarily large constant c.

Proof. Let $\{(v_i^*, f_i^*)\}_{i=1,2,\cdots,k''}$ denote the set of tones returned by Lemma 11.3.10, where $k'' = O(k)$ and $k'' > k$. For any $i \in [k]$, tone (v_i^*, f_i^*) was mapped to tone $(v_{\pi(i)}, f_{\pi(i)})$ in Lemma 11.3.10. Let $\{(v_i', f_i')\}_{i=1,2,\cdots,k}$ denote a subset of $\{(v_i^*, f_i^*)\}_{i=1,2,\cdots,k''}$ that satisfies the following two conditions (1) for any $i \in [k]$, $|v_i'|$ is one of the top-k largest magnitude tones; (2) for any $i \in [k]$, $|v_i'| \geq |v_i^*|$. By Lemma 11.3.10, we also know that $\min_{i \neq j} |f_i' - f_j'| \gtrsim \eta$.

For any $i \in [k]$, we consider these three tones $(v_{\pi(i)}, f_{\pi(i)}), (v_i^*, f_i^*), (v_i', f_i')$. If $(v_i^*, f_i^*) \neq (v_i', f_i')$, then applying Corollary 11.7.3 we have

$$\frac{1}{T} \int_0^T \left| v_i' e^{2\pi f_i' t \mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t \mathbf{i}} \right|^2 \mathrm{d}t \lesssim \frac{1}{T} \int_0^T \left| v_i^* e^{2\pi f_i^* t \mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t \mathbf{i}} \right|^2 \mathrm{d}t + |v_i'|^2.$$

Otherwise $(v_i^*, f_i^*) = (v_i', f_i')$, we also have

$$\frac{1}{T} \int_0^T \left| v_i' e^{2\pi f_i' t \mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t \mathbf{i}} \right|^2 \mathrm{d}t \quad = \quad \frac{1}{T} \int_0^T \left| v_i^* e^{2\pi f_i^* t \mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t \mathbf{i}} \right|^2 \mathrm{d}t,$$

which means there exists some universal constant α such that $\forall i \in [k]$, if $(v_i^*, f_i^*) = (v_i', f_i')$ then

$$\frac{1}{T} \int_0^T \left| v_i' e^{2\pi f_i' t \mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t \mathbf{i}} \right|^2 \mathrm{d}t \leq \alpha \cdot \left(\frac{1}{T} \int_0^T \left| v_i^* e^{2\pi f_i^* t \mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t \mathbf{i}} \right|^2 \mathrm{d}t + |v_i'|^2 \right)$$

holds. Otherwise $(v_i^*, f_i^*) \neq (v_i', f_i')$, then

$$\frac{1}{T}\int_0^T \left|v_i' e^{2\pi f_i' t\mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t\mathbf{i}}\right|^2 \mathrm{d}t \;=\; \alpha \frac{1}{T}\int_0^T \left|v_i^* e^{2\pi f_i^* t\mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t\mathbf{i}}\right|^2 \mathrm{d}t$$

holds. Let S denote the set of indices i such that $(v_i^*, f_i^*) \neq (v_i', f_i')$. Taking the summation from $i = 1$ to $i = k$,

$$\begin{aligned}
&\sum_{i=1}^{k} \frac{1}{T}\int_0^T \left|v_i' e^{2\pi f_i' t\mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t\mathbf{i}}\right|^2 \mathrm{d}t \\
\leq\; &\sum_{i\in S} \alpha \cdot \left(\frac{1}{T}\int_0^T \left|v_i^* e^{2\pi f_i^* t\mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t\mathbf{i}}\right|^2 \mathrm{d}t + |v_i'|^2\right) \\
+\; &\sum_{i\in[k]\setminus S} \alpha \cdot \left(\frac{1}{T}\int_0^T \left|v_i^* e^{2\pi f_i^* t\mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t\mathbf{i}}\right|^2 \mathrm{d}t\right),
\end{aligned}$$

furthermore, we have

$$\begin{aligned}
\sum_{i=1}^{k} \frac{1}{T}\int_0^T \left|v_i' e^{2\pi f_i' t\mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t\mathbf{i}}\right|^2 \mathrm{d}t \leq\; &\alpha \sum_{i=1}^{k} \left(\frac{1}{T}\int_0^T \left|v_i^* e^{2\pi f_i^* t\mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t\mathbf{i}}\right|^2 \mathrm{d}t\right) \\
&+ \alpha \sum_{i\in S} |v_i'|^2.
\end{aligned}$$

To finish the proof, we need to show that $\sum_{i\in S} |v_i'|^2 \leq \sum_{i=k+1}^{k''} |v_i^*|^2$. The point is, for any $i \in S$, we know that $(v_i', f_i') \neq (v_i^*, f_i^*)$ which implies that $(v_i', f_i') \notin \{(v_i^*, f_i^*)\}_{i=1}^{k}$. Thus,

$$\begin{aligned}
&\sum_{i=1}^{k} \frac{1}{T}\int_0^T \left|v_i' e^{2\pi f_i' t\mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t\mathbf{i}}\right|^2 \mathrm{d}t \\
\leq\; &\alpha \sum_{i=1}^{k} \left(\frac{1}{T}\int_0^T \left|v_i^* e^{2\pi f_i^* t\mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t\mathbf{i}}\right|^2 \mathrm{d}t\right) + \alpha \sum_{i=k+1}^{k''} |v_i^*|^2 \\
\lesssim\; &\sum_{i=1}^{k} \left(\frac{1}{T}\int_0^T \left|v_i^* e^{2\pi f_i^* t\mathbf{i}} - v_{\pi(i)} e^{2\pi f_{\pi(i)} t\mathbf{i}}\right|^2 \mathrm{d}t\right) + \sum_{i=k+1}^{k''} |v_i^*|^2 \\
\lesssim\; &C^2\mathcal{N}^2,
\end{aligned}$$

where $k'' = O(k)$ is defined in Lemma 11.3.10 and the last inequality follows by using Equation (11.5) in Lemma 11.3.10.

□

11.8 Proofs for converting (11.2) into (11.3)

In this section, we show that as long as the sample duration T is sufficiently large, it is possible to convert Equation (11.2) to Equation (11.3). First, we show an auxiliary lemma, Lemma 11.8.3, which bounds an integral that will appear in the analysis.

We will show that

$$\int_{-\infty}^{+\infty} \min(T, \frac{1}{|f_i - \theta|}) \cdot \min(T, \frac{1}{|f_j - \theta|}) \mathrm{d}\theta \lesssim \frac{\log(T|f_i - f_j|)}{|f_i - f_j|}.$$

for $f_j - f_i \geq 2/T$. We split this into two pieces.

Claim 11.8.1. *Given two frequencies f_i, f_j and $f_j - f_i \geq \frac{2}{T}$, we have*

$$\int_{f_i - \frac{1}{T}}^{f_i} \min(T, \frac{1}{|f_i - \theta|}) \cdot \frac{1}{|f_j - \theta|} \mathrm{d}\theta \lesssim \frac{1}{f_j - f_i}.$$

Proof. By $f_i - \frac{1}{T} < \theta < f_i$, we have

$$\text{LHS} = \int_{f_i - \frac{1}{T}}^{f_i} T \cdot \frac{1}{f_j - \theta} \mathrm{d}\theta.$$

Since $\frac{1}{f_j - \theta} \eqsim \frac{1}{f_j - f_i}$ for all $\theta \in [f_i - \frac{1}{T}, f_i]$,

$$\text{LHS} \lesssim \int_{f_i - \frac{1}{T}}^{f_i} \frac{T}{f_j - f_i} \mathrm{d}\theta = \frac{1}{f_j - f_i}.$$

□

Claim 11.8.2. *Given two frequencies f_i, f_j and $f_j - f_i \geq \frac{2}{T}$, we have*

$$\int_{-\infty}^{f_i - \frac{1}{T}} \min(T, \frac{1}{|f_i - \theta|}) \cdot \frac{1}{|f_j - \theta|} \mathrm{d}\theta \lesssim \frac{\log(T|f_j - f_i|)}{f_j - f_i}.$$

Proof. By $\theta < f_i - \frac{1}{T} < f_j$, we have that

$$\begin{aligned}
\text{LHS} &= \int_{-\infty}^{f_i - \frac{1}{T}} \frac{1}{f_i - \theta} \cdot \frac{1}{f_j - \theta} \mathrm{d}\theta \\
&= \frac{1}{f_j - f_i} \int_{-\infty}^{f_i - \frac{1}{T}} \frac{f_j - f_i}{(f_i - \theta)(f_j - \theta)} \mathrm{d}\theta \\
&= \frac{1}{f_j - f_i} \int_{-\infty}^{f_i - \frac{1}{T}} \frac{1}{f_i - \theta} - \frac{1}{f_j - \theta} \mathrm{d}\theta \\
&= -\frac{1}{f_j - f_i} \log \frac{f_i - f_i + \frac{1}{T}}{f_j - f_i + \frac{1}{T}} \\
&= -\frac{1}{f_j - f_i} \log \frac{1}{T(f_j - f_i) + 1} \\
&\lesssim \frac{\log(T(f_j - f_i))}{f_j - f_i}.
\end{aligned}$$

□

Lemma 11.8.3. *Given two frequencies f_i, f_j and $f_j - f_i \geq \frac{2}{T}$, we have*

$$\int_{-\infty}^{+\infty} \min(T, \frac{1}{|f_i - \theta|}) \cdot \min(T, \frac{1}{|f_j - \theta|}) \mathrm{d}\theta \lesssim \frac{\log(T|f_i - f_j|)}{|f_i - f_j|}.$$

Proof. By symmetry, we have

$$\text{LHS} = 2 \int_{-\infty}^{\frac{f_i + f_j}{2}} \min(T, \frac{1}{|f_i - \theta|}) \cdot \min(T, \frac{1}{|f_j - \theta|}) \mathrm{d}\theta.$$

Since $T > \frac{1}{f_j - \theta}$ when $\theta < \frac{f_i + f_j}{2}$,

$$\text{LHS} \leq 2 \int_{-\infty}^{\frac{f_i + f_j}{2}} \min(T, \frac{1}{|f_i - \theta|}) \cdot \frac{1}{|f_j - \theta|} \mathrm{d}\theta.$$

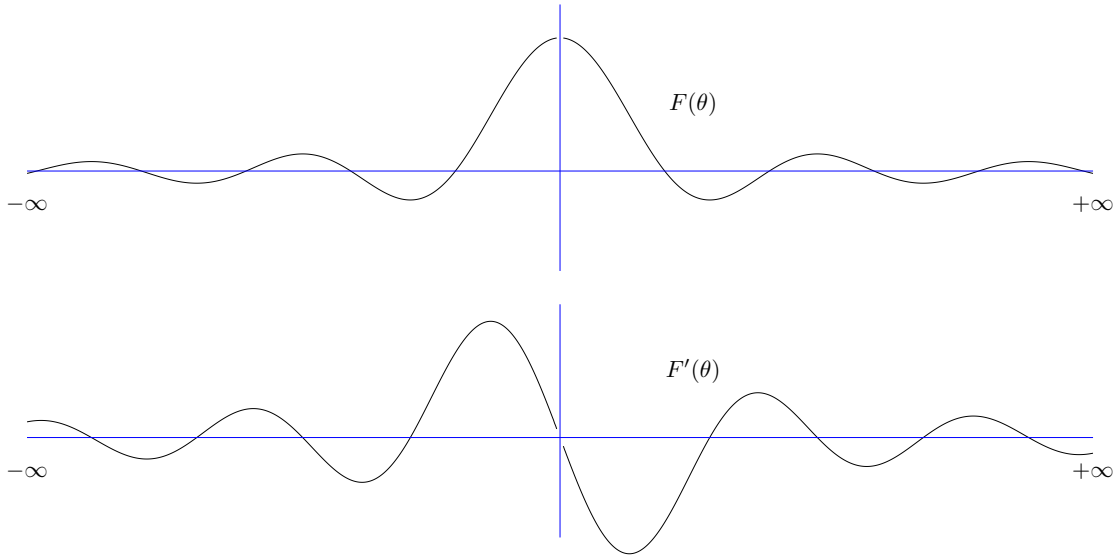

Figure 11.5: $F(\theta)$ is a sinc function and has derivate function $F'(\theta)$.

We also observe that $\frac{1}{|f_j-\theta|} \approx \frac{1}{|f_j-f_i|}$ for all $\theta \in [f_i - \frac{f_j-f_i}{2}, f_i + \frac{f_j-f_i}{2}]$,

$$\int_{f_i-\frac{f_j-f_i}{2}}^{\frac{f_j+f_i}{2}} \min(T, \frac{1}{|f_i-\theta|}) \cdot \frac{1}{|f_j-\theta|} \mathrm{d}\theta \approx \int_{f_i-\frac{f_j-f_i}{2}}^{f_i} \min(T, \frac{1}{|f_i-\theta|}) \cdot \frac{1}{|f_j-\theta|} \mathrm{d}\theta.$$

Thus, we get

$$\text{LHS} \lesssim \int_{-\infty}^{f_i} \min(T, \frac{1}{|f_i-\theta|}) \cdot \frac{1}{|f_j-\theta|} \mathrm{d}\theta.$$

Plugging Claim 11.8.1 and 11.8.2 into the above formula completes the proof. □

Lemma 11.8.4. *For any i, let $a_i(t) = v_i e^{2\pi f_i t \mathbf{i}} - v_i' e^{2\pi f_i' t \mathbf{i}}$, then for $i \neq j$,*

$$\frac{1}{T}\int_0^T a_i(t)\overline{a_j(t)}\mathrm{d}t \lesssim \frac{\log(\Delta f_{i,j} T)}{\Delta f_{i,j} T} \cdot \left(\frac{1}{T}\int_0^T |a_i(t)|^2 \mathrm{d}t \cdot \frac{1}{T}\int_0^T |a_j(t)|^2 \mathrm{d}t\right)^{\frac{1}{2}}, \tag{11.24}$$

where $\Delta f_{i,j} = \min(|f_i - f_j|, |f_i - f_j'|, |f_i' - f_j|, |f_i - f_j'|)$.

Proof. Let $\nu_i = |f_i - f_i'|$ and $\nu_j = |f_j - f_j'|$. Define $\|a_i\| = \left(\frac{1}{T}\int_0^T |a_i(t)|^2 \mathrm{d}t\right)^{1/2}$. We define $f(t)$ and $F(\theta)$ to be a rectangle and sinc function respectively:

$$f(t) = \begin{cases} 1 & \text{if } 0 \le t \le T \\ 0 & \text{otherwise} \end{cases}$$

$$F(\theta) = \frac{\sin(2\pi\theta T)}{2\pi\theta}$$

where $F = \widehat{f}$.

$F(\theta)$ has the derivative,

$$F'(\theta) = \frac{2\pi\theta T\cos(2\pi\theta T) - \sin(2\pi\theta T)}{2\pi\theta^2},$$

which means that

$$|F'(\theta)| \lesssim \begin{cases} T^2 & \text{if } \theta \le 1/T \\ T/|\theta| & \text{otherwise} \end{cases}$$

Let $y_i(t) = a_i(t) \cdot f(t)$, then

$$\begin{aligned} \widehat{y_i}(\theta) &= \widehat{a_i}(\theta) * \widehat{f}(\theta) \\ &= \widehat{a_i}(\theta) * F(\theta) \text{ by } F = \widehat{f} \\ &= v_i F(f_i - \theta) - v_i' F(f_i' - \theta) \\ &= (v_i - v_i')F(f_i - \theta) + v_i'(f_i - f_i') \cdot F'(x - \theta) \text{ some } x \in [f_i, f_i']. \end{aligned}$$

We split into two cases. First, if $\nu_i \le \frac{1}{T}$, then

$$\begin{aligned} |\widehat{y_i}(\theta)| &\lesssim (|v_i - v_i'| + \nu_i T|v_i'|) \cdot \min(T, \frac{1}{|f_i - \theta|}) \\ &\lesssim \|a_i\| \cdot \min(T, \frac{1}{|f_i - \theta|}) \quad \text{by Lemma 11.3.1,} \end{aligned} \tag{11.25}$$

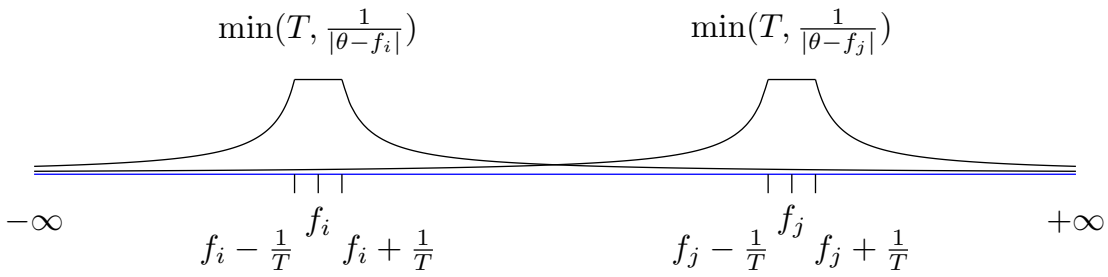

Figure 11.6: $\int_{-\infty}^{+\infty} \min(T, \frac{1}{|\theta-f_i|}) \cdot \min(T, \frac{1}{|\theta-f_j|}) \mathrm{d}\theta$

where the first step holds for both $f_i > f_i'$ and $f_i \leq f_i'$ since the triangle inequality.

Therefore

$$\begin{aligned}
\frac{1}{T}\int_0^T a_i(t)\overline{a_j(t)}\mathrm{d}t &= \frac{1}{T}\int_{-\infty}^{\infty} y_i(t)\overline{y_j(t)}\mathrm{d}t \\
&= \frac{1}{T}\int_{-\infty}^{\infty} \widehat{y}_i(\theta)\overline{\widehat{y}_j(\theta)}\mathrm{d}\theta \\
&\lesssim \frac{1}{T}\|a_i\|\|a_j\| \underbrace{\int_{-\infty}^{+\infty} \min(T, \frac{1}{|f_i-\theta|}) \cdot \min(T, \frac{1}{|f_j-\theta|})\mathrm{d}\theta}_{C}, \quad (11.26)
\end{aligned}$$

where the first step follows from $y_i(t) = a_i(t) \cdot f(t)$ and $f(t) = 1$ if $t \in [0, T]$, the second step follows from the property of Fourier transform, and the last step follows from Equation (11.25).

Using Lemma 11.8.3, we have following bound for term C,

$$\int_{-\infty}^{+\infty} \min(T, \frac{1}{|f_i-\theta|}) \cdot \min(T, \frac{1}{|f_j-\theta|})\mathrm{d}\theta \lesssim \frac{\log T|f_j - f_i|}{|f_j - f_i|}.$$

This gives the result for $\nu_i \leq \frac{1}{T}$. In the alternate case, we have $\nu_i > \frac{1}{T}$, then

$$\begin{aligned}
|\widehat{y}_i(\theta)| &\lesssim v_i \cdot \min(T, \frac{1}{|f_i - \theta|}) + v_i' \cdot \min(T, \frac{1}{|f_i' - \theta|}) \\
&\lesssim \|a_i\| \cdot \left(\min(T, \frac{1}{|f_i - \theta|}) + \min(T, \frac{1}{|f_i' - \theta|}) \right) \quad \text{by Lemma 11.3.1.}
\end{aligned}$$

By similar reason for Equation (11.26), we have

$$\begin{aligned}
& \frac{1}{T} \int_0^T a_i(t) \overline{a_j(t)} \mathrm{d}t \\
\lesssim\ & \frac{1}{T} \|a_i\| \|a_j\| \underbrace{\int_{-\infty}^{+\infty} \min(T, \frac{1}{|f_i - \theta|}) \cdot \min(T, \frac{1}{|f_j - \theta|}) \mathrm{d}\theta}_{C_1} \\
+\ & \frac{1}{T} \|a_i\| \|a_j\| \underbrace{\int_{-\infty}^{+\infty} \min(T, \frac{1}{|f_i - \theta|}) \cdot \min(T, \frac{1}{|f_j' - \theta|}) \mathrm{d}\theta}_{C_2} \\
+\ & \frac{1}{T} \|a_i\| \|a_j\| \underbrace{\int_{-\infty}^{+\infty} \min(T, \frac{1}{|f_i' - \theta|}) \cdot \min(T, \frac{1}{|f_j - \theta|}) \mathrm{d}\theta}_{C_3} \\
+\ & \frac{1}{T} \|a_i\| \|a_j\| \underbrace{\int_{-\infty}^{+\infty} \min(T, \frac{1}{|f_i' - \theta|}) \cdot \min(T, \frac{1}{|f_j' - \theta|}) \mathrm{d}\theta}_{C_4}.
\end{aligned}$$

Applying Lemma 11.8.3 on the term C_1, C_2, C_3 and C_4 respectively,

$$\frac{1}{T} \int_0^T a_i(t) \overline{a_j(t)} \lesssim \|a_i\| \|a_j\| \frac{\log(T \Delta f_{i,j})}{\Delta f_{i,j}},$$

where $\Delta f_{i,j} = \min(|f_i - f_j|, |f_i - f_j'|, |f_i' - f_j|, |f_i' - f_j'|)$.

□

Lemma 11.8.5. *Let $\{(v_i, f_i)\}$ and $\{(v'_i, f'_i)\}$ be two sets of k tones for which $\min_{i\neq j} |f_i - f_j| \geq \eta$ and $\min_{i\neq j} |f'_i - f'_j| \geq \eta$ for some $\eta > 0$. Suppose that $T > C/\eta$ for a sufficiently large constant C. Then these sets can be indexed such that*

$$\frac{1}{T}\int_0^T \left|\sum_{i=1}^{k}(v'_i e^{2\pi \mathbf{i} f'_i t} - v_i e^{2\pi \mathbf{i} f_i t})\right|^2 \mathrm{d}t \leq \alpha \cdot \sum_{i=1}^{k} \frac{1}{T}\int_0^T \left|v'_i e^{2\pi \mathbf{i} f'_i t} - v_i e^{2\pi \mathbf{i} f_i t}\right|^2 \mathrm{d}t, \tag{11.27}$$

where

$$\alpha = \left(1 + O\left(\frac{\log(k\eta T)\log(k)}{\eta T}\right)\right).$$

Proof. For simplicity, let $a_i(t) = v_i e^{2\pi f_i t \mathbf{i}} - v'_i e^{2\pi f'_i t \mathbf{i}}$. Let's express the square of summations by diagonal term and off-diagonal term, and then bound them separately.

$$\begin{aligned}
&\int_0^T \left|\sum_{i=1}^{k} a_i(t)\right|^2 \mathrm{d}t \\
=\ &\int_0^T \left(\sum_{i=1}^{k} a_i(t)\right)\left(\sum_{i=1}^{k} \overline{a_i(t)}\right) \mathrm{d}t \\
=\ &\int_0^T \sum_{i=1}^{k} \underbrace{a_i(t)\overline{a_i(t)}}_{\text{diagonal}} + \sum_{i\neq j}^{k} \underbrace{a_i(t)\overline{a_j(t)}}_{\text{off-diagonal}} \mathrm{d}t.
\end{aligned} \tag{11.28}$$

Using the result of Lemma 11.8.4 and $a^2 + b^2 \geq 2ab$, we can upper bound the off-diagonal term,

$$\begin{aligned}
&\int_0^T a_i(t)\overline{a_j(t)}\mathrm{d}t \\
\lesssim\ &\frac{\log(\Delta f_{i,j} T)}{\Delta f_{i,j} T} \cdot \left(\int_0^T |a_i(t)|^2 \mathrm{d}t \int_0^T |a_j(t)|^2 \mathrm{d}t\right)^{1/2} && \text{by Lemma 11.8.4} \\
\lesssim\ &\frac{\log(\Delta f_{i,j} T)}{\Delta f_{i,j} T} \cdot \left(\int_0^T |a_i(t)|^2 \mathrm{d}t + \int_0^T |a_j(t)|^2 \mathrm{d}t\right). && \text{by } 2ab \leq a^2 + b^2
\end{aligned}$$

where $\Delta f_{i,j} = \min(|f_i - f_j|, |f_i - f'_j|, |f'_i - f_j|, |f'_i - f'_j|)$. If we index such that any f_i is matched with any f'_j with $|f_i - f'_j| < \eta/3$ – which is possible, since at most one such f'_j will exist by the separation among the f'_j, and that f'_j will be within $\eta/3$ of at most on f_i – then we have $\Delta f_{i,j} \gtrsim |f_i - f_j|$. If we order the f_i in increasing order, then in fact $\Delta f_{i,j} \gtrsim \eta|i-j|$.

If $T > C/\eta$ for a sufficiently large constant C, this means that $\Delta f_{i,j} T \gtrsim |i-j|\eta T \geq e$. Since $\frac{\log x}{x}$ is decreasing on the region, this implies

$$\frac{\log(\Delta f_{i,j} T)}{\Delta f_{i,j} T} \lesssim \frac{\log(|i-j|\eta T)}{|i-j|\eta T}.$$

Thus, we have

$$\int_0^T a_i(t)\overline{a_j(t)}\mathrm{d}t \lesssim \frac{\log(|i-j|\eta T)}{|i-j|\eta T} \cdot \left(\int_0^T |a_i(t)|^2 \mathrm{d}t + \int_0^T |a_j(t)|^2 \mathrm{d}t \right) \quad . \quad (11.29)$$

Finally, we have

$$
\begin{aligned}
&\int_0^T \left|\sum_{i=1}^k a_i(t)\right|^2 \mathrm{d}t - \sum_{i=1}^k \int_0^T |a_i(t)|^2 \mathrm{d}t \\
&= \sum_{i\neq j}^k \int_0^T a_i(t)\overline{a_j(t)}\mathrm{d}t && \text{by Equation (11.28)} \\
&\lesssim \sum_{i\neq j}^k \frac{\log(|i-j|\eta T)}{|i-j|\eta T} \cdot \left(\int_0^T |a_i(t)|^2\mathrm{d}t + \int_0^T |a_j(t)|^2\mathrm{d}t\right) && \text{by Equation (11.29)} \\
&\leq \frac{\log(k\eta T)}{\eta T} \sum_{i=1}^k \sum_{j\neq i}^k \frac{1}{|i-j|} \cdot \left(\int_0^T |a_i(t)|^2\mathrm{d}t + \int_0^T |a_j(t)|^2\mathrm{d}t\right) \\
&= 2\frac{\log(k\eta T)}{\eta T} \sum_{i=1}^k \sum_{j\neq i}^k \frac{1}{|i-j|} \int_0^T |a_i(t)|^2\mathrm{d}t && \text{by symmetry} \\
&\lesssim \frac{\log(k\eta T)}{\eta T} \sum_{i=1}^k \int_0^T |a_i(t)|^2\mathrm{d}t \sum_{j\neq i}^k \frac{1}{|i-j|} \\
&\lesssim \frac{\log(k\eta T)\log(k)}{\eta T} \sum_{i=1}^k \int_0^T |a_i(t)|^2\mathrm{d}t \quad \text{by } \sum_{i=1}^k \frac{1}{i} \eqsim \log(k)\ .
\end{aligned}
$$

Thus, we complete the proof. □

Lemma 11.3.13. Let $\{(v_i, f_i)\}$ and $\{(v'_i, f'_i)\}$ be two sets of k tones for which $\min_{i\neq j} |f_i - f_j| \geq \eta$ and $\min_{i\neq j} |f'_i - f'_j| \gtrsim \eta$ for some $\eta > 0$. Suppose that $T > O(\frac{\log^2 k}{\eta})$. Then these sets can be indexed such that

$$
\frac{1}{T}\int_0^T \left|\sum_{i=1}^k (v'_i e^{2\pi \mathbf{i} f'_i t} - v_i e^{2\pi \mathbf{i} f_i t})\right|^2 \mathrm{d}t \lesssim \sum_{i=1}^k \frac{1}{T}\int_0^T \left|v'_i e^{2\pi \mathbf{i} f'_i t} - v_i e^{2\pi \mathbf{i} f_i t}\right|^2 \mathrm{d}t. \tag{11.30}
$$

Proof. Directly follows by Lemma 11.8.5. □

11.9 Lower Bound

Lemma 11.3.15. There exists a constant $c > 0$ such that, for a given sample duration T, one cannot recover the frequency f to within

$$c\frac{\mathcal{N}}{T|\widehat{x}^*(f)|}$$

with 3/4 probability, for all $\delta > 0$, even if $k = 1$.

Proof. Suppose this were possible, and consider two one-sparse signals y and y' containing tones (v, f) and (v, f'), respectively. By Lemma 11.3.1,

$$\int_0^T |y(t) - y(t)|^2 \mathrm{d}t \lesssim |v|^2 T^2 |f - f'|^2.$$

Consider recovery of the signal $x(t) = y(t)$, and suppose it outputs some frequency f^*. This must simultaneously be a good recovery for the decomposition $(x^*, g) = (y, 0)$ and $(x^*, g) = (y', y - y')$. These have noise levels $\mathcal{N}^2$ bounded by $\delta|v|^2$ and $\delta|v|^2 + O(|v|^2 T^2 |f - f'|^2)$, respectively. By the assumption of good recovery, and the triangle inequality, we require

$$c \cdot \frac{2\sqrt{\delta|v|^2} + \sqrt{O(|v|^2 T^2 |f - f'|^2)}}{Tv} \gtrsim |f - f'|$$

or

$$c \cdot O\left(\left(\frac{\delta}{T|f - f'|}\right)^{1/2} + 1\right) \geq 1.$$

Because δ may be chosen arbitrarily small, we can choose a small constant c such that this is a contradiction. □

Algorithm 11.1 Continuous Fourier Sparse Recovery - Part 1

procedure ContinuousFourierSparseRecovery($x, k, \delta, \alpha, C, F, T, \eta$) — The Main Algorithm
    F is the upper bound of frequency, T is the sample duration, C is the approximation factor.
    δ, α are the parameters associated with Hash function.
    $c = 1/10$ and $b = 8/10$
    $R_1 \leftarrow$ NoisyKSparseCFFT$(x, k, \delta, \alpha, C, F)$
    $S_1 \leftarrow$ MergedStages$(R_1, O(k \log k), \eta, c, b)$
    $R_2 \leftarrow$ NoisyKSparseCFFT$(x, O(k), \delta, \alpha, C, F, T)$
    $S_2 \leftarrow$ MergedStages$(R_2, O(k \log k), \Omega(\eta), c, b)$
    $S \leftarrow S_1 \cap S_2$, which means only keeping the tones that S_1 agrees with S_2 by Lemma 11.3.10.
    $S^* \leftarrow$ Prune(S, k), which means only keeping the top-k largest magnitude tones.
    return S^*
end procedure

Algorithm 11.2 Continuous Fourier Sparse Recovery - Part 2

Chapter 12

Continuous Fourier Transform II

We consider the problem of estimating a Fourier-sparse signal from noisy samples, where the sampling is done over some interval $[0, T]$ and the frequencies can be "off-grid". Previous methods for this problem required the gap between frequencies to be above $1/T$, the threshold required to robustly identify individual frequencies. We show the frequency gap is not necessary to estimate the signal as a whole: for arbitrary k-Fourier-sparse signals under ℓ_2 bounded noise, we show how to estimate the signal with a constant factor growth of the noise and sample complexity polynomial in k and logarithmic in the bandwidth and signal-to-noise ratio.

As a special case, we get an algorithm to interpolate degree d polynomials from noisy measurements, using $O(d)$ samples and increasing the noise by a constant factor in ℓ_2.

12.1 Introduction

In an interpolation problem, one can observe $x(t) = x^*(t) + g(t)$, where $x^*(t)$ is a structured signal and $g(t)$ denotes noise, at points t_i of one's choice in some interval $[0, T]$. The goal is to recover an estimate $\widetilde{x}$ of x^* (or of x). Because we can sample over a particular interval, we would like our approximation to be good on that interval, so for any function $y(t)$ we define

$$\|y\|_T^2 = \frac{1}{T}\int_0^T |y(t)|^2 \mathrm{d}t.$$

to be the ℓ_2 error on the sample interval. For some parameters C and δ, we would then like to get

$$\|\widetilde{x} - x^*\|_T \leq C\,\|g\|_T + \delta\,\|x^*\|_T \tag{12.1}$$

while minimizing the number of samples and running time. Typically, we would like C to be $O(1)$ and to have δ be very small (either zero, or exponentially small). Note that, if we do not care about changing C by $O(1)$, then by the triangle inequality it doesn't matter whether we want to estimate x^* or x (i.e. we could replace the LHS of (12.1) by $\|\widetilde{x} - x\|_T$).

Of course, to solve an interpolation problem one also needs x^* to have structure. One common form of structure is that x^* have a sparse Fourier representation. We say that a function x^* is k-Fourier-sparse if it can be expressed as a sum of k complex exponentials:

$$x^*(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}.$$

for some $v_j \in \mathbb{C}$ and $f_j \in [-F, F]$, where F is the "bandlimit". Given F, T, and k, how many samples must we take for the interpolation (12.1)?

If we ignore sparsity and just use the bandlimit, then Nyquist sampling and Shannon-Whittaker interpolation uses $FT + 1/\delta$ samples to achieve (12.1). Alternatively, in the absence of noise, x^* can be found from $O(k)$ samples by a variety of methods, including Prony's method from 1795 or Reed-Solomon syndrome decoding [Mas69], but these methods are not robust to noise.

If the signal is periodic with period T—i.e., the frequencies are multiples of $1/T$—then we can use sparse discrete Fourier transform methods, which take $O(k \log^c(FT/\delta))$ time and samples (e.g. [GGI+02, HIKP12a, IKP14]). If the frequencies are not multiples of $1/T$ (are "off the grid"), then the discrete approximation is only k/δ sparse, making the interpolation less efficient; and even this requires that the frequencies be well separated.

A variety of algorithms have been designed to recover off-grid frequencies directly, but they require the minimum gap among the frequencies to be above some threshold. With frequency gap at least $1/T$, we can achieve a k^c approximation factor using $O(FT)$ samples [Moi15], and with gap above $O(\log^2 k)/T$ we can get a constant approximation using $O(k \log^c(FT/\delta))$ samples and time [PS15].

Having a dependence on the frequency gap is natural. If two frequencies are very close together—significantly below $1/T$—then the corresponding complex exponentials will be close on $[0, T]$, and hard to distinguish in the presence of noise. In fact, from a lower bound in [Moi15], below $1/T$ frequency gap one cannot recover the frequencies in the presence of noise as small as $2^{-\Omega(k)}$. The lower bound proceeds by constructing two signals using significantly different frequencies that are exponentially close over $[0, T]$.

But if two signals are so close, do we need to distinguish them? Such a lower bound

doesn't apply to the interpolation problem, it just says that you can't solve it by finding the frequencies. Our question becomes: can we benefit from Fourier sparsity in a regime where we can't recover the individual frequencies?

We answer in the affirmative, giving an algorithm for the interpolation using

$$\mathrm{poly}(k \log(FT/\delta))$$

samples. Our main theorem is the following:

Theorem 12.1.1. Let $x(t) = x^*(t) + g(t)$, where x^* is k-Fourier-sparse signal with frequencies in $[-F, F]$. Given samples of x over $[0, T]$ we can output $\widetilde{x}(t)$ such that with probability at least $1 - 2^{-\Omega(k)}$,

$$\|\widetilde{x} - x^*\|_T \lesssim \|g\|_T + \delta \|x^*\|_T .$$

Our algorithm uses $\mathrm{poly}(k, \log(1/\delta)) \cdot \log(FT)$ samples and $\mathrm{poly}(k, \log(1/\delta)) \cdot \log^2(FT)$ time. The output $\widetilde{x}$ is $\mathrm{poly}(k, \log(1/\delta))$-Fourier-sparse signal.

Relative to previous work, this result avoids the need for a frequency gap, but loses a polynomial factor in the sample complexity and time. We lose polynomial factors in a number of places; some of these are for ease of exposition, but others are challenging to avoid.

Degree d polynomials are the special case of d-Fourier-sparse functions in the limit of $f_j \to 0$, by a Taylor expansion. This is a regime with no frequency gap, so previous sparse Fourier results would not apply but Theorem 12.1.1 shows that $\mathrm{poly}(d \log(1/\delta))$ samples suffices. In fact, in this special case we can get a better polynomial bound:

Theorem 12.1.2. For any degree d polynomial $P(t)$ and an arbitrary function $g(t)$, Procedure RobustPolynomialLearning in Algorithm 12.5 takes $O(d)$ samples from $x(t) = P(t) + g(t)$ over $[0, T]$ and reports a degree d polynomial $Q(t)$ in time $O(d^\omega)$ such that, with probability at least 99/100,

$$\|P(t) - Q(t)\|_T^2 \lesssim \|g(t)\|_T^2.$$

where $\omega < 2.373$ is matrix multiplication exponent [Str69],[CW87],[Wil12].

We also show how to reduce the failure probability to an arbitrary $p > 0$ with $O(\log(1/p))$ independent repetitions, in Theorem 12.4.5.

Although we have not seen such a result stated in the literature, our method is quite similar to one used in [CDL13]. Since d samples are necessary to interpolate a polynomial without noise, the result is within constant factors of optimal.

One could apply Theorem 12.1.2 to approximate other functions that are well approximated by polynomials or piecewise polynomials. For example, a Gaussian of standard deviation at least σ can be approximated by a polynomial of degree $O((\frac{T}{\sigma})^2 + \log(1/\delta))$; hence the same bound applies as the sample complexity of improper interpolation of a positive mixture of Gaussians.

12.1.1 Related work

Sparse discrete Fourier transforms. There is a large literature on sparse discrete Fourier transforms. Results generally are divided into two categories: one category of results that carefully choose measurements that allow for sublinear recovery time, including [GGI+02, GMS05, HIKP12b, Iwe13, HIKP12a, IK14, IKP14, Kap16]. The other category of results expect randomly chosen measurements and show that a generic recovery algorithm such as ℓ_1 minimization will work with high probability; these results often focus on proving the Restricted Isometry Property [CRT06b, RV08, Bou14, HR16]. At the moment, the first category of results have better theoretical sample complexity and running time, while results in the second category have better failure probabilities and empirical performance. Our result falls in the first category. The best results here can achieve $O(k \log n)$ samples [IK14], $O(k \log^2 n)$ time [HIKP12b], or within $\log \log n$ factors of both [IKP14].

For signals that are not periodic, the discrete Fourier transform will not be sparse: it takes k/δ frequencies to capture a $1 - \delta$ fraction of the energy. To get a better dependence on δ, one has to consider frequencies "off the grid", i.e. that are not multiples of $1/T$.

Off the grid. Finding the frequencies of a signal with sparse Fourier transform off the grid has been a question of extensive study. The first algorithm was by Prony in 1795, which worked in the noiseless setting. This was refined by classical algorithms like MUSIC [Sch81] and ESPRIT [RPK86], which empirically work better with noise. Matrix pencil [BM86] is a method for computing the maximum likelihood signal under Gaussian noise and evenly spaced samples. The question remained how accurate the maximum likelihood estimate is; [Moi15] showed that it has an $O(k^c)$ approximation factor if the frequency gap is at least

$1/T$.

Now, the above results all use FT samples, which is analogous to n in the discrete setting. This can be decreased down till $O(k)$ by only looking at a subset of time, i.e. decreasing T; but doing so increases the frequency gap needed for decent robustness results.

A variety of works have studied how to adapt sparse Fourier techniques from the discrete setting to get sublinear sample complexity; they all rely on the minimum separation among the frequencies to be at least c/T for $c \geq 1$. [TBSR13] showed that a convex program can recover the frequencies exactly in the noiseless setting, for $c \geq 4$. This was improved in [CF14] to $c \geq 2$ for complex signals and $c \geq 1.87$ for real signals. [CF14] also gave a result for $c \geq 2$ that was stable to noise, but this required the signal frequencies to be placed on a finely spaced grid. [YX15] gave a different convex relaxation that empirically requires smaller c in the noiseless setting. [DB13] used model-based compressed sensing when $c = \Omega(1)$, again without theoretical noise stability. Note that, in the noiseless setting, exact recovery can be achieved without any frequency separation using Prony's method or Berlekamp-Massey syndrome decoding [Mas69]; the benefit of the above results is that a convex program might be robust to noise, even if it has not been proven to be so.

In the noisy setting, [FL12] gave an extension of Orthogonal Matching Pursuit (OMP) that can recover signals when $c = \Omega(k)$, with an approximation factor $O(k)$, and a few other assumptions. Similarly, [BCG+12] gave a method that required $c = \Omega(k)$ and was robust to certain kinds of noise. [HK15] got the threshold down to $c = O(1)$, in multiple dimensions, but with approximation factor $O(FTk^{O(1)})$.

[TBR15] shows that, under Gaussian noise and with separation $c \geq 4$, a semidefinite

program can optimally estimate $x^*(t_i)$ at evenly spaced sample points t_i from observations $x^*(t_i) + g(t_i)$. This is somewhat analogous to our setting, the differences being that (a) we want to estimate the signal over the entire interval, not just the sampled points, (b) our noise g is adversarial, so we cannot hope to reduce it—if g is also k-Fourier-sparse, we cannot distinguish x^* and g, and of course (c) we want to avoid requiring frequency separation.

In [PS15], we gave the first algorithm with $O(1)$ approximation factor, finding the frequencies when $c \gtrsim \log(1/\delta)$, and the signal when $c \gtrsim \log(1/\delta) + \log^2 k$.

Now, all of the above results algorithms are designed to recover the frequencies; some of the ones in the noisy setting then show that this yields a good approximation to the overall signal (in the noiseless setting this is trivial). Such an approach necessitates $c \geq 1$: [Moi15] gave a lower bound, showing that any algorithm finding the frequencies with approximation factor $2^{o(k)}$ must require $c \geq 1$.

Thus, in the current literature, we go from not knowing how to get any approximation for $c < 1$, to getting a polynomial approximation at $c = 1$ and a constant approximation at $c \gtrsim \log^2 k$. In this work, we show how to get a constant factor approximation to the signal regardless of c.

Polynomial interpolation. Our result is a generalization of robust polynomial interpolation, and in Theorem 12.1.2 we construct an optimal method for polynomial interpolation as a first step toward interpolating Fourier-sparse signals.

Our result here can be seen as essentially an extension of a technique shown in [CDL13]. The focus of [CDL13] is on the setting where sample points x_i are chosen independently, so

$\Theta(d \log d)$ samples are necessary. One of their examples, however, shows essentially the same thing as our Corollary 12.4.2. From this, getting our theorem is not difficult.

The recent work [GZ16] looks at robust polynomial interpolation in a different noise model, featuring ℓ_∞ bounded noise with some outliers. In this setting they can get a stronger ℓ_∞ guarantee on the output than is possible in our setting.

Nyquist sampling. The classical method for learning bandlimited signals uses Nyquist sampling—i.e., samples at rate $1/F$, for FT points—and interpolates them using Shannon-Nyquist interpolation. This doesn't require any frequency gap, but also doesn't benefit from sparsity like sparse Fourier transform-based techniques. As discussed in [PS15], on the signal $x(t) = 1$ it takes $FT + O(1/\delta)$ samples to get δ error on average. Our dependence is logarithmic on both those terms.

12.1.2 Our techniques

Previous results on sparse Fourier transforms with robust recovery all required a frequency gap. So consider the opposite situation, where all the frequencies converge to zero and the coefficients are adjusted to keep the overall energy fixed. If we take a Taylor expansion of each complex exponential, then the signal will converge to a degree k polynomial. So robust polynomial interpolation is a necessary subproblem for our algorithm.

Polynomial interpolation. Let $P(x)$ be a degree d polynomial, and suppose that we can query $f(x) = P(x) + g(x)$ over the interval $[-1, 1]$, where g represents adversarial noise. We would like to query f at $O(d)$ points and output a degree d polynomial $Q(x)$ such that $\|P - Q\| \lesssim \|g\|$, where we define $\|h\|^2 := \int_{-1}^{1} |h(x)|^2 \mathrm{d}x$.

One way to do this would be to sample points $S \subset [-1, 1]$ uniformly, then output the degree d polynomial Q with the smallest empirical error

$$\|P + g - Q\|_S^2 := \frac{1}{|S|} \sum_{x \in S} |(P + g - Q)(x)|^2$$

on the observed points. If $\|R\|_S \approx \|R\|$ for all degree d polynomials R, in particular for $P - Q$, then since usually $\|g\|_S \lesssim \|g\|$ by Markov's inequality, the result follows.

This has two problems: first, uniform sampling is poor because polynomials like Chebyshev polynomials can have most of their energy within $O(1/d^2)$ of the edges of the interval. This necessitates $\Omega(d^2)$ uniform samples before $\|R\|_S \approx \|R\|$ with good probability on a single polynomial. Second, the easiest method to extend from approximating one polynomial to approximating all polynomials uses a union bound over a net exponential in d, which would give an $O(d^3)$ bound.

To fix this, we need to bias our sampling toward the edges of the interval and we need our sampling to not be iid. We partition $[-1, 1]$ into $O(d)$ intervals $I_1, \ldots, I_n$ so that the interval containing each x has width at most $O(\sqrt{1-x^2})$, except for the $O(1/d^2)$ size regions at the edges. For any degree d polynomial R and any choice of n points $x_i \in I_i$, the appropriately weighted empirical energy is close to $\|R\|$. This takes care of both issues with uniform sampling. If the points are chosen uniformly at random from within their intervals, then $\|g\|$ is probably bounded as well, and the empirically closest degree d polynomial Q will satisfy our requirements.

This result is shown in Section 12.4.

Clusters. Many previous sparse Fourier transform algorithms start with a one-sparse recovery algorithm, then show how to separate frequencies to get a k-sparse algorithm by reducing to the one-sparse case. Without a frequency gap, we cannot hope to reduce to the one-sparse case; instead, we reduce to individual clusters of nearby frequencies.

Essentially the problem is that one *cannot* determine all of the high-energy frequencies of a function x only by sampling it on a bounded interval, as some of the frequencies might cancel each other out on this interval. We also cannot afford to work merely with the frequencies of the truncation of x to the interval $[0, T]$, as the truncation operation will spread the frequencies of x over too wide a range. To fix this problem, we must do something in between the two. In particular, we instead study $x \cdot H$ for a judiciously chosen function H. We want H to approximate the indicator function of the interval $[0, T]$ and have small Fourier-support, $\text{supp}(\widehat{H}) \subset [-k^c/T, k^c/T]$. By using some non-trivial lemmas about the growth rate of x^*, we can show that the difference between $x \cdot H$ on $\mathbb{R}$ and the truncation of

x to $[0, T]$ has small L^2 mass, so that we can use the former as a substitute for the latter.

On the other hand, the Fourier transform of $x \cdot H$ is the convolution $\widehat{x} * \widehat{H}$, which has most of its mass within $\text{poly}(k)/T$ of the frequencies of x^*. Although it is impossible to determine the individual frequencies of x^*, we can hope to identify $O(k)$ intervals each of length $\text{poly}(k)/T$ so that all but a small fraction of the energy of $\widehat{x}$ is contained within these intervals.

Note that many of these intervals will represent not individual frequencies of x^*, but small clusters of such frequencies. Furthermore, some frequencies of x^* might not show up in these intervals either because they are too small, or because they cancel out other frequencies when convolved with $\widehat{H}$.

One-cluster recovery. Given our notion of clusters, we start looking at Fourier-sparse interpolation in the special case of *one-cluster recovery*. This is a generalization of one-sparse recovery where we can have multiple frequencies, but they all lie in $[f - \Delta, f + \Delta]$ for some base frequency f and bandwidth $\Delta = k^c/T$. Because all the frequencies are close to each other, values $x(a)$ and $x(a + \beta)$ will tend to have ratio close to $e^{2\pi \mathbf{i} f \beta}$ when β is small enough. We find that $\beta < \frac{1}{\Delta\sqrt{T\Delta}}$ is sufficient, which lets us figure out a frequency $\widetilde{f}$ with $|\widetilde{f} - f| \leq \Delta\sqrt{T\Delta} = k^{O(1)}/T$.

Once we have the frequency $\widetilde{f}$, we can consider $x'(t) = x(t)e^{-2\pi \mathbf{i} \widetilde{f}}$. This signal is k-Fourier-sparse with frequencies bounded by $k^{O(1)}/T$. By taking a Taylor approximation to each complex exponential[1], can show x^* is δ-close to $P(t)e^{2\pi \mathbf{i} \widetilde{f}}$ for a degree $d = O(k^c +$

[1]There is a catch here, that the coefficients of the exponentials are potentially unbounded, if the frequencies are arbitrarily close together. We first use Gram determinants to show that the signal is δ-close to one

$k \log(1/\delta))$ polynomial P. Thus we could apply our polynomial interpolation algorithm to recover the signal.

k-cluster frequency estimation. Reminiscent of algorithms such as [HIKP12a, PS15], we choose random variables $\sigma \approx T/k^c$, $a \in [0,1]$, and $b \in [0, 1/\sigma]$ and look at $v \in \mathbb{C}^{k^c}$ given by

$$v_i = (x \cdot H)(\sigma(i-a))e^{-2\pi \mathbf{i} \sigma b i} G(i)$$

where G is a filter function. That is, G has compact support ($\mathrm{supp}(G) \subset [-k^c, k^c]$), and $\widehat{G}$ approximates an interval of length $\Theta(\frac{2\pi}{k})$. In other words, G is the same as $\widehat{H}$ with different parameters: an interval convolved with itself k^c times, multiplied by a sinc function.

We alias v down to $O(k)$ dimensions and take the discrete Fourier transform, getting $\widehat{u}$. It has been implicit in previous work—and we make it explicit—that $\widehat{u}_j$ is equal to $z_{\sigma a}$ for a vector z defined by

$$\widehat{z} = (\widehat{x} * \widehat{H}) \cdot \widehat{G}^{(j)}_{\sigma,b}$$

where $\widehat{G}^{(j)}_{\sigma,b}$ is a particular permutation of $\widehat{G}$. In particular, $\widehat{G}^{(j)}_{\sigma,b}$ has period $1/\sigma$, and approximates an interval of size $\frac{1}{\sigma B}$ within each period.

In previous work, when σ and b were chosen randomly, each individual frequency would have a good chance of being the only frequency preserved in $\widehat{z}$, and we could apply one-sparse recovery by choosing a variety of a. Without a frequency gap we can't quite say that: we pick $1/\sigma \gg \Delta$ so that the entire cluster usually lands in the same bin, but then nearby clusters can also often land in the same bin. Fortunately, it is still usually true

with frequency gap $\delta 2^{-k}$, and coefficients at most $2^k/\delta$.

that only nearby clusters will collide. Since our 1-cluster algorithm works when the signal frequencies are nearby, we apply it to find a frequency approximation within $\frac{\sqrt{T/\sigma}}{\sigma} = k^{O(1)}/T$ of the cluster.

The above algorithm recovers each individual frequency with constant probability. By repeating it $O(\log k)$ times, with high probability we find a list L of $O(k)$ frequencies within $k^{O(1)}/T$ of each significant cluster.

k-sparse recovery. Because different clusters aren't anywhere close to orthogonal, we can't simply approximate each cluster separately and add them up. Instead, given the list L of candidate frequencies, we consider the $O(kd)$-dimensional space of functions

$$\widetilde{x}(t) := \sum_{\widetilde{f} \in L} \sum_{i=0}^{d} \alpha_{\widetilde{f},i} t^i e^{2\pi \mathbf{i} \widetilde{f} t}$$

where $d = O(k^{O(1)} + \log(1/\delta))$. We then take a bunch of random samples of x, and choose the $\widetilde{x}(t)$ minimizing the empirical error using linear regression. This regression can be made slightly faster using oblivious subspace embeddings [CW13], [NN13a], [Woo14b],[CNW15].

Our argument to show this works is analogous to the naive method we considered for polynomial recovery. Similarly to the one-cluster setting, using Taylor approximations and Gram determinants, we can show that this space includes a sufficiently close approximation to x. Since polynomials are the limit of sparse Fourier as frequencies tend to zero, these functions are arbitrarily close to $O(kd)$-Fourier-sparse functions. Hence we know that the maximum of $|\widetilde{x}(t)|$ is at most a poly(kd) factor larger than its average over $[0, T]$. Using a net argument, this shows poly(kd) samples are sufficient to find a good approximation to the nearest function in our space.

Growth rate of Fourier-sparse signals. We need that $\frac{1}{\sqrt{T}}\|x^* \cdot H\|_2 \approx \|x^*\|_T$, where H approximates the interval $1_{[0,T]}$. Because H has support size k^c/T, it has a transition region of size $T/k^{c'}$ at the edges, and it decays as $(t/T)^{-k^{c''}}$ for $t \gg T$. The difference between $\frac{1}{\sqrt{T}}\|x^* \cdot H\|_2$ and $\|x^*\|_T$ involves two main components: mass in the transition region that is lost, and mass outside the sampling interval that is gained. To show the approximation, we need that $|x^*(t)| \lesssim \widetilde{O}(k^2)\|x^*\|_T$ within the interval and $|x^*(t)| \lesssim (kt/T)^{O(k)}\|x^*\|_T$ outside.

We outline the bound of $\max_{t\in[0,T]}|x^*(t)|$ in terms of its average $\|x^*\|_T$ to bound $|x^*(t)|$ within the interval. Notice that we can assume $|x^*(0)| = \max_{t\in[0,T]}|x^*(t)|$: if $t^* = \arg\max_{t\in[0,T]}|x^*(t)|^2$ is not 0 or T, we can rescale the two intervals $[0,t^*]$ and $[t^*,T]$ to $[0,T]$ separately. Then we show that for any t', there exist $m = \widetilde{O}(k^2)$ and constants $C_1,\cdots,C_m$ such that $x^*(0) = \sum_{j\in[m]} C_j \cdot x^*(j\cdot t')$. Then we take the integration of t' over $[0,T/m]$ to bound $|x^*(0)|^2$ by its average. For any outside $t > T$, we follow this approach to show $x^*(t) = \sum_{j\in[k]} C_j \cdot x^*(t_j)$ where $t_j \in [0,T]$ and $|C_j| \leq \mathrm{poly}(k)\cdot(kt/T)^{O(k)}$ for each $j \in [k]$. These results are shown in Section 12.5.

12.1.3 Organization

This paper is organized as follows. We provide a brief overview about signal recovery in Section 12.2. We introduce some notations and tools in Section 12.3. Then we show our main Theorem 12.1.2 about polynomial interpolation in Section 12.4. For signals with k-sparse Fourier transform, we show two bounds on their growth rate in Section 12.5 and describe the hash functions and filter functions in Section 12.6. We provide the algorithm for frequency estimation and its proof in Section 12.7. In Section 12.8, we describe the algorithm for one-cluster recovery. In Section 12.9, we show the proof of Theorem 12.1.1. We defer several technical proofs in Section 12.10. Section 12.11 gives a summary of several well-known facts are existing in literature. We provide the analysis of hash functions and filter functions in Section 12.12.

12.2 Proof Sketch

We first consider one-cluster recovery centered at zero, i.e., $x^*(t) = \sum_{j=1}^{k} v_j \cdot e^{2\pi \mathbf{i} f_j t}$ where every f_j is in $[-\Delta, \Delta]$ for some small $\Delta > 0$. The road map is to replace x^* by a low degree polynomial P such that $\|x^*(t) - P(t)\|_T^2 \lesssim \delta \|x^*\|_T^2$ then recover a polynomial Q to approximate P through the observation $x(t) = P(t) + g'(t)$ where $g'(t) = g(t) + \big(x^*(t) - P(t)\big)$.

A natural way to replace $x^*(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$ by a low degree polynomial $P(t)$ is the Taylor expansion. To bound the error after taking the low degree terms in the expansion by $\delta \|x^*\|_T$, we show the existence of $x'(t) = \sum_{j=1}^{k} v'_j e^{2\pi \mathbf{i} f'_j t}$ approximating x^* on $[0, T]$ with an extra property—any coefficient v'_j in $x'(t)$ has an upper bound in terms of $\|x'\|_T^2 = \frac{1}{T}\int_0^T |x'(t)|^2 \mathrm{d}t$. We prove the existence of $x'(t)$ via two more steps, both of which rely on the estimation of some Gram matrix constituted by these k signals.

The first step is to show the existence of a k-Fourier-sparse signal $x'(t)$ with frequency gap $\eta \geq \frac{\exp(-\operatorname{poly}(k)) \cdot \delta}{T}$ that is sufficiently close to $x^*(t)$.

Lemma 12.2.1. There is a universal constant $C_1 > 0$ such that, for any $x^*(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$ and any $\delta > 0$, there always exist $\eta \geq \frac{\delta}{T} \cdot k^{-C_1 k^2}$ and $x'(t) = \sum_{j=1}^{k} v'_j e^{2\pi \mathbf{i} f'_j t}$ satisfying

$$\|x'(t) - x^*(t)\|_T \leq \delta \|x^*(t)\|_T$$

with $\min_{i \neq j} |f'_i - f'_j| \geq \eta$ and $\max_{j \in [k]} \{|f'_j - f_j|\} \leq k\eta$.

We outline our approach and defer the proof to Section 12.8. We focus on the replacement of one frequency f_k in $x^* = \sum_{j \in [k]} v_j e^{2\pi \mathbf{i} f_j t}$ by a new frequency $f_{k+1} \neq f_k$ and its error. The idea is to consider every signal $e^{2\pi \mathbf{i} f_j t}$ as a vector and prove that for any vector

x^* in the linear subspace $\text{span}\{e^{2\pi \mathbf{i} f_j t} | j \in [k]\}$, there exists a vector in the linear subspace $\text{span}\{e^{2\pi \mathbf{i} f_{k+1} t}, e^{2\pi \mathbf{i} f_j t} | j \in [k-1]\}$ with distance at most $\exp(k^2) \cdot (|f_k - f_{k+1}|T) \cdot \|x^*\|_T$ to x^*.

The second step is to lower bound $\|x'\|_T^2$ by its coefficients through the frequency gap η in x'.

Lemma 12.2.2. There exists a universal constant $c > 0$ such that for any $x(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$ with frequency gap $\eta = \min_{i \neq j} |f_i - f_j|$,

$$\|x(t)\|_T^2 \geq k^{-ck^2} \min\left((\eta T)^{2k}, 1\right) \sum_{j=1}^{k} |v_j|^2.$$

Combining Lemma 12.2.1 and Lemma 12.2.2, we bound $|v'_j|$ by $\exp(\text{poly}(k)) \cdot \delta^{-O(k)} \cdot \|x'\|_T$ for any coefficient v'_j in x'. Now we apply the Taylor expansion on $x'(t)$ and keep the first $d = O(\Delta T + \text{poly}(k) + k \log \frac{1}{\delta})$ terms of every signal $v'_j \cdot e^{2\pi \mathbf{i} f'_j t}$ in the expansion to obtain a polynomial $P(t)$ of degree at most d. To bound the distance between $P(t)$ and $x'(t)$, we observe that the error of every point $t \in [0, T]$ is at most $(\frac{2\pi\Delta \cdot T}{d})^d \sum_j |v'_j|$, which can be upper bounded by $\delta \|x'(t)\|_T$ via the above connection. We summarize all discussion above as follows.

Lemma 12.2.3. For any $\Delta > 0$ and any $\delta > 0$, let $x^*(t) = \sum_{j \in [k]} v_j e^{2\pi \mathbf{i} f_j t}$ where $|f_j| \leq \Delta$ for each $j \in [k]$. There exists a polynomial $P(t)$ of degree at most

$$d = O(T\Delta + k^3 \log k + k \log 1/\delta)$$

such that

$$\|P(t) - x^*(t)\|_T^2 \leq \delta \|x^*\|_T^2.$$

To recover $x^*(t)$, we observe $x(t)$ as a degree d polynomial $P(t)$ with noise. We use properties of the Legendre polynomials to design a method of random sampling such that we only need $O(d)$ random samples to find a polynomial $Q(t)$ approximating $P(t)$.

Theorem 12.1.2. For any degree d polynomial $P(t)$ and an arbitrary function $g(t)$, Procedure RobustPolynomialLearning in Algorithm 12.5 takes $O(d)$ samples from $x(t) = P(t) + g(t)$ over $[0, T]$ and reports a degree d polynomial $Q(t)$ in time $O(d^\omega)$ such that, with probability at least 99/100,

$$\|P(t) - Q(t)\|_T^2 \lesssim \|g(t)\|_T^2.$$

where $\omega < 2.373$ is matrix multiplication exponent [Str69],[CW87],[Wil12].

We can either report the polynomial $Q(t)$ or transfer $Q(t)$ to a signal with d-sparse Fourier transform. We defer the technical proofs and the formal statements to Section 12.8 and discuss the recovery of k clusters from now on.

As mentioned before, we apply the filter function $(H(t), \widehat{H}(f))$ on x^* such that $\widehat{x^* \cdot H}$ has at most k clusters given $\widehat{x^*}$ with k-sparse Fourier transform. First, we show that all frequencies in the "heavy" clusters of $\widehat{x^* \cdot H}$ constitute a good approximation of x^* in Section 12.9.

Definition 12.2.4. Given $x^*(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$, any $\mathcal{N} > 0$, and a filter function $(H, \widehat{H})$ with bounded support in frequency domain. Let L_j denote the interval of $\operatorname{supp}(\widehat{e^{2\pi \mathbf{i} f_j t} \cdot H})$ for each $j \in [k]$.

Define an equivalence relation $\sim$ on the frequencies f_i by the transitive closure of the relation $f_i \sim f_j$ if $L_i \cap L_j \neq \emptyset$. Let $S_1, \ldots, S_n$ be the equivalence classes under this relation.

Define $C_i = \bigcup_{f \in S_i} L_i$ for each $i \in [n]$. We say C_i is a "heavy" cluster iff $\int_{C_i} |\widehat{H \cdot x^*}(f)|^2 \mathrm{d}f \geq T \cdot \mathcal{N}^2/k$.

Claim 12.2.5. Given $x^*(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$ and any $\mathcal{N} > 0$, let H be the filter function defined in Section 12.12.1 and $C_1, \cdots, C_l$ be the heavy clusters from Definition 12.2.4. For

$$S = \left\{ j \in [k] \middle| f_j \in C_1 \cup \cdots C_l \right\},$$

we have $x^{(S)}(t) = \sum_{j \in S} v_j e^{2\pi \mathbf{i} f_j t}$ approximating x^* within distance $\|x^{(S)}(t) - x^*(t)\|_T^2 \lesssim \mathcal{N}^2$.

Hence it is enough to recover $x^{(S)}$ for the recovery of x^*. Let Δ_h denote the bandwidth of $\widehat{H}$. In Section 12.7, we choose $\Delta > k \cdot \Delta_h$ such that for any $j \in S$, $\int_{f_j - \Delta}^{f_j + \Delta} |\widehat{H \cdot x^*}(f)|^2 \mathrm{d}f \geq T \cdot \mathcal{N}^2/k$ from the fact $|C_i| \leq k \cdot \Delta_h$. Then we prove Theorem 12.2.6 in Section 12.7, which finds $O(k)$ frequencies to cover all heavy clusters of $\widehat{x^* \cdot H}$.

Theorem 12.2.6. Let $x^*(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$ and $x(t) = x^*(t) + g(t)$ be our observable signal where $\|g(t)\|_T^2 \leq c\|x^*(t)\|_T^2$ for a sufficiently small constant c. Then Procedure FrequencyRecoveryKCluster returns a set L of $O(k)$ frequencies that covers all heavy clusters of x^*, which uses $\mathrm{poly}(k, \log(1/\delta)) \log(FT)$ samples and $\mathrm{poly}(k, \log(1/\delta)) \log^2(FT)$ time. In particular, for $\Delta = \mathrm{poly}(k, \log(1/\delta))/T$ and $\mathcal{N}^2 := \|g(t)\|_T^2 + \delta \|x^*(t)\|_T^2$, with probability $1 - 2^{-\Omega(k)}$, for any f^* with

$$\int_{f^* - \Delta}^{f^* + \Delta} |\widehat{x \cdot H}(f)|^2 \mathrm{d}f \geq T\mathcal{N}^2/k, \tag{12.2}$$

there exists an $\widetilde{f} \in L$ satisfying

$$|f^* - \widetilde{f}| \lesssim \Delta\sqrt{\Delta T}.$$

Let $L = \{\widetilde{f}_1, \cdots, \widetilde{f}_l\}$ be the list of frequencies from the output of Procedure FrequencyRecoveryKCluster in Theorem 12.2.6. The guarantee is that, for any f_j in

$x^{(S)}$, there exists some $p_j \in [l]$ such that $|\widetilde{f}_{p_j} - f_j| \lesssim \Delta\sqrt{\Delta T}$ for $\Delta = \mathrm{poly}(k, \log(1/\delta))/T$. Hence we rewrite $x^{(S)}(t) = \sum_{i\in[l]} e^{2\pi\mathbf{i}\widetilde{f}_i t}(\sum_{j\in S:p_j=i} e^{2\pi\mathbf{i}(f_j-\widetilde{f}_i)t})$. For each $i \in [l]$, we apply Lemma 12.2.3 of one-cluster recovery on $\sum_{j\in S:p_j=i} e^{2\pi\mathbf{i}(f_j-\widetilde{f}_i)t}$ to approximate it by a degree d polynomial $P_i(t)$.

Now we consider $x(t) = \sum_{i\in[l]} e^{2\pi\mathbf{i}\widetilde{f}_i t} \cdot P_i(t) + g''(t)$ where $\|g''(t)\|_T \lesssim \|g(t)\|_T + \delta\|x^*(t)\|_T$. To recover $\sum_{i\in[l]} e^{2\pi\mathbf{i}\widetilde{f}_i t} \cdot P_i(t)$, we treat it as a vector in the linear subspace

$$V = \mathrm{span}\left\{ e^{2\pi\mathbf{i}\widetilde{f}_i t} \cdot t^j \middle| j \in \{0, \cdots, d\}, i \in [l] \right\}$$

with dimension at most $l(d+1)$ and find a vector in this linear subspace approximating it.

We show that for any $v \in V$, the average of $\mathrm{poly}(kd)$ random samples on v is enough to estimate $\|v\|_T^2$. In particular, any vector in this linear subspace satisfies that the maximum of it in $[0, T]$ has an upper bound in terms of its average in $[0, T]$. Then we apply the Chernoff bound to prove that $\mathrm{poly}(kd)$ random samples are enough for the estimation of one vector $v \in V$.

Claim 12.2.7. For any $\vec{u} \in \mathrm{span}\left\{ e^{2\pi\mathbf{i}\widetilde{f}_i t} \cdot t^j \middle| j \in \{0, \cdots, d\}, i \in [l] \right\}$, there exists some universal constants $C_1 \leq 4$ and $C_2 \leq 3$ such that

$$\max_{t\in[0,T]}\{|\vec{u}(t)|^2\} \lesssim (ld)^{C_1} \log^{C_2}(ld) \cdot \|\vec{u}\|_T^2$$

At last we use an ϵ-net to argue that $\mathrm{poly}(kd)$ random samples from $[0, T]$ are enough to interpolate $x(t)$ by a vector $v \in V$. Because the dimension of this linear subspace is at most $l(d+1) = O(kd)$, there exists an ϵ-net in this linear subspace for unit vectors with size at most $\exp(kd)$. Combining the Chernoff bound on all vectors in the ϵ-net and Claim 12.2.7, we know that $\mathrm{poly}(kd)$ samples are sufficient to estimate $\|v\|_T^2$ for any vector $v \in V$.

In Section 12.9, we show that a vector $v \in V$ minimizing the distance on $\mathrm{poly}(kd)$ random samples is a good approximation for $\sum_{i\in[l]} e^{2\pi \mathbf{i} \widetilde{f}_i t} \cdot P_i(t)$, which is a good approximation for $x^*(t)$ from all discussion above.

Theorem 12.1.1. Let $x(t) = x^*(t) + g(t)$, where x^* is k-Fourier-sparse signal with frequencies in $[-F, F]$. Given samples of x over $[0, T]$ we can output $\widetilde{x}(t)$ such that with probability at least $1 - 2^{-\Omega(k)}$,

$$\|\widetilde{x} - x^*\|_T \lesssim \|g\|_T + \delta \|x^*\|_T .$$

Our algorithm uses $\mathrm{poly}(k, \log(1/\delta)) \cdot \log(FT)$ samples and $\mathrm{poly}(k, \log(1/\delta)) \cdot \log^2(FT)$ time. The output $\widetilde{x}$ is $\mathrm{poly}(k, \log(1/\delta))$-Fourier-sparse signal.

12.3 Preliminaries

We first provide some notations in Section 12.3.1 and basic Fourier facts in Section 12.3.2. Then we review some probability inequalities in Section 12.3.3. At last, we introduce Legendre polynomials in Section 12.3.4 and review some basic properties of Gram matrix and its determinant in Section 12.3.5.

12.3.1 Notation

For any function f, we define $\widetilde{O}(f)$ to be $f \cdot \log^{O(1)}(f)$. We use $[n]$ to denote $\{1, 2, \cdots, n\}$. Let $\mathbf{i}$ denote $\sqrt{-1}$. For any Complex number $z = a + \mathbf{i}b \in C$, where $a, b \in \mathbb{R}$. We define $\overline{z}$ to be $a - \mathbf{i}b$ and $|z| = \sqrt{a^2 + b^2}$ such that $|z|^2 = z\overline{z}$. For any function $f(t) : \mathbb{R} \to \mathbb{C}$, we use $\mathrm{supp}(f)$ to denote the support of f.

For convenience, we define the sinc function and the Gaussian distribution $\mathrm{Gaussian}_{\mu,\sigma}$ on $\mathbb{R}$ with expectation μ and variance σ^2 as follows:

$$\mathrm{sinc}(t) = \frac{\sin(\pi t)}{\pi t}, \quad \mathrm{Gaussian}_{\mu,\sigma}(t) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(t-\mu)^2}{2\sigma^2}}.$$

For a fixed $T > 0$, we define the inner product of two functions $x, y : [0, T] \to \mathbb{C}$ as

$$\langle x, y \rangle_T = \frac{1}{T} \int_0^T x(t)\overline{y}(t)\mathrm{d}t.$$

We define the $\| \cdot \|_T$ norm as

$$\|x(t)\|_T = \sqrt{\langle x(t), x(t) \rangle_T} = \sqrt{\frac{1}{T} \int_0^T |x(t)|^2 \mathrm{d}t}.$$

12.3.2 Facts about the Fourier transform

In this work, we always use $x(t)$ to denote a signal from $\mathbb{R} \to \mathbb{C}$. The Fourier transform $\widehat{x}(f)$ of an integrable function $x : \mathbb{R} \to \mathbb{C}$ is defined as

$$\widehat{x}(f) = \int_{-\infty}^{+\infty} x(t) e^{-2\pi \mathbf{i} f t} \mathrm{d}t, \text{ for any real number } f.$$

Similarly, $x(t)$ is determined from $\widehat{x}(f)$ by the inverse transform:

$$x(t) = \int_{-\infty}^{+\infty} \widehat{x}(f) e^{2\pi \mathbf{i} f t} \mathrm{d}f, \text{ for any real number } t.$$

Let CFT denote the continuous Fourier transform, DTFT denote the discrete-time Fourier transform, DFT denote the discrete Fourier transform, and FFT denote the fast Fourier transform.

For any signal $x(t)$ and $n \in \mathbb{N}_+$, we define $x^{*n}(t) = \underbrace{x(t) * \cdots * x(t)}_{n}$ and $\widehat{x}^{\cdot n}(f) = \underbrace{\widehat{x}(f) \cdot \cdots \cdot \widehat{x}(f)}_{n}$.

Fact 12.3.1. *Let $\delta_\Delta(f)$ denote the Dirac delta at Δ. Then*

$$\widehat{\delta}_\Delta(t) = \int_{-\infty}^{+\infty} \delta_\Delta(f) e^{2\pi \mathbf{i} f t} \mathrm{d}f = e^{2\pi \mathbf{i} t \Delta}.$$

Fact 12.3.2. *For any $s > 0$, let $\mathrm{Comb}_s(t) = \sum_{j \in \mathbb{Z}} \delta_{js}(t)$. Then the Fourier transform of $\mathrm{Comb}_s(t)$ is*

$$\widehat{\mathrm{Comb}_s}(f) = \frac{1}{s} \mathrm{Comb}_{1/s}(f).$$

The following fact says the the Fourier transform of a rectangle function is a sinc function.

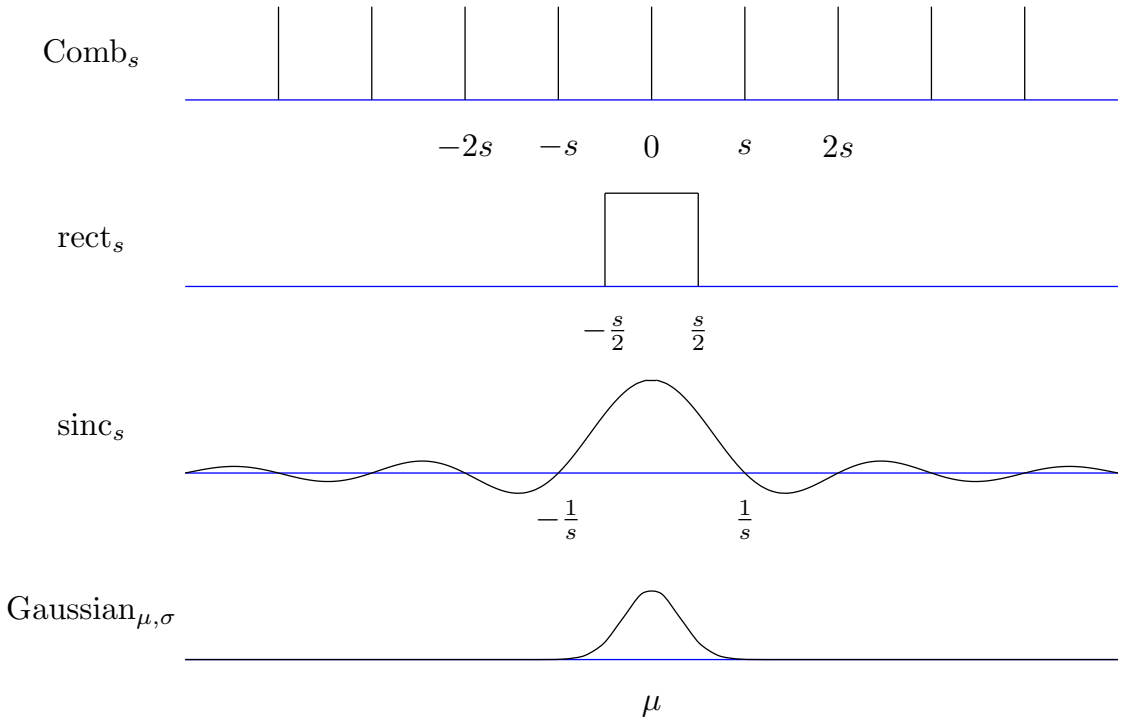

Figure 12.1: A picture of a Comb$_s$, rect$_s$, sinc$_s$, Gaussian$_{\mu,\sigma}$.

Fact 12.3.3. *We use*

$$\text{rect}_s(t) = \begin{cases} 1 & \text{if } |\text{t}| \leq \frac{\text{s}}{2}, \\ 0 & \text{otherwise.} \end{cases}$$

Then the Fourier transform of rect$_s(t)$ *is* $\widehat{\text{rect}_s}(f) = \frac{\sin(\pi f s)}{\pi f s} = \text{sinc}(fs)$.

The Fourier transform of a Gaussian function is another Gaussian function.

Fact 12.3.4. *For* $\text{Gaussian}_{\mu,\sigma}(t) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(t-\mu)^2}{2\sigma^2}}$. *Then the Fourier transform is*

$$\widehat{\text{Gaussian}}_{\mu,\sigma}(f) = e^{-2\pi \mathbf{i} f u} \frac{1}{\sigma\sqrt{2\pi}} \text{Gaussian}_{0,\sigma'}(f) \text{ for } \sigma' = 1/(2\pi\sigma).$$

Proof. From the definition of the Fourier transform,

$$\begin{aligned}
\widehat{\text{Gaussian}}_{\mu,\sigma}(f) &= \int_{-\infty}^{+\infty} \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(t-\mu)^2}{2\sigma^2}} e^{-2\pi \mathbf{i} f t} \mathrm{d}t \\
&= e^{-2\pi \mathbf{i} f u} \int_{-\infty}^{+\infty} \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{t^2}{2\sigma^2}} e^{-2\pi \mathbf{i} f t} \mathrm{d}t \\
&= e^{-2\pi \mathbf{i} f u} \int_{-\infty}^{+\infty} \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(t+2\pi \mathbf{i}\sigma^2 f)^2}{2\sigma^2} - 2\pi^2 f^2 \sigma^2} \mathrm{d}t \\
&= e^{-2\pi \mathbf{i} f u} e^{-\frac{f^2}{2\sigma'^2}}
\end{aligned}$$

where $\sigma' = 1/(2\sigma\pi)$, which is $e^{-2\pi \mathbf{i} f u} \cdot \sigma'\sqrt{2\pi} \cdot \text{Gaussian}_{0,\sigma'}(f)$. □

12.3.3 Tools and inequalities

From the Chernoff Bound (Lemma A.1.1), we show that if the maximum of a signal is bounded by d times its energy over some fixed interval, then taking more than d samples (each sample is drawn i.i.d. over that interval) suffices to approximate the energy of the signal on the interval with high probability.

Lemma 12.3.5. Given any function $x(t) : \mathbb{R} \to \mathbb{C}$ with $\max_{t\in[0,T]} |x(t)|^2 \leq d\|x(t)\|_T^2$. Let S denote a set of points from 0 to T. If each point of S is chosen uniformly at random from $[0, T]$, we have

$$\Pr\left[\left|\frac{1}{|S|}\sum_{i\in S}|x(t_i)|^2 - \|x(t)\|_T^2]\right| \geq \epsilon\|x(t)\|_T^2\right] \quad \leq \quad e^{-\Omega(\epsilon^2|S|/d)}$$

We provide a proof in Section 12.10.5.

Because $d \cdot \frac{1}{2d} + \frac{1}{2} \cdot (1 - \frac{1}{2d}) \leq 1$, we have the following inequality when the maximum of $|x(t)|^2$ is at most d times its average.

Lemma 12.3.6. *Given any function $x(t) : \mathbb{R} \to \mathbb{C}$ with $\max_{t\in[0,T]} |x(t)|^2 \leq d\|x(t)\|_T^2$. Let S denote a set of points from 0 to T. For any point a is sampled uniformly at random from $[0, T]$, we have,*

$$\Pr_{a\sim[0,T]}\left[|x(a)|^2 \geq \frac{1}{2}\|x(t)\|_T^2\right] \geq \frac{1}{2d}.$$

12.3.4 Legendre polynomials

We provide an brief introduction to Legendre polynomials (please see [Dun10] for a complete introduction). For convenience, we fix $\|f(t)\|_T^2 = \frac{1}{2}\int_{-1}^{1} |f(t)|^2 \mathrm{d}t$ in this section.

Definition 12.3.1. Let $L_n(x)$ denote the Legendre polynomials of degree n, the solution to Legendre's differential equation:

$$\frac{\mathrm{d}}{\mathrm{d}x}\left[(1-x^2)\frac{\mathrm{d}}{\mathrm{d}x}L_n(x)\right] + n(n+1)L_n(x) = 0 \tag{12.3}$$

We will the following two facts about the Legendre polynomials in this work.

Fact 12.3.7. *$L_n(1) = 1$ for any $n \geq 0$ in the Legendre polynomials.*

Fact 12.3.8. *The Legendre polynomials constitute an orthogonal basis with respect to the inner product on interval $[-1, 1]$:*

$$\int_{-1}^{1} L_m(x)L_n(x)\mathrm{d}x = \frac{2}{2n+1}\delta_{mn}$$

where δ_{mn} denotes the Kronecker delta, i.e., it equals to 1 if $m = n$ and to 0 otherwise.

For any polynomial $P(x)$ of degree at most d with complex coefficients, there exists a set of coefficients from the above properties such that

$$P(x) = \sum_{i=0}^{d} \alpha_i \cdot L_i(x), \text{ where } \alpha_i \in \mathbb{C}, \forall i \in \{0, 1, 2, \cdots, d\}.$$

Lemma 12.3.9. For any polynomial $P(t)$ of degree at most d from R to $\mathbb{C}$, for any interval $[S, T]$,

$$\max_{t\in[S,T]} |P(t)|^2 \leq (d+1)^2 \cdot \frac{1}{T-S}\int_S^T |P(t)|^2 \mathrm{d}x.$$

We provide a proof in Section 12.10.6.

12.3.5 Gram matrix and its determinant

We provide an brief introduction to Gramian matrices (please see [Haz01] for a complete introduction). We use $\langle x, y\rangle$ to denote the inner product between vector x and vector y.

Let $\vec{v}_1, \cdots, \vec{v}_n$ be n vectors in an inner product space and $\text{span}\{\vec{v}_1, \cdots, \vec{v}_n\}$ be the linear subspace spanned by these n vectors with coefficients in $\mathbb{C}$, i.e.,

$$\left\{ \sum_{i\in[n]} \alpha_i \vec{v}_i \;\middle|\; \forall i \in [n], \alpha_i \in \mathbb{C} \right\}.$$

The Gram matrix Gram_n of $\vec{v}_1, \cdots, \vec{v}_n$ is an $n \times n$ matrix defined as $\text{Gram}_n(i, j) = \langle \vec{v}_i, \vec{v}_j \rangle$ for any $i \in [n]$ and $j \in [n]$.

Fact 12.3.10. $\det(\text{Gram}_n)$ *is the square of the volume of the parallelotope formed by* $\vec{v}_1, \cdots, \vec{v}_n$.

Let Gram_{n-1} be the Gram matrix of $\vec{v}_1, \cdots, \vec{v}_{n-1}$. Let $\vec{v}_n^{\parallel}$ be the projection of v_n onto the linear subspace $\text{span}\{\vec{v}_1, \cdots, \vec{v}_{n-1}\}$ and $\vec{v}_n^{\perp} = \vec{v}_n - \vec{v}_n^{\parallel}$. We use $\|\vec{v}\|$ to denote the length of $\vec{v}$ in the inner product space, which is $\sqrt{\langle \vec{v}, \vec{v} \rangle}$.

Claim 12.3.11.

$$\|\vec{v}_n^{\perp}\|^2 = \frac{\det(\text{Gram}_{n-1})}{\det(\text{Gram}_n)}.$$

Proof.

$$\det(\text{Gram}_n) = \text{volume}^2(\vec{v}_1, \cdots, \vec{v}_n) = \text{volume}^2(\vec{v}_1, \cdots, \vec{v}_{n-1}) \cdot \|\vec{v}_n^{\perp}\|^2 = \det(\text{Gram}_n) \cdot \|\vec{v}_n^{\perp}\|^2.$$

□

12.4 Robust Polynomial Interpolation Algorithm

In Section 12.4.1, we show how to learn a low degree polynomial by using linear number of samples, running polynomial time, and achieving constant success probability. In Section 12.4.2, we show to how boost the success probability by rerunning previous algorithm several times.

12.4.1 Constant success probability

We show how to learn a degree-d polynomial P with $n = O(d)$ samples and prove Theorem 12.1.2 in this section. For convenience, we first fix the interval to be $[-1, 1]$ and use $\|f\|^2_{[-1,1]} = \frac{1}{2}\int_{-1}^{1} |f(t)|^2 \mathrm{d}t$.

Lemma 12.4.1. *Let $d \in \mathbb{N}$ and $\epsilon \in \mathbb{R}^+$, there exists an efficient algorithm to compute a partition of $[-1, 1]$ to $n = O(d/\epsilon)$ intervals $I_1, \cdots, I_n$ such that for any degree d polynomial $P(t) : \mathbb{R} \to \mathbb{C}$ and any n points $x_1, \cdots, x_n$ in the intervals $I_1, \cdots, I_n$ respectively, the function $Q(t)$ defined by*

$$Q(t) = P(x_j) \quad \text{if} \quad t \in I_j$$

approximates P by

$$\|Q - P\|_{[-1,1]} \leq \epsilon \|P\|_{[-1,1]}. \tag{12.4}$$

One direct corollary from the above lemma is that observing $n = O(d/\epsilon)$ points each from $I_1, \cdots, I_n$ provides a good approximation for all degree d polynomials. For any set $S = \{t_1, \cdots, t_m\}$ where each $t_i \in [-1, 1]$ and a distribution with support $\{w_1, \cdots, w_m\}$ on S where $\sum_{i=1}^{m} w_i = 1$ and $w_i \geq 0$ for each $i \in [m]$, we define $\|x\|_{S,w} = (\sum_{i=1}^{m} w_i \cdot |x(t_i)|^2)^{1/2}$.

Corollary 12.4.2. *Let $I_1, \cdots, I_n$ be the intervals in the above lemma and $w_j = |I_j|/2$ for each $j \in [n]$. For any $x_1, \cdots, x_n$ in the intervals $I_1, \cdots, I_n$ respectively, we consider $S = \{x_1, \cdots, x_n\}$ with the distribution $w_1, \cdots, w_n$. Then for any degree d polynomial P, we have*

$$\|P\|_{S,w} \in \left[(1-\epsilon)\|P\|_{[-1,1]}, (1+\epsilon)\|P\|_{[-1,1]}\right].$$

We first state the main technical lemma and finish the proof of the above lemma (we defer the proof of Lemma 12.4.3 to Section 12.10.3).

Lemma 12.4.3. For any degree d polynomial $P(t) : \mathbb{R} \to \mathbb{C}$ with derivative $P'(t)$, we have,

$$\int_{-1}^{1} (1-t^2)|P'(t)|^2 \mathrm{d}t \leq 2d^2 \int_{-1}^{1} |P(t)|^2 \mathrm{d}t. \tag{12.5}$$

Proof of Lemma 12.4.1. We set $m = 10d/\epsilon$ and show a partition of $[-1, 1]$ into $n \leq 20m$ intervals. We define $g(t) = \frac{\sqrt{1-t^2}}{m}$ and $y_0 = 0$. Then we choose $y_i = y_{i-1} + g(y_{i-1})$ for $i \in \mathbb{N}^+$. Let l be the first index of y such that $y_l \geq 1 - \frac{9}{m^2}$. We show $l \lesssim m$.

Let j_k be the first index in the sequence such that $y_{j_k} \geq 1 - 2^{-k}$. Notice that

$$j_2 \leq \frac{3/4}{\frac{\sqrt{1-(3/4)^2}}{m}} \leq 1.5m$$

and

$$y_i - y_{i-1} = g(y_{i-1}) = \frac{\sqrt{1-y_{i-1}^2}}{m} \geq \frac{\sqrt{1-y_{i-1}}}{m}.$$

Then for all $k > 2$, we have

$$j_k - j_{k-1} \leq \frac{2^{-k}}{\frac{\sqrt{1-y_{(j_k-1)}}}{m}} \leq 2^{-k/2} m.$$

Therefore $j_k \leq \left(1.5 + (2^{-3/2} + \cdots 2^{-k/2})\right) m$ and $l \leq 10m$.

Because $y_{l-1} \leq 1 - \frac{9}{m^2}$, for any $j \in [l]$ and any $x \in [y_{i-1}, y_i]$, we have the following property:

$$\frac{1-x^2}{m^2} \geq \frac{1}{2} \cdot \frac{(1-y_{i-1}^2)}{m^2} = (y_i - y_{i-1})^2/2. \tag{12.6}$$

Now we set n and partition $[-1, 1]$ into $I_1, \cdots, I_n$ as follows:

1. $n = 2(l+1)$.

2. For $j \in [l]$, $I_{2j-1} = [y_{j-1}, y_j]$ and $I_{2j} = [-y_j, -y_{j-1}]$.

3. $I_{2l+1} = [y_l, 1]$ and $I_{2l+2} = [-1, -y_l]$.

For any $x_1, \cdots, x_n$ where $x_j \in I_j$ for each $j \in [n]$, we rewrite the LHS of (12.4) as follows:

$$\underbrace{\sum_{j=1}^{n-2} \int_{I_j} |P(x_j) - P(t)|^2 \, \mathrm{d}t}_{A} + \underbrace{\int_{I_{n-1}} |P(x_{n-1}) - P(t)|^2 \, \mathrm{d}t + \int_{I_n} |P(x_n) - P(t)|^2 \, \mathrm{d}t}_{B}. \tag{12.7}$$

For A in Equation (12.7), from the Cauchy-Schwarz inequality, we have

$$\sum_{j=1}^{n-2} \int_{I_j} |P(x_j) - P(t)|^2 \, \mathrm{d}t = \sum_{j=1}^{n-2} \int_{I_j} \left| \int_{x_j}^{t} P'(y) \mathrm{d}y \right|^2 \mathrm{d}t \leq \sum_{j=1}^{n-2} \int_{I_j} |t - x_j| \int_{x_j}^{t} |P'(y)|^2 \mathrm{d}y \mathrm{d}t.$$

Then we swap $\mathrm{d}t$ with $\mathrm{d}y$ and use Equation (12.6):

$$\sum_{j=1}^{n-2} \int_{I_j} |P'(y)|^2 \int_{t \notin (x_j, y)} |t - x_j| \mathrm{d}t \mathrm{d}y \leq \sum_{j=1}^{n-2} \int_{I_j} |P'(t)|^2 \cdot |I_j|^2 \mathrm{d}t \leq \sum_{j=1}^{n-2} \int_{I_j} |P'(t)|^2 \frac{2(1-t^2)}{m^2} \mathrm{d}t.$$

We use Lemma 12.4.3 to simplify it by

$$\sum_{j=1}^{n-2} \int_{I_j} |P(x_j) - P(t)|^2 \, \mathrm{d}t \leq \int_{-1}^{1} |P'(t)|^2 \frac{2(1-t^2)}{m^2} \mathrm{d}t \leq \frac{2d^2}{m^2} \int_{-1}^{1} |P(t)|^2 \mathrm{d}t.$$

For B in Equation (12.7), notice that $|I_{n-1}| = |I_n| = 1 - y_l \leq 9m^{-2}$ and for $j \in \{n-1, n\}$

$$|P(t) - P(x_j)|^2 \leq 4 \max_{t \in [-1,1]} |P(t)|^2 \leq 4(d+1)^2 \|P\|_{[-1,1]}^2$$

from the properties of degree-d polynomials, i.e., Lemma 12.3.9. Therefore B in Equation (12.7) is upper bounded by $2 \cdot 4(d+1)^2 (9m^{-2}) \|P(t)\|_{[-1,1]}^2$.

From all discussion above, $\|Q(t) - P(t)\|_{[-1,1]}^2 \leq \frac{99d^2}{m^2} \leq \epsilon^2$. □

Now we use the above lemma to provide a faster learning algorithm for polynomials on interval $[-1,1]$ with noise instead of using the ϵ-nets argument. Algorithm RobustPolynomialLearningFixedInterval works as follows:

1. Let $\epsilon = 1/20$ and $I_1, \cdots, I_n$ be the intervals for d and ϵ in Lemma 12.4.1.
2. Random choose $x_j \in I_j$ for every $j \in [n]$ and define $S = \{x_1, \cdots, x_n\}$ with weight $w_1 = \frac{|I_1|}{2}, \cdots, w_n = \frac{|I_n|}{2}$.
3. Find the degree d polynomial $Q(t)$ that minimizes $\|P(t) - Q(t)\|_{S,w}$ using Fact 12.11.1.

Lemma 12.4.4. *For any degree d polynomial $P(t)$ and an arbitrary function $g(t)$, Algorithm* RobustPolynomialLearningFixedInterval *takes $O(d)$ samples from $x(t) = P(t) + g(t)$ over $[-1,1]$ and reports a degree d polynomial $Q(t)$ in time $O(d^\omega)$ such that, with probability at least $99/100$,*

$$\|P(t) - Q(t)\|^2_{[-1,1]} \lesssim \|g(t)\|^2_{[-1,1]}.$$

Proof. Notice that $n = O(d/\epsilon) = O(d)$ and the running time depends on solving a linear regression problem(Fact 12.11.1), which takes $O(d^\omega)$ time. It is enough to bound the

distance between P and Q:

$$\begin{aligned}
& \|P-Q\|_{[-1,1]} & \\
\leq\ & 1.09\|P-Q\|_{S,w} & \text{by Corollary 12.4.2} \\
=\ & 1.09\|x-g-Q\|_{S,w} & \text{by } x=P+g \\
\leq\ & 1.09\|g\|_{S,w}+1.09\|x-Q\|_{S,w} & \text{by triangle inequality} \\
\leq\ & 1.09\|g\|_{S,w}+1.09\|x-P\|_{S,w} & Q=\arg\min_{\text{degree-}d\ R}\|R-x\|_{S,w} \\
\leq\ & 2.2\|g\|_{S,w} &
\end{aligned}$$

Because $\mathop{\mathbb{E}}_{S}[\|g\|_{S,w}^2]=\|g\|_{[-1,1]}^2$, we know that $\|P-Q\|_{[-1,1]}\leq 2200\|g\|_{[-1,1]}$ with probability $\geq .999$ by using Markov's inequality. □

For any function $f:[0,T]\to\mathbb{C}$, let $\widetilde{f}(t)=f(\frac{2t-T}{T})$. Then $\|\widetilde{f}\|_{[-1,1]}=\|f\|_T$ from the definition. Hence we can switch any interval $[0,T]$ to $[-1,1]$ and use Lemma 12.4.4.

Theorem 12.1.2. For any degree d polynomial $P(t)$ and an arbitrary function $g(t)$, Procedure RobustPolynomialLearning in Algorithm 12.5 takes $O(d)$ samples from $x(t)=P(t)+g(t)$ over $[0,T]$ and reports a degree d polynomial $Q(t)$ in time $O(d^\omega)$ such that, with probability at least 99/100,

$$\|P(t)-Q(t)\|_T^2\lesssim\|g(t)\|_T^2.$$

where $\omega<2.373$ is matrix multiplication exponent [Str69],[CW87],[Wil12].

12.4.2 Boosting success probability

Notice that the success probability of Theorem 12.1.2 is only constant, and the proof technique of obtaining that result cannot be modified to $1 - 1/\operatorname{poly}(d)$ or $1 - 2^{-\Omega(d)}$ success probability due to using Markov's inequality. However, we can use that algorithm as a black box, and rerun it $O(\log(1/p))$ (for any $p > 0$) times on fresh samples. Using the careful median analysis from [MP14] gives

Theorem 12.4.5. For any degree d polynomial $P(t)$, an arbitrary function $g(t)$, and any $p > 0$, Procedure RobustPolynomialLearning$^+$ in Algorithm 12.5 takes $O(d \log(1/p))$ samples from $x(t) = P(t) + g(t)$ over $[0, T]$ and reports a degree d polynomial $Q(t)$ in time $O(d^\omega \log(1/p))$ such that, with probability at least $1 - p$,

$$\|P(t) - Q(t)\|_T^2 \lesssim \|g(t)\|_T^2.$$

where $\omega < 2.373$ is matrix multiplication exponent.

Proof. We run algorithm RobustPolynomialLearning R rounds with $O(d)$ independent and fresh samples per round. We will obtain R degree-d polynomials $Q_1(t), Q_2(t), \cdots, Q_R(t)$. We say a polynomial $Q_i(t)$ is good if $\|Q_i(t) - P(t)\|_T^2 \lesssim \|g(t)\|_T^2$. Using the Chernoff bound, with probability at least $1 - 2^{-\Omega(R)}$, at least a $3/4$ fraction of the polynomials are "good". We output polynomial $Q(t) = Q_{j^*}(t)$ such that

$$j^* = \arg\min_{j \in [R]} (\text{median}\{\|Q_j(t) - Q_1(t)\|_T^2, \|Q_j(t) - Q_2(t)\|_T^2, \cdots, \|Q_j(t) - Q_R(t)\|_T^2\}) \quad (12.8)$$

The Equation (12.8) can be solved in following straightforward way. For $i \neq j$, it takes $O(d)$ time to compute $\|Q_j(t) - Q_i(t)\|_T^2$. Because of the number of pairs is $O(R^2)$, thus it takes

$O(R^2 d)$ time write down a $R \times R$ matrix. For each column, we run linear time 1-median algorithm. This step takes $O(R^2)$ time. At the end, j^* is index of the column that has the smallest median value. Thus, polynomial $Q(t) = Q_{j^*}(t)$ 1 the 0 with probability at least $1 - p$ by choosing $R = O(\log(1/p))$. The running time is not optimized yet.

To improve the dependence on R for running time, we replace the step of solving Equation (12.8) by an approach that is similar to [MP14]. We choose a new set of samples S, say $S = \{t_1, t_2, \cdots, t_n\}$ and $n = O(d)$. Using Fact 12.11.2, we can compute $Q_i(t_j)$ for all $i, j \in [R] \times [n]$ in $O(Rd \operatorname{poly}(\log(d)))$ time. Define

$$\widetilde{Q}_j = \operatorname*{median}_{i \in [R]} Q_i(t_j), \forall j \in [n]. \tag{12.9}$$

Our algorithm will output a degree-d polynomial Q which is the optimal solution of this problem, $\min_{\text{degree-}d\ Q'} \|Q' - \widetilde{Q}\|_{S,w}$.[2] In the rest of the proof, we will show that $\|Q - P\|_T \lesssim \|g\|_T$ with probability at least $1 - 2^{-\Omega(R)}$.

Notice that Equation (12.9) implies that $\widetilde{Q}_j - P(t_j) = \operatorname*{median}_{i \in [R]}(Q_i(t_j) - P(t_j))$. Fix a coordinate j and applying the proof argument of Lemma 6.1 in [MP14], we have

$$(\widetilde{Q}_j - P(t_j))^2 \lesssim \operatorname*{mean}_{\text{good } i}(Q_i(t_j) - P(t_j))^2$$

Taking the weighted summation over all the coordinates j, we have

$$\|\widetilde{Q} - P\|_{S,w}^2 \lesssim \operatorname*{mean}_{\text{good } i} \|Q_i - P\|_{S,w}^2$$

Using Corollary 12.4.2, for each good i,

$$\|Q_i - P\|_{S,w}^2 \lesssim \|Q_i - P\|_T^2$$

[2] Outputting $Q = \operatorname*{arg\,min}_{\text{degree-}d\ Q'} \|Q' - x\|_{S,w}$ is not good enough, because it only gives constant success probability.

Combining the above two inequalities gives

$$\|\widetilde{Q} - P\|_{S,w}^2 \lesssim \underset{\text{good } i}{\text{mean}} \|Q_i - P\|_T^2 \lesssim \|g\|_T^2 \tag{12.10}$$

Because Q is the optimal solution for $\widetilde{Q}$, then

$$\|\widetilde{Q} - Q\|_{S,w}^2 \leq \|\widetilde{Q} - P\|_{S,w}^2 \lesssim \|g\|_T^2 \tag{12.11}$$

Using Corollary 12.4.2 and for any good i, i', $\|Q_i - Q_{i'}\|_T \lesssim \|g\|_T$, we can replace P by $Q_{i'}$ in the Equation (12.10). Thus, for any $Q_{i'}$ where i' is good,

$$\|\widetilde{Q} - Q_{i'}\|_{S,w}^2 \lesssim \|g\|_T^2 \tag{12.12}$$

For any good i',

$$\begin{aligned}
&\|Q_{i'} - Q\|_T \\
\lesssim\ &\|Q_{i'} - Q\|_{S,w} && \text{by Corollary 12.4.2} \\
\leq\ &\|Q_{i'} - \widetilde{Q}\|_{S,w} + \|\widetilde{Q} - Q\|_{S,w} && \text{by triangle inequality} \\
\lesssim\ &\|g\|_T && \text{by Equation (12.11) and (12.12)}
\end{aligned}$$

Thus, our algorithm takes $O(dR)$ samples from $x(t) = P(t) + g(t)$ over $[0, T]$ and reports a polynomial $Q(t)$ in time $O(Rd^\omega)$ such that, with probability at least $1 - 2^{-\Omega(R)}$, $\|P(t) - Q(t)\|_T^2 \lesssim \|g(t)\|_T^2$. Choosing $R = O(\log(1/p))$ completes the proof. □

12.5 Bounding the Magnitude of a Fourier-sparse Signal in Terms of Its Average Norm

The main results in this section are two upper bounds, Lemma 12.5.1 on $\max_{t\in[0,T]}|x(t)|^2$ and Lemma 12.5.5 on $|x(t)|^2$ for $t > T$, in terms of the typical signal value $\|x\|_T^2 = \frac{1}{T}\int_0^T |x(t)|^2 \mathrm{d}t$. We prove Lemma 12.5.1 in Section 12.5.1 and Lemma 12.5.5 in Section 12.5.2

12.5.1 Bounding the maximum inside the interval

The goal of this section is to prove Lemma 12.5.1.

Lemma 12.5.1. For any k-Fourier-sparse signal $x(t) : \mathbb{R} \to \mathbb{C}$ and any duration T, we have

$$\max_{t\in[0,T]} |x(t)|^2 \lesssim k^4 \log^3 k \cdot \|x\|_T^2$$

Proof. Without loss of generality, we fix $T = 1$. Then $\|x\|_T^2 = \int_0^1 |x(t)|^2 \mathrm{d}t$. Because $\|x\|_T^2$ is the average over the interval $[0, T]$, if $t^* = \arg\max_{t\in[0,T]} |x(t)|^2$ is not 0 or $T = 1$, we can rescale the two intervals $[0, t^*]$ and $[t^*, T]$ to $[0, 1]$ and prove the desired property separately. Hence we assume $|x(0)|^2 = \max_{t\in[0,T]} |x(t)|^2$ in this proof.

Claim 12.5.2. *For any k, there exists $m = O(k^2 \log k)$ such that for any k-Fourier-sparse signal $x(t)$, any $t_0 \geq 0$ and $\tau > 0$, there always exist $C_1, \cdots, C_m \in \mathbb{C}$ such that the following properties hold,*

$$\text{Property I} \quad |C_j| \leq 11 \ \ \textit{for all } j \in [m],$$
$$\text{Property II} \quad x(t_0) = \sum_{j\in[m]} C_j \cdot x(t_0 + j \cdot \tau).$$

We first use this claim to finish the proof of Lemma 12.5.1. We choose $t_0 = 0$ such that $\forall \tau > 0$, there always exist $C_1, \cdots, C_m \in \mathbb{C}$, and

$$x(0) = \sum_{j\in[m]} C_j \cdot x(j \cdot \tau).$$

By the Cauchy-Schwarz inequality, it implies that for any τ,

$$\begin{aligned} |x(0)|^2 &\leq m \sum_{j\in[m]} |C_j|^2 |x(j \cdot \tau)|^2 \\ &\lesssim m \sum_{j\in[m]} |x(j \cdot \tau)|^2. \end{aligned} \tag{12.13}$$

At last, we obtain

$$\begin{aligned}
|x(0)|^2 = & \quad m \int_0^{1/m} |x(0)|^2 \mathrm{d}\tau \\
\lesssim & \quad m \cdot \int_0^{1/m} (m \sum_{j=1}^{m} |x(j \cdot \tau)|^2) \mathrm{d}\tau \\
= & \quad m^2 \cdot \sum_{j=1}^{m} \int_0^{1/m} |x(j \cdot \tau)|^2 \mathrm{d}\tau \\
= & \quad m^2 \cdot \sum_{j=1}^{m} \frac{1}{j} \int_0^{j/m} |x(\tau)|^2 \mathrm{d}\tau \\
\leq & \quad m^2 \cdot \sum_{j=1}^{m} \frac{1}{j} \cdot \int_0^{1} |x(\tau)|^2 \mathrm{d}\tau \\
\lesssim & \quad m^2 \log m \cdot \|x\|_T^2
\end{aligned}$$

where the first inequality follows by Equation (12.13), the second inequality follows by $j/m \leq 1$ and the last step follows by $\sum_{i=1}^{m} \frac{1}{i} = O(\log m)$. From $m = O(k^2 \log k)$, we obtain $|x(0)|^2 = O(k^4 \log^3 k \|x\|_T^2)$. □

To prove Claim 12.5.2, we use the following lemmas about polynomials. We defer their proofs to Section 12.10.2.

Lemma 12.5.3. Let $Q(z)$ be a degree k polynomial, all of whose roots are complex numbers with absolute value 1. For any integer n, let $r_{n,k}(z) = \sum_{l=0}^{k-1} r_{n,k}^{(l)} \cdot z^l$ denote the residual polynomial of

$$r_{n,k}(z) \equiv z^n \pmod{Q(z)}.$$

Then, each coefficient of $r_{n,k}$ is bounded: $|r_{n,k}^{(l)}| \leq 2^k n^{k-1}$ for any l.

Lemma 12.5.4. For any $k \in \mathbb{Z}$ and any $z_1, \cdots, z_k$ on the unit circle of $\mathbb{C}$, there always exists a degree $m = O(k^2 \log k)$ polynomial $P(z) = \sum_{j=0}^{m} c_j z^j$ with the following properties:

$$\begin{aligned} \text{Property I} \quad & P(z_i) = 0, \forall i \in \{1, \cdots, k\}, \\ \text{Property II} \quad & c_0 = 1, \\ \text{Property III} \quad & |c_j| \leq 11, \forall j \in \{1, \cdots, m\}. \end{aligned}$$

Proof of Claim 12.5.2. For $x(t) = \sum_{i=1}^{k} v_i e^{2\pi \mathbf{i} f_i t}$, we fix t_0 and τ then rewrite $x(t_0 + j \cdot \tau)$ as a polynomial of $b_i = v_i \cdot e^{2\pi \mathbf{i} f_i t_0}$ and $z_i = e^{2\pi \mathbf{i} f_i \tau}$ for each $i \in [k]$.

$$\begin{aligned} x(t_0 + j \cdot \tau) &= \sum_{i=1}^{k} v_i e^{2\pi \mathbf{i} f_i \cdot (t_0 + j \cdot \tau)} \\ &= \sum_{i=1}^{k} v_i e^{2\pi \mathbf{i} f_i t_0} \cdot e^{2\pi \mathbf{i} f_i \cdot j\tau} \\ &= \sum_{i=1}^{k} b_i \cdot z_i^j. \end{aligned}$$

Given k and $z_1, \cdots, z_k$, let $P(z) = \sum_{j=0}^{m} c_j z^j$ be the degree m polynomial in Lemma 12.5.4.

$$\begin{aligned} \sum_{j=0}^{m} c_j x(t_0 + j\tau) &= \sum_{j=0}^{m} c_j \sum_{i=1}^{k} b_i \cdot z_i^j \\ &= \sum_{i=1}^{k} b_i \sum_{j=0}^{m} c_j \cdot z_i^j \\ &= \sum_{i=1}^{k} b_i P(z_i) \\ &= 0, \end{aligned} \tag{12.14}$$

where the last step follows by Property I of $P(z)$ in Lemma 12.5.4. From the Property II and III of $P(z)$, we obtain $x(t_0) = -\sum_{j=1}^{m} c_j x(t_0 + j\tau)$. □

12.5.2 Bounding growth outside the interval

Here we show signals with sparse Fourier transform cannot grow too quickly outside the interval.

Lemma 12.5.5. *Let $x(t)$ be a k-Fourier-sparse signal. For any $T > 0$ and any $t > T$,*

$$|x(t)|^2 \leq k^7 \cdot (2kt/T)^{2.5k} \cdot \|x\|_T^2.$$

Proof. For any $t > T$, let $t = t_0 + n \cdot \tau$ such that $t_0 \in [0, T/k], \tau \in [0, T/k]$ and $n \leq \frac{2kt}{T}$. We define $b_i = v_i e^{2\pi \mathbf{i} f_i t_0}$, and $z_i = e^{2\pi \mathbf{i} f_i \tau}$ such that $x(t_0 + n \cdot \tau) = \sum_{j \in [k]} b_j z_j^n$.

By Lemma 12.5.3, we have for any $z_1, z_2, \cdots, z_k$ and any n,

$$z^n \equiv \sum_{i=0}^{k-1} a_i z^i \pmod{\prod_{i=1}^{k}(z - z_i)},$$

where $|a_i| \leq 2^k \cdot n^k, \forall i \in \{0, 1, \cdots, k-1\}$. Thus, we obtain

$$x(t_0 + n\tau) = \sum_{j=1}^{k} b_j z_j^n = \sum_{j=1}^{k} b_j (\sum_{i=0}^{k-1} a_i z_j^i).$$

From the fact that $x(t_0 + i \cdot \tau) = \sum_{j \in [k]} b_j z_j^i$, we simplify it to be

$$x(t_0 + n\tau) = \sum_{i=0}^{k-1} a_i \sum_{j=1}^{k} b_j z_j^i = \sum_{i=0}^{k-1} a_i x(t_0 + i \cdot \tau).$$

Because $(t_0 + i \cdot \tau) \in [0, T]$ for any $i = 0, \cdots, k-1$, we have

$$|x(t_0 + i\tau)|^2 \leq \max_{t \in [0,T]} |x(t)|^2 \lesssim k^4 \log^3 k \|x\|_T^2$$

from Lemma 12.5.1.

Hence

$$\begin{aligned} |x(t_0 + n \cdot \tau)|^2 \leq & \quad k \sum_{i=0}^{k-1} |a_i|^2 \cdot |x(t_0 + i \cdot \tau)|^2 \\ \leq & \quad k \sum_{i=0}^{k-1} n^{2.2k} \cdot \max_{t \in [0,T]} |x(t)|^2 \\ \leq & \quad k^7 \cdot (2kt/T)^{2.2k} \|x\|_T^2. \end{aligned}$$

Thus, we complete the proof. □

12.6 Hash Functions and Filter Functions

12.6.1 Permutation function and hash function

We first review the permutation function $P_{\sigma,a,b}$ and the hash function $h_{\sigma,b}$ in [PS15], which translates discrete settings to the continuous setting.

Definition 12.6.1. For any signal $x(t) : \mathbb{R} \to \mathbb{C}$ and $a, b, \sigma \in \mathbb{R}$, let $(P_{\sigma,a,b}x)(t) = x\big(\sigma(t-a)\big)e^{-2\pi \mathbf{i}\sigma bt}$.

Lemma 12.6.1. $\widehat{P_{\sigma,a,b}x}(\sigma(f-b)) = \frac{1}{\sigma}e^{-2\pi \mathbf{i}\sigma af}\widehat{x}(f)$ and $\widehat{P_{\sigma,a,b}x}(f) = \frac{1}{\sigma}e^{-2\pi \mathbf{i}\sigma a(f/\sigma+b)}\widehat{x}(f/\sigma+b)$

For completeness, we provide a proof of Lemma 12.6.1 in Section 12.10.4.

Definition 12.6.2. [PS15] Let $\pi_{\sigma,b}(f) = 2\pi\sigma(f-b) \pmod{2\pi}$ and $h_{\sigma,b}(f) = \mathrm{round}(\pi_{\sigma,b}(f) \cdot \frac{B}{2\pi})$ be the hash function that maps frequency $f \in [-F, F]$ into bins $\{0, \cdots, B-1\}$.

Claim 12.6.2. *[PS15] For any $\Delta > 0$, let σ be a sample uniformly at random from $[\frac{1}{B\Delta}, \frac{2}{B\Delta}]$.*

(I) If $\Delta \le |f^+ - f^-| < \frac{(B-1)\Delta}{2}$, then $\Pr[h_{\sigma,b}(f^+) = h_{\sigma,b}(f^-)] = 0$

(II) If $\frac{(B-1)\Delta}{2} \le |f^+ - f^-|$, then $\Pr[h_{\sigma,b}(f^+) = h_{\sigma,b}(f^-)] \lesssim \frac{1}{B}$

From previous work [HIKP12b, HIKP12a, PS15], uniformly sampling from $[A, 2A]$ for some large $A \ge \widetilde{T}$ provides an almost uniform sample on $[0, \widetilde{T}]$ when taken modulo over $\widetilde{T}$.

Lemma 12.6.3. *For any $\widetilde{T}$, and $0 \le \widetilde{\epsilon}, \widetilde{\delta} \le \widetilde{T}$, if we sample $\widetilde{\sigma}$ uniformly at random from $[A, 2A]$, then*

$$\frac{2\widetilde{\epsilon}}{\widetilde{T}} - \frac{2\widetilde{\epsilon}}{A} \le \Pr\Big[\widetilde{\sigma} \pmod{\widetilde{T}} \in [\widetilde{\delta} - \widetilde{\epsilon}, \widetilde{\delta} + \widetilde{\epsilon}\,]\Big] \le \frac{2\widetilde{\epsilon}}{\widetilde{T}} + \frac{4\widetilde{\epsilon}}{A}. \tag{12.15}$$

12.6.2 Filter function

We state the properties of filter function $(H(t), \widehat{H}(f))$ and $(G(t), \widehat{G}(f))$, the details of proofs are presented in Section 12.12.1 and 12.12.2.

Lemma 12.6.4. Given $s_0, s_1, 0 < s_3 < 1, \ell > 1, 0 < \delta < 1$, where $\ell = \Theta(k \log(k/\delta))$.The filter function $(H(t), \widehat{H}(f))$ has the following properties,

$$\begin{aligned}
\text{Property I}: \quad & H(t) \in [1-\delta, 1], \text{ when } |t| \leq (\frac{1}{2} - \frac{2}{s_1})s_3. \\
\text{Property II}: \quad & H(t) \in [0, 1], \text{ when } (\frac{1}{2} - \frac{2}{s_1})s_3 \leq |t| \leq \frac{1}{2}s_3. \\
\text{Property III}: \quad & H(t) \leq s_0 \cdot (s_1(\frac{|t|}{s_3} - \frac{1}{2}) + 2)^{-\ell}, \forall |t| > \frac{1}{2}s_3. \\
\text{Property IV}: \quad & \mathrm{supp}(\widehat{H}(f)) \subseteq [-\frac{s_1\ell}{2s_3}, \frac{s_1\ell}{2s_3}].
\end{aligned}$$

For any exact k-Fourier-sparse signal $x^*(t)$, we shift the interval from $[0, T]$ to $[-1/2, 1/2]$ and consider $x^*(t)$ for $t \in [-1/2, 1/2]$ to be our observation, which is also $x^*(t) \cdot \mathrm{rect}_1(t)$.

$$\begin{aligned}
\text{Property V}: \quad & \int_{-\infty}^{+\infty} \left|x^*(t) \cdot H(t) \cdot (1 - \mathrm{rect}_1(t))\right|^2 \mathrm{d}t < \delta \int_{-\infty}^{+\infty} |x^*(t) \cdot \mathrm{rect}_1(t)|^2 \mathrm{d}t. \\
\text{Property VI}: \quad & \int_{-\infty}^{+\infty} |x^*(t) \cdot H(t) \cdot \mathrm{rect}_1(t)|^2 \mathrm{d}t \in [1-\epsilon, 1] \cdot \int_{-\infty}^{+\infty} |x^*(t) \cdot \mathrm{rect}_1(t)|^2 \mathrm{d}t.
\end{aligned}$$

for arbitrarily small constant ϵ.

Lemma 12.6.5. Given $B > 1$, $\delta > 0$, $\alpha > 0$, we set $l = \Omega(\log(\delta/k))$. The filter function

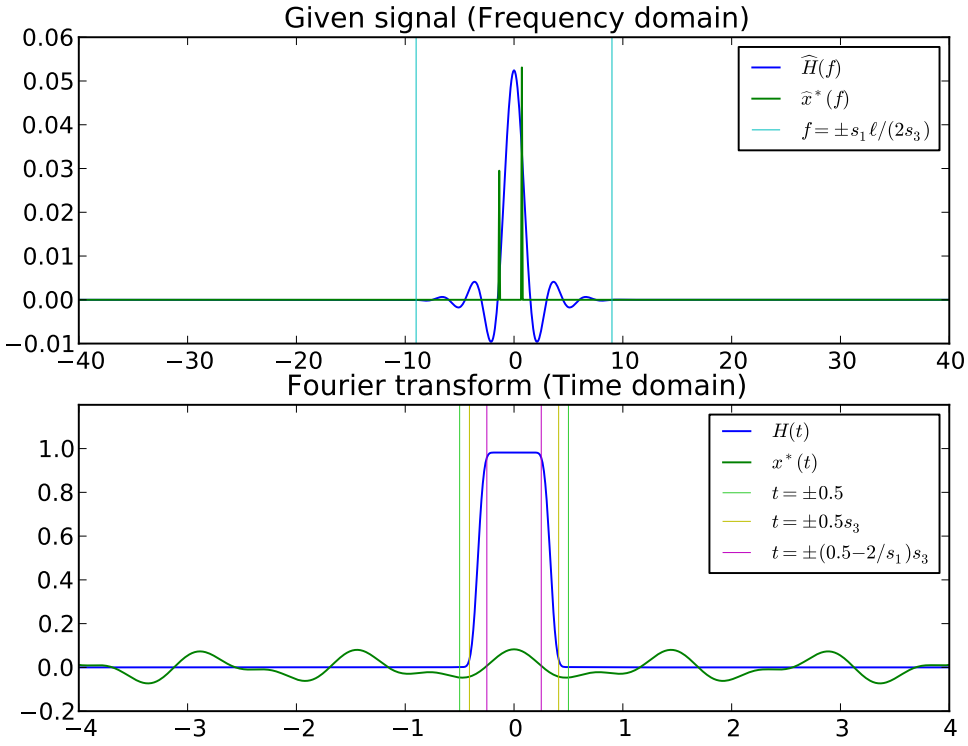

Figure 12.2: The filter function $(H(t), \widehat{H}(f))$ with a k-Fourier-sparse signal. The property I, II and III are presented in the bottom one, the property IV is presented in the top one.

$(G(t), \widehat{G}(f))[B, \delta, \alpha, l]$ satisfies the following properties,

$$\begin{aligned}
\text{Property I}: &\quad \widehat{G}(f) \in [1 - \delta/k, 1], \text{ if } |f| \leq (1-\alpha)\frac{2\pi}{2B}. \\
\text{Property II}: &\quad \widehat{G}(f) \in [0, 1], \text{ if } (1-\alpha)\frac{2\pi}{2B} \leq |f| \leq \frac{2\pi}{2B}. \\
\text{Property III}: &\quad \widehat{G}(f) \in [-\delta/k, \delta/k], \text{ if } |f| > \frac{2\pi}{2B}. \\
\text{Property IV}: &\quad \mathrm{supp}(G(t)) \subset \Big[\frac{l}{2} \cdot \frac{-B}{\pi\alpha}, \frac{l}{2} \cdot \frac{B}{\pi\alpha}\Big]. \\
\text{Property V}: &\quad \max_t |G(t)| \lesssim \mathrm{poly}(B, l).
\end{aligned}$$

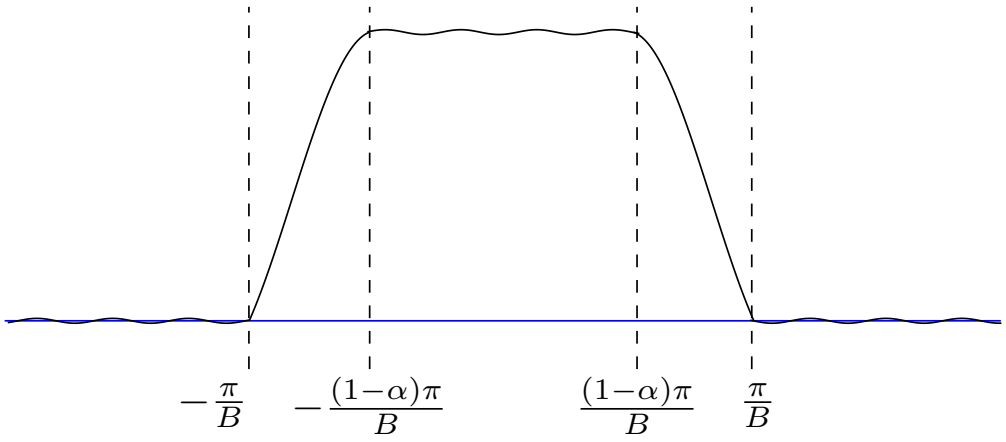

Figure 12.3: G and $\widehat{G}$. [PS15]

12.6.3 HashToBins

We first define two functions $G^{(j)}_{\sigma,b}(t)$ and $\widehat{G}^{(j)}_{\sigma,b}(f)$, then show the result returned by Procedure HashToBins in Algorithm 12.6 satisfying some nice properties. The details of proofs are presented in Section 12.12.4.

Definition 12.6.6. $\forall \sigma > 0, b$ and $j \in [B]$. Define,

$$\begin{aligned} G^{(j)}_{\sigma,b}(t) &= \frac{1}{\sigma} G(t/\sigma) e^{2\pi \mathbf{i} t(j/B - \sigma b)/\sigma} \\ \widehat{G}^{(j)}_{\sigma,b}(f) &= \widehat{G}^{\text{dis}}(\frac{j}{B} - \sigma f - \sigma b) = \sum_{i \in \mathbb{Z}} \widehat{G}(i + \frac{j}{B} - \sigma f - \sigma b) \end{aligned}$$

Lemma 12.6.7. Let $u \in \mathbb{C}^B$ be the result of HashToBins under permutation $P_{\sigma,a,b}$, and let $j \in [B]$. Define

$$\widehat{z} = \widehat{x \cdot H} \cdot \widehat{G}^{(j)}_{\sigma,b},$$

so

$$z = (x \cdot H) * G^{(j)}_{\sigma,b}.$$

Let vector $\widehat{u} \in \mathbb{C}^B$ denote the B-dimensional DFT of u, then $\forall j \in [B]$,

$$\widehat{u}[j] = z_{\sigma a}.$$

12.7 Frequency Recovery

The goal of this section is to prove Theorem 12.2.6, which is able to recover the frequencies of a signal x^* has k-sparse Fourier transform under noise.

Theorem 12.2.6. Let $x^*(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$ and $x(t) = x^*(t) + g(t)$ be our observable signal where $\|g(t)\|_T^2 \leq c\|x^*(t)\|_T^2$ for a sufficiently small constant c. Then Procedure FrequencyRecoveryKCluster returns a set L of $O(k)$ frequencies that covers all heavy clusters of x^*, which uses $\mathrm{poly}(k, \log(1/\delta)) \log(FT)$ samples and $\mathrm{poly}(k, \log(1/\delta)) \log^2(FT)$ time. In particular, for $\Delta = \mathrm{poly}(k, \log(1/\delta))/T$ and $\mathcal{N}^2 := \|g(t)\|_T^2 + \delta\|x^*(t)\|_T^2$, with probability $1 - 2^{-\Omega(k)}$, for any f^* with

$$\int_{f^*-\Delta}^{f^*+\Delta} |\widehat{x \cdot H}(f)|^2 \mathrm{d}f \geq T\mathcal{N}^2/k, \tag{12.16}$$

there exists an $\widetilde{f} \in L$ satisfying

$$|f^* - \widetilde{f}| \lesssim \Delta\sqrt{\Delta T}.$$

12.7.1 Overview

We give an overview of proving Theorem 12.2.6. Instead of starting with k-cluster recovery, we first show how to achieve one-cluster recovery.

One-cluster recovery. we start with $x^*(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$ where there exists f_0 and Δ such that f_j is in $[f_0 - \Delta, f_0 + \Delta]$ for each $j \in [k]$ and consider its properties for frequency recovery.

Definition 12.7.1 ((ϵ, Δ)-one-cluster signal)**.** We say that a signal $z(t)$ is an (ϵ, Δ)-one-cluster signal around f_0 iff $z(t)$ and $\widehat{z}(f)$ satisfy the following two properties:

$$\begin{aligned} \text{Property I} \quad &: \quad \int_{f_0-\Delta}^{f_0+\Delta} |\widehat{z}(f)|^2 \mathrm{d}f \geq (1-\epsilon) \int_{-\infty}^{+\infty} |\widehat{z}(f)|^2 \mathrm{d}f \\ \text{Property II} \quad &: \quad \int_{0}^{T} |z(t)|^2 \mathrm{d}t \geq (1-\epsilon) \int_{-\infty}^{+\infty} |z(t)|^2 \mathrm{d}t. \end{aligned}$$

The main result of one-cluster recovery is to prove that the two properties in Definition 12.7.1 with a sufficiently small constant ϵ are sufficient to return $\widetilde{f_0}$ close to f_0 with high probability, which provides a black-box for k-cluster recovery algorithm.

We first prove that the pair of conditions, Property I and Property II in Definition 12.7.1, are sufficient to obtain an estimation of $e^{2\pi \mathbf{i} f_0}$ in Section 12.7.2. We also provide the proof of the correctness of Procedures GetLegal1Sample and GetEmpirical1Engergy in Section 12.7.2.

Lemma 12.7.1. *For a sufficiently small constant $\epsilon > 0$, any $f_0 \in [-F, F]$, and $\Delta > 0$, given $\widehat{\beta} \eqsim \frac{1}{\Delta\sqrt{\Delta T}}$ and an (ϵ, Δ)-one-cluster signal $z(t)$ around f_0, Procedure* GetLegal1Sample

in Algorithm 12.3 with any $\beta \le 2\widehat{\beta}$ takes $O((T\Delta)^3)$ samples to output $\alpha \in \mathbb{R}$ satisfying

$$|z(\alpha+\beta) - z(\alpha)e^{2\pi \mathbf{i} f_0 \beta}| \le 0.08(|z(\alpha)| + |z(\alpha+\beta)|),$$

with probability at least 0.6.

The following lemma shows that for any (ϵ, Δ)-one-cluster signal $z(t)$ around f_0, we could use the above procedure to find a frequency $\widetilde{f_0}$ approximating f_0 with high probability.

Lemma 12.7.2. *For a sufficiently small constant $\epsilon > 0$, any $f_0 \in [-F, F]$, and $\Delta > 0$, given an (ϵ, Δ)-one-cluster signal $z(t)$ around f_0 , Procedure* FrequencyRecovery1Cluster *in Algorithm 12.4 returns $\widetilde{f_0}$ with $|\widetilde{f_0} - f_0| \lesssim \Delta \cdot \sqrt{\Delta T}$ with probability at least $1 - 2^{-\Omega(k)}$.*

We provide a proof of Lemma 12.7.2 in Section 12.7.4. We show $z(t) = (x^*(t) + g(t)) \cdot H(t)$ satisfy Properties I and II (Definition 12.7.1) when all frequencies in $\widehat{x^*}$ are in a small range in Section 12.7.3.

Lemma 12.7.3. *For any $f_0 \in [-F, F]$, $\Delta' > 0$, and $x^*(t) = \sum_{j=1}^k v_j e^{2\pi \mathbf{i} f_t}$ with $|f_j - f_0| \le \Delta'$ for all $j \in [k]$, let $x(t) = x^*(t) + g(t)$ be our observable signal whose noise $\|g\|_T^2 \le c\|x^*\|_T^2$ for a sufficiently small constant c and $H(t)$ be the filter function defined in Section 12.6 with $|\operatorname{supp}(\widehat{H})| = \Delta_h$. Then $z = H \cdot x$ is an $(O(\sqrt{c}), \Delta_h + \Delta')$-one-cluster signal around f_0.*

From all discussion above, we summarize the result of frequency recovery when $\widehat{x^*}$ is in one cluster.

Theorem 12.7.4. For any $f_0 \in [-F, F]$, $\Delta' > 0$, and $x^*(t) = \sum_{j=1}^k v_j e^{2\pi \mathbf{i} f_j t}$ with $|f_j - f_0| \le \Delta'$ for all $j \in [k]$, let $x(t) = x^*(t) + g(t)$ be our observable signal whose noise $\|g\|_T^2 \le c\|x^*\|_T^2$ for a sufficiently small constant c and $H(t)$ be the filter function defined in Section 12.6

with $|\mathrm{supp}(\widehat{H})| = \Delta_h$. Then Procedure FrequencyRecovery1Cluster in Algorithm 12.4 with $\Delta = \Delta' + \Delta_h$ takes $\mathrm{poly}(k, \log(1/\delta)) \cdot \log(FT)$ samples, runs in $\mathrm{poly}(k, \log(1/\delta)) \cdot \log^2(FT)$ time, returns a frequency $\widetilde{f}_0$ satisfying $|\widetilde{f}_0 - f_0| \lesssim \Delta\sqrt{\Delta T}$ with probability at least $1 - 2^{-\Omega(k)}$.

k-cluster recovery. Given any $x^*(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$, we plan to convolve the filter function $G(t)$ on $x(t) \cdot H(t)$ and use Lemma 12.7.2 as a black box to find a list of frequencies that covers $\{f_1, \cdots, f_k\}$.

We fix $\Delta = \mathrm{poly}(k, \log(1/\delta))/T$, $B = \Theta(k)$ and sample σ uniformly at random from $[\frac{1}{B\Delta}, \frac{2}{B\Delta}]$ for k-cluster recovery. We will cover all $f^* \in [-F, F]$ with the following property :

$$\int_{f^*-\Delta}^{f^*+\Delta} |\widehat{x \cdot H}(f)|^2 \mathrm{d}f \geq T\mathcal{N}^2/k, \tag{12.17}$$

We consider one frequency $f^* \in [-F, F]$ satisfying (12.17) and use $j = h_{\sigma,b}(f^*)$ to denote its index in $[B]$ after hashing (σ, b). Recall that for $j \in [B]$, any $\sigma > 0$ and any b,

$$G^{(j)}_{\sigma,b}(t) = \frac{1}{\sigma} G(t/\sigma) e^{2\pi \mathbf{i} t(j/B - \sigma b)/\sigma} \text{ such that } \widehat{G}^{(j)}_{\sigma,b}(f) = \sum_{i \in \mathbb{Z}} \widehat{G}(i + \frac{j}{B} - \sigma f - \sigma b).$$

We set $\widehat{z} = \widehat{x \cdot H} \cdot \widehat{G}^{(j)}_{\sigma,b}$ and $z = (x \cdot H) * G^{(j)}_{\sigma,b}$ for f^* and $j = h_{\sigma,b}(f^*)$. In Section 12.7.5, we show that with high probability over the hashing (σ, b), $(z, \widehat{z})$ satisfies Property I with $[f^* - \Delta, f^* + \Delta]$ and Property II in Definition 12.7.1 such that we could use Lemma 12.7.2 on z to recover f^*.

Lemma 12.7.5. *Let $f^* \in [-F, F]$ satisfy (12.17). For a random hashing (σ, b), let $j = h_{\sigma,b}(f^*)$ be the bucket that f^* maps to under the hash such that $z = (x \cdot H) * G^{(j)}_{\sigma,b}$ and $\widehat{z} = \widehat{x \cdot H} \cdot \widehat{G}^{(j)}_{\sigma,b}$. With probability at least 0.9, $z(t)$ is an (ϵ, Δ)-one-cluster signal around f^* .*

Combining Lemma 12.7.5 and Lemma 12.7.2, we could recover any heavy frequency f^* satisfying (12.17) with probability at least 0.8. Then we repeat this procedure to guarantee that we cover all heavy frequencies and finish the proof of the main frequency recovery Theorem 12.2.6 in Section 12.7.6.

12.7.2 Analysis of GetLegal1Sample and GetEmpirical1Energy

Let $I = [f_0 - \Delta, f_0 + \Delta]$ and $\overline{I} = (-\infty, +\infty) \setminus I$ in this proof. We define $\left(z^I(t), \widehat{z}^I(f)\right)$ and $\left(z^{\overline{I}}(t), \widehat{z}^{\overline{I}}(f)\right)$ as follows:

$$\widehat{z}^I(f) = \begin{cases} \widehat{z}(f) & \text{if } f \in I \\ 0 & \text{if } f \in \overline{I} \end{cases}, \quad \widehat{z}^{\overline{I}}(f) = \begin{cases} 0 & \text{if } f \in I \\ \widehat{z}(f) & \text{if } f \in \overline{I} \end{cases}$$

We consider $z^I(t)$ as the "signal" to recover f_0 and treat $z^{\overline{I}}(t)$ as the "noise". We first show some basic properties of $z^I(t)$.

Claim 12.7.6. *For $z^{\overline{I}}(t)$, we have $\int_0^T |z^{\overline{I}}(t)|^2 \mathrm{d}t \le \epsilon \int_{-\infty}^{+\infty} |z(t)|^2 \mathrm{d}t$. For $z^I(t)$, we have*

$$\int_0^T |z^I(t)|^2 \mathrm{d}t \ge (1 - 5\sqrt{\epsilon}) \int_{-\infty}^{+\infty} |z(t)|^2 \mathrm{d}t \text{ and } \int_0^T |z^I(t)|^2 \mathrm{d}t \ge (1 - 6\sqrt{\epsilon}) \int_{-\infty}^{+\infty} |z^I(t)|^2 \mathrm{d}t.$$

Proof. From the definition and Property I in Definition 12.7.1, we know

$$z(t) = z^I(t) + z^{\overline{I}}(t) \quad \text{and} \quad \int_{-\infty}^{+\infty} |\widehat{z}^{\overline{I}}(f)|^2 \mathrm{d}f \le \epsilon \int_{-\infty}^{+\infty} |\widehat{z}(f)|^2 \mathrm{d}f.$$

Notice that Property I(in Definition 12.7.1) indicates that

$$\int_0^T |z^{\overline{I}}(t)|^2 \mathrm{d}t \le \int_{-\infty}^{+\infty} |z^{\overline{I}}(t)|^2 \mathrm{d}t = \int_{-\infty}^{+\infty} |\widehat{z}^{\overline{I}}(f)|^2 \mathrm{d}f \le \epsilon \int_{-\infty}^{+\infty} |\widehat{z}(f)|^2 \mathrm{d}f.$$

On the other hand, from Property II(in Definition 12.7.1), we know

$$\begin{aligned} (1 - \epsilon) \int_{-\infty}^{+\infty} |z(t)|^2 \mathrm{d}t \le & \int_0^T |z^I(t) + z^{\overline{I}}(t)|^2 \mathrm{d}t \\ \le & \int_0^T |z^I(t)|^2 \mathrm{d}t + 2 \int_0^T |z^I(t)| \cdot |z^{\overline{I}}(t)| \mathrm{d}t + \int_0^T |z^{\overline{I}}(t)|^2 \mathrm{d}t. \end{aligned}$$

We have $\int_0^T |z^I(t)|^2 \mathrm{d}t \le 2 \int_{-\infty}^{+\infty} |z(t)|^2 \mathrm{d}t$ from the above inequality. From $\int_0^T |z^{\overline{I}}(t)|^2 \mathrm{d}t \le \epsilon \int_{-\infty}^{+\infty} |\widehat{z}(f)|^2 \mathrm{d}f$, we bound

$$\int_0^T |z^I(t)| \cdot |z^{\overline{I}}(t)| \mathrm{d}t \le \sqrt{2\epsilon} \int_{-\infty}^{+\infty} |z(t)|^2 \mathrm{d}t$$

by the Cauchy-Schwartz inequality and have

$$\int_0^T |z^I(t)|^2 \mathrm{d}t \geq (1 - 5\sqrt{\epsilon}) \int_{-\infty}^{+\infty} |z(t)|^2 \mathrm{d}t. \tag{12.18}$$

Because $\int_{-\infty}^{+\infty} |z^{\bar{I}}(t)|^2 \mathrm{d}t \leq \epsilon \int_{-\infty}^{+\infty} |z(t)|^2 \mathrm{d}t$, inequality (12.18) also indicates that

$$\int_0^T |z^I(t)|^2 \mathrm{d}t \geq (1 - 6\sqrt{\epsilon}) \int_{-\infty}^{+\infty} |z^I(t)|^2 \mathrm{d}t.$$

□

One useful property of $z^I(t)$ is that its maximum can be bounded by its average on $[0, T]$.

Claim 12.7.7. $\forall t \in [0, T], |z^I(t)| \leq 2\sqrt{\Delta T} \cdot \|z^I\|_T$.

Proof. From the definition $|z^I(t)|$, it is upper bounded by $\int_{f_0-\Delta}^{f_0+\Delta} |\widehat{z^I}(f)| \mathrm{d}f$ for any $t \in [0, T]$. On the other hand,

$$\begin{aligned}
\int_{f_0-\Delta}^{f_0+\Delta} |\widehat{z}^I(f)| \mathrm{d}f &\leq \sqrt{2\Delta} \left(\int_{f_0-\Delta}^{f_0+\Delta} |\widehat{z}^I(f)|^2 \mathrm{d}f \right)^{1/2} \\
&= \sqrt{2\Delta} \left(\int_{-\infty}^{+\infty} |z^I(t)|^2 \mathrm{d}t \right)^{1/2} \\
&\leq 2\sqrt{\Delta} \left(\int_0^T |z^I(t)|^2 \mathrm{d}t \right)^{1/2} \\
&= 2\sqrt{\Delta T} \|z^I\|_T.
\end{aligned}$$

□

Claim 12.7.8. *Given $\widehat{\beta} = \frac{C_\beta}{\Delta \cdot \sqrt{\Delta T}}$ with a sufficiently small constant C_β, for any two $\widehat{\beta}$-close samples in $z^I(t)$, we have that*

$$\forall \alpha \in [0, T],\ \forall \beta \in [\widehat{\beta}, 2\widehat{\beta}], \quad |z^I(\alpha) e^{2\pi \mathbf{i} f_0 \beta} - z^I(\alpha + \beta)| \leq 0.01 \cdot \|z^I\|_T.$$

Proof. From the definition of the Fourier transform, we have

$$\begin{aligned}
|z^I(a+\beta) - z^I(a)e^{2\pi \mathbf{i} f_0 \beta}| &= \left| \int_{f_0-\Delta}^{f_0+\Delta} \widehat{z^I}(f) e^{2\pi \mathbf{i}(fa+f_0\beta)} (e^{2\pi \mathbf{i}(f-f_0)\beta} - 1) \mathrm{d}f \right| \\
&\leq 2 \cdot (2\pi\Delta\beta) \cdot \int_{f_0-\Delta}^{f_0+\Delta} |\widehat{z^I}(f)| \mathrm{d}f && \text{by Taylor expansion} \\
&\leq 4\pi\beta\Delta \cdot \sqrt{2\Delta} \left(\int_{f_0-\Delta}^{f_0+\Delta} |\widehat{z^I}(f)|^2 \mathrm{d}f \right)^{\frac{1}{2}} && \text{by Hölder inequality} \\
&\leq 10\pi\widehat{\beta}\Delta \cdot \sqrt{2\Delta} \left(\int_0^T |z^I(t)|^2 \mathrm{d}t \right)^{\frac{1}{2}} && \text{by inequality (12.18)} \\
&\leq 10^{-2} \|z^I\|_T.
\end{aligned}$$

□

We consider how to output an α such that $e^{2\pi \mathbf{i} f_0 \beta} \approx z(\alpha+\beta)/z(\alpha)$ with high probability in the rest of this section.

If we can sample from $z^I(t)$, we already know $|z^I(\alpha)e^{2\pi \mathbf{i} f_0 \beta} - z^I(\alpha+\beta)| \leq 0.01\|z^I\|_T$ from Claim 12.7.8. Then it is enough to find any α such that $|z^I(\alpha)| \geq 0.5\|z^I\|_T$. From Claim 12.7.7, we can take $O(\sqrt{\Delta T})$ samples $\left(z^I(\alpha), z^I(\alpha+\beta)\right)$ where each α is uniformly sampled from $[0,T]$ such that with high probability, the sample $z^I(\alpha)$ with the largest norm $|z^I(\alpha)|$ satisfies $|z^I(\alpha)| \geq 0.5\|z^I\|_T$. Then we have $e^{2\pi \mathbf{i} f_0 \beta} \approx z^I(\alpha+\beta)/z^I(\alpha)$.

Next, we move to $z(t) = z^I(t) + z^{\overline{I}}(t)$ and plan to output $\alpha \in [0,T]$ with probability at least 0.5 such that $|z^{\overline{I}}(\alpha)| \leq 0.1|z^I(\alpha)|$ and $|z^{\overline{I}}(\alpha+\beta)| \leq 0.1|z^I(\alpha+\beta)|$. Because the "noise" $z^{\overline{I}}(t)$ has $\|z^{\overline{I}}(t)\|_T^2 \geq \epsilon\|z^I(t)\|_T^2$ for a constant ϵ and the bound $\sqrt{\Delta T}$ in Claim 12.7.7 is a polynomial in k, the approach for $z^I(t)$ cannot guarantee that $z(\alpha+\beta)/z(\alpha) \approx e^{2\pi \mathbf{i} f_0 \beta}$ with probability more than $1/2$.

The key observation is as follows:

Observation 12.7.9. *For a sufficiently small ϵ and $\|z^{\overline{I}}\|_T^2 \le \epsilon\|z\|_T^2$, let D_T be the weighted distribution on $[0,T]$ according to $|z(t)|^2$, i.e., $D_T(t) = \frac{|z(t)|^2}{T\|z\|_T^2}$. If we sample $\alpha \in [0,T]$ from the distribution D_T instead of the uniform distribution on $[0,T]$, $|z^{\overline{I}}(\alpha)| \le 0.01|z^I(\alpha)|$ with probability 0.9.*

It follows from the fact that

$$\mathop{\mathbb{E}}_{\alpha\sim D_T}\frac{|z^{\overline{I}}(\alpha)|^2}{|z(\alpha)|^2} = \int_0^T \frac{|z^{\overline{I}}(\alpha)|^2}{|z(\alpha)|^2}\cdot\frac{|z(\alpha)|^2}{T\|z\|_T^2}\mathrm{d}\alpha = \frac{\int_0^T |z^{\overline{I}}(\alpha)|^2\mathrm{d}\alpha}{T\|z\|_T^2} \le \epsilon.$$

In Procedure GetLegal1Sample, we collect $(\Delta T)^2$ samples (in expectation) $\big(z(\alpha), z(\alpha+\beta)\big)$ in S_{heavy} with $|z(\alpha)| \ge 0.49\|z\|_T$ and resample one α from these samples according to their norm $|z(\alpha)|^2 + |z(\alpha+\beta)|^2$. We show its correctness as follows.

Because we do not know $0.5\|z\|_T$, we use z_{emp} to approximate it.

Claim 12.7.10. *Procedure* GetEmpirical1Energy *in Algorithm 12.3 takes $O((T\Delta)^2)$ samples to output z_{emp} such that $z_{\text{emp}} \in [0.8\|z\|_T, 1.2\|z\|_T]$ with prob. 0.9.*

Proof. We know $z_{\text{emp}}^2 = \mathbb{E}_{i\in[R_{\text{est}}]}[|z(\alpha_i)|^2] = \mathbb{E}_{i\in[R_{\text{est}}]}[|z^I(\alpha_i) + z^{\overline{I}}(\alpha_i)|^2]$.

Notice that $\mathbb{E}_{i\in[R_{\text{est}}]}[|z^I(\alpha_i)|^2]$ is in $[0.99\|z^I\|_T, 1.01\|z^I\|_T]$ with prob. 0.99 from the Chernoff bound and Claim 12.7.7.

At the same time, $\mathbb{E}_{\alpha_i}[|z^{\overline{I}}(\alpha_i)|^2] = \|z^{\overline{I}}\|_T^2$. With prob. 0.92, $\mathbb{E}_{i\in[R_{\text{est}}]}[|z^{\overline{I}}(\alpha_i)|^2] \le 13\|z^{\overline{I}}\|_T^2$. For a sufficiently small ϵ and $\|z^{\overline{I}}\|_T^2 \le \epsilon\|z^I\|_T^2$, $\mathbb{E}_{i\in[R_{\text{est}}]}[|z^{\overline{I}}(\alpha_i)|^2] \le 13\epsilon\|z^I\|_T^2$.

At last, we bound the cross terms of $|z^I(\alpha_i) + z^{\overline{I}}(\alpha_i)|^2$ by the Cauchy-Schwartz in-

equality,

$$\begin{aligned}
&\mathop{\mathbb{E}}_{i\in R_{\text{est}}}[|\overline{z}^I(\alpha_i)z^{\overline{I}}(\alpha_i)| + |z^I(\alpha_i)\overline{z}^{\overline{I}}(\alpha_i)|] \\
&\le 2\mathop{\mathbb{E}}_{i\in R_{\text{est}}}[|z^I(\alpha_i)|\cdot|z^{\overline{I}}(\alpha_i)|] \\
&\le 2\left(\mathop{\mathbb{E}}_{i\in[R_{\text{est}}]}[|z^I(\alpha_i)|^2]\cdot\mathop{\mathbb{E}}_{i\in[R_{\text{est}}]}[|z^{\overline{I}}(\alpha_i)|^2]\right)^{1/2} \\
&\le 10\sqrt{\epsilon}\|z^I\|_T^2.
\end{aligned}$$

For a sufficiently small ϵ, we have $\mathbb{E}_{i\in[R_{\text{est}}]}[|z(\alpha_i)|^2]^{1/2}$ is in $[0.9\|z^I\|_T, 1.1\|z^I\|_T]$, which is also in $[0.8\|z\|_T, 1.2\|z\|_T]$ because of Property II. □

We assume $z_{\text{emp}} \in [0.8\|z\|_T, 1.2\|z\|_T]$ and focus on $U = \{t \in [0,T] \big| |z(t)| \ge 0.5 z_{\text{emp}}\}$. Notice that

$$\int_U |z(t)|^2 \mathrm{d}t = \int_0^T |z(t)|^2 \mathrm{d}t - \int_{[0,T]\setminus U} |z(t)|^2 \mathrm{d}t \ge (1-0.6^2)\int_0^T |z(t)|^2 \mathrm{d}t.$$

Let $R_{\text{heavy}} = |S_{\text{heavy}}|$. From Claim 12.7.7 and ϵ, $\mathbb{E}[R_{\text{heavy}}] \ge R_{\text{repeat}}/(T\Delta)$. So we assume $R_{\text{heavy}} \ge 0.01 R_{\text{repeat}}/(T\Delta) = 0.01(T\Delta)^2$ in the rest of this section and think each $\alpha_i \in S_{\text{heavy}}$ is a uniform sample from U over the randomness on S_{heavy}.

Claim 12.7.11. *With probability 0.95,* $\sum_{i\in S_{\text{heavy}}}(|z^{\overline{I}}(\alpha_i)|^2 + |z^{\overline{I}}(\alpha_i+\beta)|^2) \le 10^{-4}\sum_{i\in S_{\text{heavy}}}(|z(\alpha_i)|^2 + |z(\alpha_i+\beta)|^2)$ *for a sufficiently small* ϵ *and* $\|z^{\overline{I}}\|_T^2 \le \epsilon\|z\|_T^2$.

Proof. At first,

$$\mathop{\mathbb{E}}_{S_{\text{heavy}}}\left[\sum_{i\in S_{\text{heavy}}}(|z(\alpha_i)|^2 + |z(\alpha_i+\beta)|^2)\right] \ge R_{\text{heavy}}\cdot\mathop{\mathbb{E}}_{t\sim U}[|z(t)|^2] = R_{\text{heavy}}\cdot\frac{\int_U |z(t)|^2\mathrm{d}t}{|U|}.$$

At the same time,

$$\mathop{\mathbb{E}}_{S_{\text{heavy}}}\left[\sum_{i\in S_{\text{heavy}}}[|z^{\overline{I}}(\alpha_i)|^2+|z^{\overline{I}}(\alpha_i+\beta)|^2]\right]=R_{\text{heavy}}\cdot\mathop{\mathbb{E}}_{t\sim U}[|z^{\overline{I}}(t)|^2+|z^{\overline{I}}(t+\beta)|^2]\leq\frac{2\int_T^0|z^{\overline{I}}(t)|^2\mathrm{d}t}{|U|}.$$

From $\int_U|z(t)|^2\mathrm{d}t\geq 0.64\int_0^T|z(t)|^2\mathrm{d}t$ and $\int_T^0|z^{\overline{I}}(t)|^2\mathrm{d}t\leq\epsilon\int_0^T|z(t)|^2\mathrm{d}t$, we get the conclusion. □

We assume all results in the above claims hold and prove that the sample from S_{heavy} is a good sample such that $z^{\overline{I}}(\alpha)$ is small.

Claim 12.7.12. *If we sample $i\in S_{\text{heavy}}$ according to the weight $|z(\alpha_i)|^2+|z(\alpha_i+\beta)|^2$, with prob. at least 0.9, $|z^{\overline{I}}(\alpha_i)|+|z^{\overline{I}}(\alpha_i+\beta)|\leq 0.05(|z(\alpha_i)|+|z(\alpha_i+\beta)|)$.*

Proof. Similar to the proof of the key observation, we compute the expectation of $\frac{|z^{\overline{I}}(\alpha_i)|^2+|z^{\overline{I}}(\alpha_i+\beta)|^2}{|z(\alpha_i)|^2+|z(\alpha_i+\beta)|^2}$ over the sampling in S_{heavy}:

$$\begin{aligned}&\sum_{i\in S_{\text{heavy}}}\frac{|z(\alpha_i)|^2+|z(\alpha_i+\beta)|^2}{\sum_{j\in S_{\text{heavy}}}|z(\alpha_j)|^2+|z(\alpha_j+\beta)|^2}\cdot\frac{|z^{\overline{I}}(\alpha_i)|^2+|z^{\overline{I}}(\alpha_i+\beta)|^2}{|z(\alpha_i)|^2+|z(\alpha_i+\beta)|^2}\\ =\;&\frac{\sum_{i\in S_{\text{heavy}}}|z^{\overline{I}}(\alpha_i)|^2+|z^{\overline{I}}(\alpha_i+\beta)|^2}{\sum_{i\in S_{\text{heavy}}}|z(\alpha_i)|^2+|z(\alpha_i+\beta)|^2}\\ \leq\;&10^{-4}.\end{aligned}$$

By Markov's inequality, when we sample $i\in S_{\text{heavy}}$ according to the weight $|z(\alpha_i)|^2+|z(\alpha_i+\beta)|^2$, $\frac{|z^{\overline{I}}(\alpha_i)|^2+|z^{\overline{I}}(\alpha_i+\beta)|^2}{|z(\alpha_i)|^2+|z(\alpha_i+\beta)|^2}\leq 10^{-3}$ with probability 0.9. We have that with prob. at least 0.9, $|z^{\overline{I}}(\alpha_i)|+|z^{\overline{I}}(\alpha_i+\beta)|\leq 0.05(|z(\alpha_i)|+|z(\alpha_i+\beta)|)$. □

We assume all above claims hold and finish the proof by setting $\alpha = \alpha_i$. From Claim 12.7.8, we know that

$$|z^I(\alpha)e^{2\pi \mathbf{i} f_0 \beta} - z^I(\alpha+\beta)| \leq 0.01 \cdot \mathop{\mathbb{E}}_{t\in[0,T]}[|z^I(\alpha)|^2]^{1/2} \leq 0.03|z^I(\alpha)|.$$

Now we add back the noise $z^{\overline{I}}(\alpha)$ and $z^{\overline{I}}(\alpha+\beta)$ to get

$$\begin{aligned}|z(\alpha)e^{2\pi \mathbf{i} f_0 \beta} - z(\alpha+\beta)| &\leq |z^I(\alpha)e^{2\pi \mathbf{i} f_0 \beta} - z^I(\alpha+\beta)| + |z^{\overline{I}}(\alpha)| + |z^{\overline{I}}(\alpha+\beta)| \\ &\leq 0.08(|z(\alpha)| + |z(\alpha+\beta)|).\end{aligned}$$

12.7.3 A cluster of frequencies, times H, is a one-cluster signal per Definition 12.7.1

The goal of this section is to prove Lemma 12.7.3. Without loss of generality, we assume $g(t) = 0$ for any $t \notin [0, T]$ and notice that $\mathrm{supp}(\widehat{H} * \widehat{x^*}) \subseteq f_0 + [-\Delta, \Delta]$ for $\Delta = \Delta' + \Delta_h$ from the definition of $\widehat{H}$. From the Property VI (presented in Lemma 12.6.4) of $(H, \widehat{H})$,

$$\int_0^T |x^*(t)|^2 \mathrm{d}t = (1 \pm c) \int_{-\infty}^{+\infty} |H(t) \cdot x^*(t)|^2 \mathrm{d}t.$$

From the first two properties of $(H, \widehat{H})$, we bound the energy of $g \cdot H$:

$$\int_{-\infty}^{+\infty} |H(t) \cdot g(t)|^2 \mathrm{d}t \leq (1 + c) \int_0^T |g(t)|^2 \mathrm{d}t.$$

Let $z(t) = (x^*(t) + g(t))H(t)$. We use the triangle inequality on the above two inequalities:

$$\begin{aligned}
&\int_0^T |z(t)|^2 \mathrm{d}t \\
\geq\ & \int_0^T |H(t) \cdot x^*(t)|^2 \mathrm{d}t - \int_0^T |H(t) \cdot g(t)|^2 \mathrm{d}t - 2 \int_0^T |H(t) \cdot x^*(t)| \cdot |H(t) \cdot g(t)| \mathrm{d}t \\
\geq\ & (1 - c) \int_0^T |x^*(t)|^2 \mathrm{d}t - (1 + c) \int_0^T |g(t)|^2 \mathrm{d}t - 2 \int_0^T |H(t) \cdot x^*(t)| \cdot |H(t) \cdot g(t)| \mathrm{d}t \\
\geq\ & (1 - c) \int_0^T |x^*(t)|^2 \mathrm{d}t - (1 + c) \int_0^T |g(t)|^2 \mathrm{d}t - 2 \left((1 + c)^2 \int_0^T |g(t)|^2 \mathrm{d}t \int_0^T |x^*(t)|^2 \mathrm{d}t \cdot \right)^{1/2} \\
\geq\ & (1 - c) \int_0^T |x^*(t)|^2 \mathrm{d}t - (1 + c) c \int_0^T |x^*(t)|^2 \mathrm{d}t - 2\sqrt{c}(1 + c) \int_0^T |x^*(t)|^2 \mathrm{d}t \\
\geq\ & \left(1 - 5\sqrt{c}\right) \int_0^T |x^*(t)|^2 \mathrm{d}t,
\end{aligned}$$

where the third step follows from Cauchy-Schwarz inequality, the fourth step follows from $\int_0^T |g(t)|^2 \mathrm{d}t \leq c \int_0^T |x^*(t)|^2 \mathrm{d}t$, and the last step follows from choosing $c \in (0, 1)$ sufficiently small.

Similarly,

$$\begin{aligned}
&\int_{-\infty}^{+\infty} |z(t)|^2 \mathrm{d}t \\
&\leq (1+c)\int_0^T |x^*(t)|^2\mathrm{d}t + (1+c)\int_0^T |g(t)|^2\mathrm{d}t + 2\left((1+c)^2\int_0^T |x^*(t)|^2\mathrm{d}t\int_0^T |g(t)|^2\mathrm{d}t\right)^{1/2} \\
&\leq (1+5\sqrt{c})\int_0^T |x^*(t)|^2\mathrm{d}t.
\end{aligned}$$

Hence we obtain Property II(in Definition 12.7.1) when $c \in (0,1)$ is sufficiently small.

Then we observe that

$$\begin{aligned}
&\int_{f_0-\Delta_h}^{f_0+\Delta_h} |\widehat{z}(f)|^2\mathrm{d}f \\
&\geq \int_{f_0-\Delta_h}^{f_0+\Delta_h} |H\cdot\widehat{(x^*+g)}|^2\mathrm{d}f \\
&\geq \int_{f_0-\Delta_h}^{f_0+\Delta_h} |\widehat{H\cdot x^*}|^2 - |\widehat{H\cdot g}|^2 - 2|\widehat{H\cdot x^*}|\cdot|\widehat{H\cdot g}|\mathrm{d}f \\
&\geq \int_{f_0-\Delta_h}^{f_0+\Delta_h} |\widehat{H\cdot x^*}|^2\mathrm{d}f - \int_{-\infty}^{+\infty} |\widehat{H\cdot g}|^2\mathrm{d}f - 2\left(\int_{f_0-\Delta_h}^{f_0+\Delta_h} |\widehat{H\cdot x^*}|^2\mathrm{d}f\int_{-\infty}^{+\infty} |\widehat{H\cdot g}|^2\mathrm{d}f\right)^{1/2} \\
&= \int_{-\infty}^{+\infty} |H\cdot x^*|^2\mathrm{d}t - \int_{-\infty}^{+\infty} |H\cdot g|^2\mathrm{d}t - 2\left(\int_{f_0-\Delta_h}^{f_0+\Delta_h} |H\cdot x^*|^2\mathrm{d}t\int_{-\infty}^{+\infty} |H\cdot g|^2\mathrm{d}t\right)^{1/2} \\
&\geq \frac{(1-c)-c(1+c)-3\sqrt{c}}{1+5\sqrt{c}}\int_{-\infty}^{+\infty} |z(t)|^2\mathrm{d}t.
\end{aligned}$$

Thus we have Property I(in Definition 12.7.1) for z.

12.7.4 Frequency recovery of one-cluster signals

The goal of this section is prove Theorem 12.7.4. We first show the correctness of Procedure LOCATE1INNER. Second, we analyze the Procedure LOCATE1SIGNAL. At end, we rerun Procedure LOCATE1SIGNAL and use median analysis to boost the constant success probability.[3]

Lemma 12.7.13. *Let $f_0 \in \text{region}(q')$. Let β is sampled from $[\frac{st}{4\Delta}, \frac{st}{2\Delta l}]$ and let γ denote the output of Procedure* GETLEGAL1SAMPLE *in Algorithm 12.4. Then using the pair of samples $z(\gamma+\beta)$ and $z(\gamma)$, we have*

I. for the q' with probability at least $1-s$, $v_{q'}$ will increase by one.

II. for any q such that $|q-q'|>3$, with probability at least $1-15s$, v_q will not increase.

Proof. We replace f_0 by θ in the rest of the proof. By Lemma 12.7.1, we have that for any $\widehat{\beta} \le \beta \le 2\widehat{\beta}$, Procedure GETLEGAL1SAMPLE outputs a $\gamma \in [0,T]$ satisfying

$$|z(\gamma+\beta) - z(\gamma)e^{2\pi \mathbf{i} f_0 \beta}| \le 0.1(|z(\gamma)| + |z(\gamma+\beta)|)$$

with probability at least 0.6.

Furthermore, there exists such some constant $g \in (0,1)$ such that with probability $1-g$,

$$\|\phi(z(\gamma+\beta)) - (\phi(z(\gamma)) - 2\pi\beta\theta)\|_{\bigcirc} \lesssim \sin^{-1}(\frac{1}{g}),$$

where $\|x-y\|_{\bigcirc} = \min_{z\in\mathbb{Z}} |x-y+2\pi z|$ denote the "circular distance" between x and y. We can set $s = \Theta(g^{-1})$. There exists some constant $p = \Theta(s)$, with probability at least $1-p$,

$$\|o - 2\pi\beta\theta\|_{\bigcirc} < s\pi/2$$

[3]The proofs in this section are identical to [HIKP12a] and [PS15].

where $o := \phi(z(\gamma+\beta)/z(\gamma))$. The above equation shows that o is a good estimate for $2\pi\beta\theta$ with good probability. We will now show that this means the true region $Q_{q'}$ gets a vote with large probability.

For each q' with $\theta \in [l - \frac{\Delta l}{2} + \frac{q'-1}{t}\Delta l, l - \frac{\Delta l}{2} + \frac{q'}{t}\Delta l] \subset [-F, F]$, we have that $\theta_{q'} = l - \frac{\Delta l}{2} + \frac{q'-0.5}{t}\Delta l$ satisfies that

$$\theta - \theta_{q'} \leq \frac{\Delta l}{2t}.$$

Note that we sample β uniformly at random from $[\widehat{\beta}, 2\widehat{\beta}]$, then $2\widehat{\beta} = \frac{st}{2\Delta l} \leq \frac{cT}{10A^{\frac{3}{2}}}$ (Note that A is some constant > 1), which implies that $2\pi\beta\frac{\Delta l}{2t} \leq \frac{s\pi}{2}$. Thus, we can show the observation o is close to the true region in the following sense,

$$\begin{aligned}
& \|o - 2\pi\beta\theta_{q'}\|_{\bigcirc} \\
\leq\ & \|o - 2\pi\beta\theta\|_{\bigcirc} + \|2\pi\beta\theta - 2\pi\beta\theta_{q'}\|_{\bigcirc} \text{ by triangle inequality} \\
\leq\ & \frac{s\pi}{2} + 2\pi\|\beta\theta - \beta\theta_{q'}\|_{\bigcirc} \\
\leq\ & s\pi.
\end{aligned}$$

Thus, $v_{q'}$ will increase in each round with probability at least $1 - s$.

On the other side, consider q with $|q - q'| > 3$. Then $|\theta - \theta_q| \geq \frac{7\Delta l}{2t}$, and (assuming $\beta \geq \frac{st}{4\Delta l}$) we have

$$2\pi\beta|\theta - \theta_q| \geq 2\pi\frac{st}{4\Delta l}|\theta - \theta_q| = \frac{s\pi t}{2\Delta l}|\theta - \theta_q| \geq \frac{7s\pi}{4} > \frac{3s\pi}{2}.$$

There are two cases: $|\theta - \theta_q| \leq \frac{\Delta l}{st}$ and $|\theta - \theta_q| > \frac{\Delta l}{st}$.

First, if $|\theta - \theta_q| \leq \frac{\Delta l}{st}$. In this case, from the definition of β it follows that

$$2\pi\beta|\theta - \theta_q| \leq \frac{s\pi t}{\Delta l}|\theta - \theta_q| \leq \pi$$

Combining the above equations implies that

$$\Pr\big[2\pi\beta(\theta-\theta_q) \pmod{2\pi} \in [-\frac{3s}{4}2\pi, \frac{3s}{4}2\pi]\big] = 0$$

Second, if $|\theta-\theta_q| > \frac{\Delta l}{st}$. We show this claim is true : $\Pr[2\pi\beta(\theta-\theta_q) \pmod{2\pi} \in [-\frac{3s}{4}2\pi, \frac{3s}{4}2\pi]] \lesssim s$. To prove it, we apply Lemma 12.6.3 by setting $\widetilde{T} = 2\pi$, $\widetilde{\sigma} = 2\pi\beta$, $\widetilde{\delta} = 0$, $\epsilon = \frac{3s}{4}2\pi$, $A = 2\pi\widehat{\beta}$, $\Delta f = |\theta-\theta_q|$. By upper bound of Lemma 12.6.3, the probability is at most

$$\frac{2\widetilde{\epsilon}}{\widetilde{T}} + \frac{4\widetilde{\epsilon}}{A\Delta f} = \frac{3s}{2} + \frac{3s}{\widehat{\beta}\Delta f} \leq \frac{3s}{2} + \frac{3s}{\frac{st}{4\Delta l}\frac{\Delta l}{st}} < 15s$$

Then in either case, with probability at least $1-15s$, we have

$$\|2\pi\beta\theta_q - 2\pi\beta\theta\|_{\bigcirc} > \frac{3s}{4}2\pi$$

which implies that v_q will not increase. □

Lemma 12.7.14. *Procedure* LOCATE1INNER *in Algorithm 12.4 uses* R_{loc} *"legal" samples, and then after Procedure* LOCATE1SIGNAL *in Algorithm 12.4 running Procedure* LOCATE1INNER $D_{\max}$ *times, it outputs a frequency* $\widetilde{f}_0$ *such that*

$$|\widetilde{f}_0 - f_0| \lesssim \Delta \cdot \sqrt{T\Delta}$$

with arbitrarily large constant probability.

Proof. For each observation, $v_{q'}$ incremented with probability at least $1-p$ and v_q is incremented with probability at most $15s+p$ for $|q-q'| > 3$. The probabilities corresponding to different observations are independent. Then after R_{loc} observations, there exists some

constant $c < \frac{1}{2}$, for any q such that $|q - q'| > 3$,

$$\begin{aligned} & \Pr[\text{False region gets more than half votes}] \\ = \; & \Pr[v_{j,q} > R_{\text{loc}}/2] \\ \leq \; & \binom{R_{\text{loc}}}{R_{\text{loc}}/2}(15s+p)^{R_{\text{loc}}/2} \\ \leq \; & c^{\Omega(R_{\text{loc}})} \end{aligned}$$

Similarly, on the other side,

$$\begin{aligned} & \Pr[\text{True region gets less than half votes}] \\ = \; & \Pr[v_{j,q'} < R_{\text{loc}}/2] \\ \leq \; & \binom{R_{\text{loc}}}{R_{\text{loc}}/2}(p)^{R_{\text{loc}}/2} \\ \leq \; & c^{\Omega(R_{\text{loc}})} \end{aligned}$$

Taking the union bound over all the t regions, it gives with probability at least $1 - tf^{\Omega(R_{\text{loc}})}$ we can find some region q such that $|q - q'| < 3$.

If we repeat the above procedure $D_{\max}$ rounds, each round we choose the "False" region with probability at most $1 - tc^{\Omega(R_{\text{loc}})}$. Thus, taking the union bound over all the $D_{\max}$ rounds, we will report a region has size $\approx \Delta\sqrt{\Delta T}$ and contains f_0 with probability at least $1 - D_{\max}tc^{\Omega(R_{\text{loc}})}$.

The reason for not ending up with region that has size $\approx \Delta$ is, the upper bound of the sample range of β force us to choose β is at most $\lesssim \frac{T}{(\Delta T)^{\frac{3}{2}}}$ by Claim 12.7.8

It remains to explain how to set $D_{\max}, t$, and R_{loc}. At the beginning of the first round, we start with frequency interval of length $2F$, at the beginning of the last round, we start

with frequency interval of length $t \cdot \Delta\sqrt{T\Delta}$. Each round we do a t-ary search, thus

$$D_{\max} = \log_t(\frac{2F}{t\Delta\sqrt{T\Delta}}) \leq \log_t(F/\Delta).$$

We can set $R_{\text{loc}} \approx \log_{1/c}(t/c)$ and $t > D_{\max}$, e.g. $t = \log(F/\Delta)$. Thus, the probability becomes,

$$1 - D_{\max} t c^{\Omega(R_{\text{loc}})} \geq 1 - t^2 c^{\Omega(R_{\text{loc}})} \geq 1 - \text{poly}(1/t, c)$$

which is larger than any constant probability. □

Using the same parameters setting in the proof of Lemma 12.7.14, we show the running time and sample complexity of Procedure LOCATE1SIGNAL,

Lemma 12.7.15. *Procedure* LOCATE1SIGNAL *in Algorithm 12.4 uses* $O(\text{poly}(k, \log(1/\delta))) \cdot \log(FT)$ *samples and runs in* $O(\text{poly}(k, \log(1/\delta))) \cdot \log^2(FT)$ *time.*

Proof. The number of "legal" observations is

$$D_{\max} R_{\text{loc}} = O(\log_t(F/\Delta) \log_{1/c}(t/c)) = O(\log(F/\Delta))$$

The total number of samples is

$$R_{\text{est}} + R_{\text{repeat}} D_{\max} R_{\text{loc}} = O(T\Delta_h)^2 + (T\Delta_h)^3 \cdot \log(FT) = \text{poly}(k, \log(1/\delta)) \cdot \log(FT)$$

where the first step follows by Claim 12.7.10 and Lemma 12.7.1 and the last step follows by the setting of Δ_h in Section 12.12.3.

The running time includes two parts, one is approximately computing $H(t)$ for all the samples, each sample takes $\text{poly}(k, \log(1/\delta))$ time according to Lemma 12.12.5; the other is for each legal sample we need to assign vote to some regions.

$$\text{poly}(k, \log(1/\delta)) \cdot (R_{\text{est}} + R_{\text{repeat}} D_{\max} R_{\text{loc}}) + D_{\max} R_{\text{loc}} t = \text{poly}(k, \log(1/\delta)) \log^2(FT)$$

□

Lemma 12.7.16 only achieves constant success probability, using median analysis we can boost the success probability,

Lemma 12.7.16. *Let $\widetilde{f}_0$ denote the frequency output by Procedure* FrequencyRecovery1Cluster *in Algorithm 12.5, then with probability at least $1 - 2^{-\Omega(k)}$,*

$$|\widetilde{f}_0 - f_0| \lesssim \Delta\sqrt{T\Delta}$$

Proof. Because of Procedure FrequencyRecovery1Cluster taking the median of $O(k)$ independent results by repeating algorithm Locate1Signal $O(k)$ times. Each sample L_r is close to $\widetilde{f}_0$ with sufficiently large probability. Thus, using the Chernoff bound will output $\widetilde{f}_0$ with probability $1 - 2^{-\Omega(k)}$ such that

$$|\widetilde{f}_0 - f_0| \lesssim \Delta\sqrt{T\Delta}.$$

□

Combining Lemma 12.7.16 with the sample complexity and running time in Lemma 12.7.14, we are able to finish the proof of Theorem 12.7.4.

12.7.5 The full signal, after multiplying by H and convolving with G, is one-clustered.

The goal of this section is to prove Lemma 12.7.5. We fix $f^* \in [-F, F]$ satisfying (12.17) in this section. We first define a good hashing (σ, b) of f^* as follows.

Definition 12.7.2. We say that a frequency f^* is *well-isolated* under the hashing (σ, b) if, for $j = h_{\sigma,b}(f^*)$, we have that the signal

$$\widehat{z}^{(j)} = \widehat{x \cdot H} \cdot \widehat{G}^{(j)}_{\sigma,b}$$

satisfies, over the interval $\overline{I_{f^*}} = (-\infty, \infty) \setminus (f^* - \Delta, f^* + \Delta)$,

$$\int_{\overline{I_{f^*}}} |\widehat{z}^{(j)}(f)|^2 df \lesssim \epsilon \cdot T\mathcal{N}^2/k.$$

For convenience, we simplify $z^{(j)}$ by using z in the rest of this section.

Lemma 12.7.17. *Let f^* be any frequency. Then f^* is well-isolated by a hashing (σ, b) with probability ≥ 0.9 given $B = \Theta(k)$ and $\sigma \in [\frac{1}{B\Delta}, \frac{2}{B\Delta}]$ chosen uniformly at random.*

Proof. For any other frequency f' in x^*, its contribution in $\widehat{z}$ depends on how far it is from f^*. Either it is:

- Within Δ of f^*, f' and f^* will be mapped into the same bucket with probability at least 0.99.
- Between Δ and $1/\sigma$ far, from Claim 12.6.2, f' and f^* will always mapped into different buckets. Hence f' always contributes in the $\frac{\epsilon\delta}{k}$ region of Property III in Lemma 12.6.5

about filter function $(G(t), \widehat{G}(f))$, i.e., it contributes at most $\frac{\epsilon\delta}{k} \cdot \int_{f'-\Delta}^{f'+\Delta} |\widehat{x \cdot H}|^2 \mathrm{d}f$. Overall it will contribute

$$\frac{\epsilon\delta}{k} \cdot \int |\widehat{x \cdot H}|^2 \mathrm{d}f = \frac{\epsilon\delta}{k} \int |x \cdot H|^2 \mathrm{d}t.$$

- More than $1/\sigma$ far, in which case they contribute in the same region with probability at most $3/B$. By a union bound, it is at most $3k/B \leq 0.01$

□

Without loss of generality, we assume $\mathrm{supp}(\widehat{g \cdot H}) \cap \mathrm{supp}(\widehat{x^* \cdot H}) = \emptyset$, otherwise we treat it as a part of $x^* \cdot H$. We first consider frequency $f^* \in \widehat{x^* \cdot H}$ under $G^{(j)}_{\sigma,b}$.

Lemma 12.7.18. *Let f^* satisfying $\int_{f^*-\Delta}^{f^*+\Delta} |\widehat{x^* \cdot H}(f)|^2 \mathrm{d}f \geq T\mathcal{N}^2/k$ and $\widehat{z} = \widehat{x^* \cdot H} \cdot \widehat{G}^{(j)}_{\sigma,b}$ where $j = h_{\sigma,b}(f^*)$. If f^* is well-isolated, then z and $\widehat{z}$ satisfying Property I(in Definition 12.7.1), i.e.,*

$$\int_0^T |z(t)|^2 \mathrm{d}t \geq (1-\epsilon) \int_{-\infty}^{+\infty} |z(t)|^2 \mathrm{d}t.$$

Proof. We first notice that $z(t) = x^*(t) \cdot H(t) * G^{(j)}_{\sigma,b}(t)$ and lower bound $\int_{-\infty}^{+\infty} |z(t)|^2 \mathrm{d}t$ as

follows :

$$\begin{aligned}
& \int_{-\infty}^{+\infty} |x^*(t) \cdot H(t) * G_{\sigma,b}^{(j)}(t)|^2 \mathrm{d}t \\
= & \int_{-\infty}^{+\infty} |\widehat{x^* \cdot H}(f) \cdot \widehat{G}_{\sigma,b}^{(j)}(f)|^2 \mathrm{d}f \qquad \text{by FT} \\
\geq & \int_{f_0-\Delta}^{f_0+\Delta} |\widehat{x^* \cdot H}(f) \cdot \widehat{G}_{\sigma,b}^{(j)}(f)|^2 \mathrm{d}f \\
\geq & (1-\delta)^2 \int_{f_0-\Delta}^{f_0+\Delta} |\widehat{x^* \cdot H}(f)\ |^2 \mathrm{d}f \\
\geq & (1-\delta)^2 T \mathcal{N}^2 / k \\
\geq & 0.9 \frac{\delta}{k} \int_0^T |x^*(t)|^2 \mathrm{d}t \qquad (12.19)
\end{aligned}$$

We give an upper bound $\int_{-\infty}^{0} |z(t)|^2 \mathrm{d}t + \int_T^{+\infty} |z(t)|^2 \mathrm{d}t \lesssim \epsilon \frac{\delta}{k} \int_0^T |x^*(t) H(t)|^2 \mathrm{d}t$ in the rest of this proof.

Consider the case $t < 0$, by definition of Convolution,

$$z^{(j)}(t) \quad = \quad x^*(t) \cdot H(t) * G_{\sigma,b}^{(j)}(t) = \int_{-\infty}^{+\infty} G_{\sigma,b}^{(j)}(t-\tau) \cdot (x^* \cdot H)(\tau) \mathrm{d}\tau$$

Without loss of generality, we can shift the original signal and $H(t)$ from $[0, T]$ to $[-T/2, T/2]$, by Property of $H(t)$, we know that if $s_3 T/2 \leq |t| \leq T/2$, then $H(t) \leq 2^{-O\Theta(\ell)}$. Note that $G(t)$ is compact and has support DB, we also assume its compact region is $[-DB/2, DB/2]$ (Recall that $D = \frac{l}{\alpha\pi}$).

Thus, by definition of convolution,

$$\begin{aligned}
& z(t) \\
= & \int_{-DB\sigma/2}^{DB\sigma/2} G_{\sigma,b}^{(j)}(s) \cdot (x \cdot H)(t-\tau) \mathrm{d}\tau \\
= & \frac{1}{\sigma} \int_{-DB\sigma/2}^{DB\sigma/2} G(s/\sigma) e^{2\pi \mathbf{i} s(j/B - \sigma b)/\sigma} \cdot (x \cdot H)(t-\tau) \mathrm{d}\tau \\
\leq & \frac{1}{\sigma} \int_{-DB\sigma/2}^{DB\sigma/2} |G(\tau/\sigma)| \cdot |(x \cdot H)(t-\tau)| \mathrm{d}\tau \\
\leq & \left(\frac{1}{\sigma} \int_{-DB\sigma/2}^{DB\sigma/2} |G(\tau/\sigma)| \mathrm{d}\tau \right) \cdot \left(\max_{|\tau| \leq DB\sigma/2} |(x \cdot H)(t-\tau)| \right)
\end{aligned}$$

So, if $t \notin [-T/2, T/2]$, then $t - s \notin [-T/2 + DB\sigma/2, T/2 - DB\sigma/2]$. By Property V of $G(t)$, $|G(t)| \leq \mathrm{poly}(k, \log(1/\delta))$. Because of the parameter setting[4], we have the fact $[-Ts_3/2, Ts_3/2] \subseteq [-T/2 + DB\sigma/2, T/2 - DB\sigma/2] \subseteq [-T/2, T/2]$. Thus, we know $T(1 - s_3)/2 > DB\sigma/2$, then for any $t - \tau \in [-T/2, -T/2 + DB\sigma/2] \cup [T/2 - DB\sigma/2, T/2] = S$, then

$$|z(t)|^2 \lesssim \big(DB\sigma \cdot \frac{1}{\sigma} \cdot \mathrm{poly}(k, \log(1/\delta))\big)^2 \cdot 2^{-\Theta(\ell)} \cdot k^4 \cdot \|x^*(t)\|_T^2 \lesssim \mathrm{poly}(k, \log(1/\delta)) \cdot 2^{-\Theta(\ell)} \cdot \|x^*(t)\|_T^2.$$

Thus, taking the integral over S,

$$\int_S |z(t)|^2 \mathrm{d}t \lesssim |S| \cdot 2^{-\Theta(\ell)} \, \mathrm{poly}(k, \log(1/\delta)) \cdot \|x^*(t)\|^2 \lesssim 2^{-\Theta(\ell)} T \|x^*(t) \cdot H(t)\|_T^2$$

By property of filter function $H(t), \widehat{H}(f)$, we have

$$|(x \cdot H)(t)|^2 \leq (\frac{t}{T})^{-\ell} \|x^*(t) \cdot H(t)\|_T^2 \text{ if } t \geq 3T$$

[4]We will set B to be $O(k)$, D to be $\mathrm{poly}(k)$ and σ to be $T/\mathrm{poly}(k)$.

Thus for any constant ϵ,

$$\int_{-\infty}^{-T/2} |z(t)|^2 \mathrm{d}t + \int_{T/2}^{+\infty} |z(t)|^2 \mathrm{d}t \lesssim 2^{-\ell} T \|x^*(t) \cdot H(t)\|_T^2 \leq 0.9\epsilon \cdot \frac{\delta}{k} \int_{-T/2}^{T/2} |x^*(t)|^2 \mathrm{d}t \quad (12.20)$$

where the last inequality follows by $\ell \gtrsim k \log(k/\delta)$. Shifting the interval from $[-T/2, T/2]$ to $[0, T]$, the same result is still holding. Combining Equation (12.19) and (12.20) completes the proof of Property II.

□

We consider frequency $f^* \in \widehat{g \cdot H}$ under $G_{\sigma,b}^{(j)}$ and show the energy of noise $g(t)$ is evenly distributed over B bins on expectation.

Lemma 12.7.19. *Given any noise $g(t) : [0, T] \to \mathbb{C}$ and $g(t) = 0, \forall t \notin [0, T]$. We have, $\forall j \in [B]$,*

$$\mathop{\mathbb{E}}_{\sigma,b} \left[\int_{-\infty}^{+\infty} |g(t)H(t) * G_{\sigma,b}^{(j)}(t)|^2 \mathrm{d}t \right] \lesssim \frac{1}{B} \int_{-\infty}^{+\infty} |g(t)H(t)|^2 \mathrm{d}t$$

Proof. Because of Fourier Transform preserves ℓ_2 norm, it suffices to prove

$$\mathop{\mathbb{E}}_{\sigma,b} \left[\int_{-\infty}^{+\infty} |\widehat{g \cdot H}(f) \cdot \widehat{G}_{\sigma,b}^{(j)}(f)|^2 \mathrm{d}f \right] \lesssim \frac{1}{B} \int_{-\infty}^{+\infty} |\widehat{g \cdot H}(f)|^2 \mathrm{d}f$$

Since $\widehat{G}_{\sigma,b}^{(j)}(f)$ is a periodic function and outputs at most 1 on $O(1/B)$ fraction of the period, and outputs $\leq \delta$ on other part. Thus, for any frequency f, we have

$$\mathop{\mathbb{E}}_{\sigma,b} \left[|\widehat{G}_{\sigma,b}^{(j)}(f)|^2 \right] \lesssim \frac{1}{B}$$

Thus, we have

$$\begin{aligned}
& \mathop{\mathbb{E}}_{\sigma,b}\left[\int_{-\infty}^{+\infty} |\widehat{g\cdot H}(f)\cdot \widehat{G}^{(j)}_{\sigma,b}(f)|^2 \mathrm{d}f\right] \\
\leq\ & \mathop{\mathbb{E}}_{\sigma,b}\left[\int_{-\infty}^{+\infty} |\widehat{g\cdot H}(f)|^2\cdot |\widehat{G}^{(j)}_{\sigma,b}(f)|^2 \mathrm{d}f\right] \\
=\ & \int_{-\infty}^{+\infty} |\widehat{g\cdot H}(f)|^2\cdot \mathop{\mathbb{E}}_{\sigma,b}[|\widehat{G}^{(j)}_{\sigma,b}(f)|^2]\mathrm{d}f \\
\leq\ & \int_{-\infty}^{+\infty} |\widehat{g\cdot H}(f)|^2 \mathrm{d}f \cdot \max_f \left[\mathop{\mathbb{E}}_{\sigma,b}\left|\widehat{G}^{(j)}_{\sigma,b}(f)\right|^2\right] \\
\lesssim\ & \frac{1}{B}\int_{-\infty}^{+\infty} |\widehat{g\cdot H}(f)|^2 \mathrm{d}f,
\end{aligned}$$

which completes the proof. □

Proof of Lemma 12.7.5. Let $j = h_{\sigma,b}(f^*)$, signal

$$\widehat{z} = \widehat{x\cdot H}\cdot \widehat{G}^{(j)}_{\sigma,b}, \tag{12.21}$$

and region $I_{f^*} = (f^* - \Delta, f^* + \Delta)$ with complement $\overline{I_{f^*}} = (-\infty,\infty)\setminus I_{f^*}$. From Property I of G in Lemma 12.6.5, we have that

$$\widehat{G}^{(l)}_{\sigma,b}(f) \gtrsim 1$$

for all $f \in I_{f^*}$, so by (12.17)

$$\int_{I_{f^*}} |\widehat{z}(f)|^2 \mathrm{d}f \geq T\mathcal{N}^2/k.$$

On the other hand, f^* is will-isolated with probability 0.9:

$$\int_{\overline{I_{f^*}}} |\widehat{z}(f)|^2 \mathrm{d}f \lesssim \epsilon T\mathcal{N}^2/k.$$

Hence, $\widehat{z}$ satisfies the Property I(in Definition 12.7.1) of one-mountain recovery. Combining Lemma 12.7.18 and Lemma 12.7.19, we know that $(x^* \cdot H) * G_{\sigma,b}^{(j)}$ always satisfies Property II(in Definition 12.7.1) and $\int_{-\infty}^{+\infty} |g(t)H(t) * G_{\sigma,b}^{(j)}(t)|^2 \mathrm{d}t$ is less than $20T\mathcal{N}^2/B \leq \epsilon T\mathcal{N}^2/k$ with probability at least 0.95, which indicates that $z = (x^* + g) \cdot H * G_{\sigma,b}^{(j)}$ satisfies Property II(in Definition 12.7.1) with probability 0.95. □

12.7.6 Frequency recovery of k-clustered signals

The goal of this section is to prove that the frequencies found by Procedure FrequencyRecoveryKCluster in Algorithm 12.8 have some reasonable guarantee.

We first notice that Lemma 12.7.5 and Lemma 12.7.2 imply the following lemma by a union bound.

Lemma 12.7.20. *Let $x^*(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$. We observe $x(t) = x^*(t) + g(t)$, where $\|g(t)\|_T^2 \le c\|x^*(t)\|_T^2$ for a sufficiently small constant c and define $\mathcal{N}^2 := \|g(t)\|_T^2 + \delta\|x^*(t)\|_T^2$. Then Procedure OneStage returns a set L of $O(k)$ frequencies that covers the heavy frequencies of x^*. In particular, for any f^* with*

$$\int_{f^*-\Delta}^{f^*+\Delta} |\widehat{x \cdot H}(f)|^2 \mathrm{d}f \ge T\mathcal{N}^2/k, \tag{12.22}$$

there will exist an $\widetilde{f} \in L$ satisfying $|f^* - \widetilde{f}| \lesssim \sqrt{T\Delta} \cdot \Delta T$ with probability 0.99.

Lemma 12.7.21. *Let $x^*(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$ and $R = O(k)$. We observe $x(t) = x^*(t) + g(t)$, where $\|g(t)\|_T^2 \le c\|x^*(t)\|_T^2$ for a sufficiently small constant c and choose $\mathcal{N}^2 := \|g(t)\|_T^2 + \delta\|x^*(t)\|_T^2$. Then Algorithm MultipleStages returns a set L of $O(k)$ frequencies that approximates the heavy frequencies of x^*. In particular, with probability $1 - 2^{-\Omega(k)}$, for any f^* such that*

$$\int_{f^*-\Delta}^{f^*+\Delta} |\widehat{x \cdot H}(f)|^2 \mathrm{d}f \ge T\mathcal{N}^2/k, \tag{12.23}$$

there will exist an $\widetilde{f} \in L$ satisfying $|f^* - \widetilde{f}| \lesssim \sqrt{T\Delta}\Delta$.

Proof. Let $A \subset [-F, F]$ denote the set of frequencies f^* satisfying Equation (12.22). Let $A' \subset [-F, F]$ denote a net of A of distance 2Δ, so the intervals used in Equation (12.22) for

each $f^* \in A'$ are disjoint. Then

$$|A'| \le 2k + k = 3k$$

because each frequency in x^* contributes to at most two of the intervals, and the total mass of $\widehat{g}$ is at most k times the threshold $T\mathcal{N}^2$.

Let $L_1, \ldots, L_R$ be the results of R rounds of Algorithm OneStage. We say that a frequency $f \in A'$ is *successfully recovered in round* r if there exists an $\widetilde{f} \in L_r$ such that $|f - \widetilde{f}| \le \Delta_a$, where

$$\Delta_a = \Delta\sqrt{T\Delta} \lesssim \sqrt{T\Delta}\Delta.$$

By Lemma 12.7.20, each frequency is successfully recovered with 0.8 probability in each round. Then by the Chernoff bound, with $1 - 2^{-\Omega(k)}$ probability, every $f \in A'$ will be successfully recovered in at least $0.6R$ rounds.

Then, by Lemma 12.7.22, we output a set L of $O(B)$ frequencies such that every $f \in A'$ is within Δ_a of some $\widetilde{f} \in L$. Hence every $f \in A$ is within $2\Delta_a$ of some $\widetilde{f} \in L$. □

Lemma 12.7.22. *Let $L_1, \ldots, L_R$ by sets of frequencies and f^* be any frequency. Then $L = \text{MergedStages}(L_1, \ldots, L_R)$ is a set of $2\frac{\sum |L_r|}{R}$ frequencies satisfying*

$$\min_{\widetilde{f} \in L} |f^* - \widetilde{f}| \le \operatorname*{median}_{r \in [R]} \min_{f \in L_r} |f^* - f|.$$

Proof. The algorithm is to take the union, sort, and take every $\frac{R}{2}$th entry of the sorted list.

Let $\Delta = \text{median}_{r\in[R]} \min_{f\in L_r} |f^* - f|$. We have that at least $R/2$ different $f \in \bigcup_r L_r$ lie within Δ of f^*. This set forms a sequential subsequence of the sorted list of frequencies, so our output will include one. □

12.7.7 Time and sample complexity of frequency recovery of k-clustered signals

The goal of this section is to show that Procedure FrequencyRecoveryKCluster takes

$\mathrm{poly}(k, \log(1/\delta)) \log(FT)$ samples, and runs in $\mathrm{poly}(k, \log(1/\delta)) \log^2(FT)$ time.

In order to analyze the running time and sample complexity. We need to extend the one-cluster version Procedure GetLegal1Sample and GetEmpirical1Energy (in Algorithm 12.3) to k-cluster version GetLegalKSample and GetEmpiricalKEnergy(in Algorithm 12.7)[5],

Lemma 12.7.23. *Procedure* GetLegalKSample *in Algorithm 12.7 runs Procedure* HashToBins $R_{\mathrm{repeat}} = O((T\Delta)^3)$ *times to output two vectors* $\widehat{v}, \widehat{v}' \in \mathbb{C}^B$ *such that, for each* $j \in [B]$,

$$|\widehat{v}_j - \widehat{v}'_j e^{2\pi \mathbf{i} f_j \beta}| \leq 0.08(|\widehat{v}_j| + |\widehat{v}'_j|),$$

holds with probability at least 0.6.

Using the definition of z in Definition 12.7.2.

Claim 12.7.24. *Procedure* GetEmpiricalKEnergy *in Algorithm 12.7 runs Procedure* HashTobins $R_{\mathrm{est}} O((T\Delta)^2)$ *times to output a vector* $z_{\mathrm{emp}} \in \mathbb{R}^B$ *such that, for each* $j \in [B]$,

$$z^j_{\mathrm{emp}} \in [0.8\|z^{(j)}\|_T, 1.2\|z^{(j)}\|_T],$$

holds with probability at least 0.9.

[5] We omitted the proofs here, because the proofs are identical to the one-cluster situation.

Claim 12.7.25. *Algorithm* LocateKSignal *in Algorithm 12.6 uses* $O(\text{poly}(k, \log(1/\delta)) \cdot \log(FT))$, *and runs in* $O(\text{poly}(k, \log(1/\delta)) \cdot \log^2(FT))$.

Proof. We first calculate the number of samples. All the samples is basically all the Fourier samples, each time needs $B \log(k/\delta)$. In total it calls HashToBins $O(R_{\text{est}} + R_{\text{repeat}} D_{\max} R_{\text{loc}})$ times where $D_{\max} R_{\text{loc}} = \Theta(\log(FT))$ by similar analysis as one-cluster frequency recovery. Thus, the total number of samples is

$$(R_{\text{est}} + R_{\text{repeat}} D_{\max} R_{\text{loc}}) B \log(k/\delta) = \text{poly}(k, \log(1/\delta)) \cdot \log(FT).$$

Then, we analyze the running time.

The expected running time includes the following parts: the first part is running Procedure HashToBins $O(R_{\text{est}} + R_{\text{repeat}} D_{\max} R_{loc})$ times, each run takes $O(B \log(k/\delta) + B \log B)$ samples. For each such sample we need $\text{poly}(k, \log(1/\delta))$ time to compute $H(t)$ according to Lemma 12.12.5 and there are $\text{poly}(k, \log(1/\delta)) \log(FT))$ many samples; the second part is updating the counter v,which takes $O(D_{\max} R_{loc} B t)$ time. Thus, in total

$$\begin{aligned} &\text{poly}(k, \log(1/\delta)) \cdot O(R_{\text{est}} + R_{\text{repeat}} D_{\max} R_{\text{loc}}) \cdot O(B \log(k/\delta) + B \log B) + O(D_{\max} R_{loc} B t) \\ =& \text{poly}(k, \log(1/\delta)) \cdot \log^2(FT), \end{aligned}$$

where by similar analysis as one-cluster recovery, $t = \Theta(\log(FT))$ and $D_{\max} R_{\text{loc}} = \Theta(\log(FT))$.

□

To boost the success probability, Procedure MultipleStages reruns Procedure LocateKSignal $O(k)$ times. At the end, Procedure FrequencyRecoveryKCluster combining Procedure MultipleStages and MergedStages directly, and the running time

and sample complexity of MultipleStages are dominating MergedStages. Thus we have

Lemma 12.7.26. *Procedure* FrequencyRecoveryKCluster *in Algorithm 12.8 uses*

$$\text{poly}(k, \log(1/\delta)) \cdot \log(FT)$$

samples and runs in $\text{poly}(k, \log(1/\delta)) \cdot \log^2(FT)$ *time.*

12.8 One-cluster Signal Recovery

12.8.1 Overview

In this section, we consider x^* whose frequencies in $\widehat{x}^*$ are in the range $[f_0 - \Delta', f_0 + \Delta']$ for some frequency f_0 and $\Delta' > 0$ and provide an algorithm to approximate it by a polynomial.

We fix T in this section and recall that $\langle f(t), g(t)\rangle_T := \frac{1}{T}\int_0^T f(t)\overline{g}(t)\mathrm{d}t$ such that $\|e^{2\pi \mathbf{i} f_i t}\|_T = \sqrt{\langle e^{2\pi \mathbf{i} f_i t}, e^{2\pi \mathbf{i} f_i t}\rangle_T} = 1$. For convenience, given $\sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$, we say the frequency gap of this signal is $\min_{i\neq j}|f_i - f_j|$.

For simplicity, we first consider frequencies clustered around 0. The main technical lemma in this section is that any signal x^* with bounded frequencies in $\widehat{x}^*$ can be approximated by a low-degree polynomial on $[0, T]$.

Lemma 12.2.3. For any $\Delta > 0$ and any $\delta > 0$, let $x^*(t) = \sum_{j\in[k]} v_j e^{2\pi \mathbf{i} f_j t}$ where $|f_j| \leq \Delta$ for each $j \in [k]$. There exists a polynomial $P(t)$ of degree at most

$$d = O(T\Delta + k^3 \log k + k \log 1/\delta)$$

such that

$$\|P(t) - x^*(t)\|_T^2 \leq \delta \|x^*\|_T^2.$$

One direct corollary is that when $\widehat{x}^*$ are in the range $[f_0 + \Delta', f_0 + \Delta']$, we can approximate x^* by $P(t) \cdot e^{2\pi \mathbf{i} f_0 t}$ for some low degree polynomial P.

We give an overview of this section first. We first show some technical tools in Section 12.8.2, 12.8.3. In Section 12.8.4, using those tools, we can show for any k-Fourier-sparse signal, there exists another k-Fourier-sparse signal with bounded frequency gap close to the

original signal. In Section 12.8.5, we show that for any k-Fourier-sparse signal with bounded frequency gap, then there exists a low degree polynomial close to it. In Section 12.8.6, we show how to transfer low degree polynomial back to a Fourier-sparse signal. Combining all the above steps finishes the proof of Lemma 12.2.3.

We apply Theorem 12.7.4 of frequency estimation on x^* to obtain an estimation $\widetilde{f}_0$ of f_0 and use Theorem 12.4.5 on the approximation $Q(t)e^{2\pi \mathbf{i} \widetilde{f}_0 t}$ of x^* to recover the signal. We summarize this result as follows.

Theorem 12.8.1 (One-cluster Signal Recovery)**.** *Let* $x^*(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$ *where* $\forall j \in [k], |f_j - f_0| \leq \Delta$ *and* $x(t) = x^*(t) + g(t)$ *be our observable signal. For any* $\delta > 0$ *and any* $T > 0$*, let* $\mathcal{N}^2 := \|g\|_T^2 + \delta \|x^*\|_T^2$*. Procedure* CFT1CULSTER *in Algorithm 12.5 finds a polynomial* $P(t)$ *of degree at most* $d = O\left((T\Delta_h + T\Delta)^{1.5} + k^3 \log k + k \log 1/\delta\right)$ *and a frequency* $\widetilde{f}_0$ *such that*

$$\|P(t) \cdot e^{2\pi \mathbf{i} \widetilde{f}_0 t} - x^*(t)\|_T^2 \lesssim \mathcal{N}^2 \tag{12.24}$$

The algorithm uses $O(kd)+\mathrm{poly}(k, \log(1/\delta)) \log(FT)$ *samples, run in* $O(kd^\omega)+\mathrm{poly}(k, \log(1/\delta)) \log^2(FT)$ *time, and succeeds with probability at least* $1 - 2^{-\Omega(k)}$*.*

Proof. We apply the algorithm in Theorem 12.7.4 to obtain an estimation $\widetilde{f}_0$ with $\mathrm{poly}(k) \log(FT)$ samples and $\mathrm{poly}(k) \log^2(FT)$ running time such that $|\widetilde{f}_0 - f_0| \lesssim (\Delta_h + \Delta)\sqrt{T(\Delta_h + \Delta)}$ holds with probability at least $1 - 2^{-\Omega(k)}$. Notice that $|f_j - \widetilde{f}_0| \leq |f_j - f_0| + |\widetilde{f}_0 - f_0| \lesssim (T(\Delta_h + \Delta))^{1.5}$.

We consider $x'(t) = e^{-2\pi \mathbf{i} \widetilde{f}_0 t} x(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} (f_j - \widetilde{f}_0) t}$. By Lemma 12.2.3, there exists a polynomial $P(t)$ of degree at most

$$d = O\left((T\Delta_h + T\Delta)^{1.5} + k^3 \log k + k \log 1/\delta\right)$$

such that it approximates x' by

$$\|P(t) - x'(t)\|_T \leq \frac{\delta}{4}\|x'(t)\|_T = \frac{\delta}{4}\|x^*(t)\|_T.$$

which indicates $\|Q(t) - e^{-2\pi \mathbf{i} \widetilde{f}_0 t} \cdot x^*(t)\|_T \leq \frac{\delta}{4}\|x^*(t)\|_T$.

Because we can sample $x(t)$, we can also sample $e^{-2\pi \mathbf{i} \widetilde{f}_0 t} \cdot x(t) = Q(t) + g'(t)$ for $g'(t) = e^{-2\pi \mathbf{i} \widetilde{f}_0 t} \cdot g(t) + (e^{-2\pi \mathbf{i} \widetilde{f}_0 t} \cdot x^*(t) - Q(t))$. Hence we apply the algorithm in Theorem 12.4.5 and choose $R = O(k)$ in that proof. Then Procedure RobustPolynomialLearning$^+$ takes $O(kd)$ samples and $O(kd^\omega)$ time to find a degree d polynomial $P(t)$ approximating $Q(t)$ such that

$$\|P(t) - Q(t)\|_T \lesssim \|g'(t)\|_T,$$

holds with probability at least $1 - 2^{-\Omega(k)}$. It indicates

$$\|P(t) - e^{-2\pi \mathbf{i} \widetilde{f}_0 t} \cdot x^*(t)\|_T \lesssim \|P(t) - Q(t)\|_T + \|Q(t) - x^*(t)\| \lesssim \delta \|x^*(t)\|_T + \|g(t)\|_T \eqsim \mathcal{N}.$$

Therefore we know $\|e^{2\pi \mathbf{i} \widetilde{f}_0 t} \cdot P(t) - x^*(t)\|_T^2 \lesssim \mathcal{N}^2$. □

12.8.2 Bounding the Gram matrix determinant

We define Gram matrix for $e^{2\pi \mathbf{i} f_1 t}, e^{2\pi \mathbf{i} f_2 t}, \cdots, e^{2\pi \mathbf{i} f_k t}$ and provide lower/upper bounds for its determinant.

Definition 12.8.1 (Gram matrix)**.** We define $\mathrm{Gram}_{f_1,\cdots,f_k}$ to be

$$\begin{bmatrix} \langle e^{2\pi \mathbf{i} f_1 t}, e^{2\pi \mathbf{i} f_1 t}\rangle_T & \langle e^{2\pi \mathbf{i} f_1 t}, e^{2\pi \mathbf{i} f_2 t}\rangle_T & \cdots & \langle e^{2\pi \mathbf{i} f_1 t}, e^{2\pi \mathbf{i} f_k t}\rangle_T \\ \langle e^{2\pi \mathbf{i} f_2 t}, e^{2\pi \mathbf{i} f_1 t}\rangle_T & \langle e^{2\pi \mathbf{i} f_2 t}, e^{2\pi \mathbf{i} f_2 t}\rangle_T & \cdots & \langle e^{2\pi \mathbf{i} f_2 t}, e^{2\pi \mathbf{i} f_k t}\rangle_T \\ \cdots & \cdots & \cdots & \cdots \\ \langle e^{2\pi \mathbf{i} f_k t}, e^{2\pi \mathbf{i} f_1 t}\rangle_T & \langle e^{2\pi \mathbf{i} f_k t}, e^{2\pi \mathbf{i} f_2 t}\rangle_T & \cdots & \langle e^{2\pi \mathbf{i} f_k t}, e^{2\pi \mathbf{i} f_k t}\rangle_T \end{bmatrix}$$

Note that the above matrix is a Hermitian matrix with complex entries, thus both its determinant and all eigenvalues are in $\mathbb{R}$.

We defer the proof of the following Theorem to Section 12.10.1.

Theorem 12.8.2. For real numbers $\xi_1, \ldots, \xi_k$, let $G_{\xi_1,\ldots,\xi_k}$ be the matrix whose (i,j)-entry is

$$\int_{-1}^{1} e^{2\pi \mathbf{i}(\xi_i - \xi_j)t} dt.$$

Then

$$\det(G_{\xi_1,\ldots,\xi_k}) = 2^{\widetilde{O}(k^2)} \prod_{i<j} \min(|\xi_i - \xi_j|^2, 1).$$

We use the following corollary in this section.

Corollary 12.8.3. *There exists a universal constant $\alpha > 0$ such that, for any $T > 0$ and real numbers $f_1, \cdots, f_k$, the $k \times k$ Gram matrix of $e^{2\pi \mathbf{i} f_1 t}, e^{2\pi \mathbf{i} f_2 t}, \cdots, e^{2\pi \mathbf{i} f_k t}$ whose (i,j)-entry is*

$$\mathrm{Gram}_{f_1,\cdots,f_k}(i,j) = \langle e^{2\pi \mathbf{i} f_i t}, e^{2\pi \mathbf{i} f_j t}\rangle_T = \frac{1}{T}\int_0^T e^{2\pi \mathbf{i}(f_i - f_j)t} \mathrm{d}t.$$

satisfies

$$k^{-\alpha k^2} \prod_{i<j} \min((|f_i - f_j|T)^2, 1) \le \det\left(\mathrm{Gram}_{f_1,\cdots,f_k}\right) \le k^{\alpha k^2} \prod_{i<j} \min((|f_i - f_j|T)^2, 1).$$

Based on Corollary 12.8.3, we show the coefficients of a k-Fourier-sparse signal can be upper bounded by the energy $\|x\|_T^2$.

Lemma 12.2.2. There exists a universal constant $c > 0$ such that for any $x(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$ with frequency gap $\eta = \min_{i \neq j} |f_i - f_j|$,

$$\|x(t)\|_T^2 \geq k^{-ck^2} \min\left((\eta T)^{2k}, 1\right) \sum_{j=1}^{k} |v_j|^2.$$

Proof. Let $\vec{v_i}$ denote the vector $e^{2\pi \mathbf{i} f_i t}$ and $V = \{\vec{v_1}, \cdots, \vec{v_k}\}$. Notice that $\|\vec{v_i}\|_T^2 = \langle \vec{v_i}, \vec{v_i} \rangle = 1$. For each $\vec{v_i}$, we define $\vec{v_i}^{\parallel}$ to be the projection of $\vec{v_i}$ into the linear subspace $\text{span}\{V \setminus \vec{v_i}\} = \text{span}\{\vec{v_1}, \cdots, \vec{v_{i-1}}, \vec{v_{i+1}}, \cdots, \vec{v_k}\}$ and $\vec{v_i}^{\perp} = \vec{v_i} - \vec{v_i}^{\parallel}$ which is orthogonal to $\text{span}\{V \setminus \vec{v_i}\}$ by the definition.

Therefore from the orthogonality,

$$\|x(t)\|_T^2 \geq \max_{j \in [k]} \{|v_j|^2 \cdot \|\vec{v_j}^{\perp}\|_T^2\} \geq \frac{1}{k} \sum_{j=1}^{k} |v_j|^2 \cdot \|\vec{v_j}^{\perp}\|_T^2.$$

It is enough to estimate $\|\vec{v_j}^{\perp}\|_T^2$ from Claim 12.3.11:

$$\|\vec{v_j}^{\perp}\|_T^2 = \frac{\det(\text{Gram}(V))}{\det(\text{Gram}(V \setminus \vec{v_i}))} \geq k^{-2\alpha k^2} \prod_{j \neq i} \min\left((f_j - f_i)T, 1\right)^2 \geq k^{-2\alpha k^2} (\eta T)^{2k-2},$$

where we use Corollary 12.8.3 to lower bound it in the last step. □

12.8.3 Perturbing the frequencies does not change the subspace much

We show that for a k-Fourier-sparse signal with unboundedly close frequency gap, there always exists another k-Fourier-sparse signal with slightly separated gap.

Lemma 12.8.4 (Slightly Shifting one Frequency)**.** *There is a universal constant $C_0 > 0$ such that for any $x(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$ and any frequency f_{k+1}, there always exists*

$$x'(t) = \sum_{j=1}^{k-1} v'_j e^{2\pi \mathbf{i} f_j t} + v'_{k+1} e^{2\pi \mathbf{i} f_{k+1} t}$$

with k coefficients $v'_1, v'_2, \cdots, v'_{k-1}, v'_{k+1}$ satisfying

$$\|x'(t) - x(t)\|_T \leq k^{C_0 k^2} \cdot (|f_k - f_{k+1}|T) \cdot \|x(t)\|_T$$

Proof. We abuse the notation $e^{2\pi \mathbf{i} f_j t}$ to denote a vector in the linear subspace. We plan to shift f_k to f_{k+1} and define

$$\begin{aligned} V &= \{e^{2\pi \mathbf{i} f_1 t}, \cdots, e^{2\pi \mathbf{i} f_{k-1} t}, e^{2\pi \mathbf{i} f_k t}\} \\ V' &= \{e^{2\pi \mathbf{i} f_1 t}, \cdots, e^{2\pi \mathbf{i} f_{k-1} t}, e^{2\pi \mathbf{i} f_{k+1} t}\} \\ U &= \{e^{2\pi \mathbf{i} f_1 t}, \cdots, e^{2\pi \mathbf{i} f_{k-1} t}\} \\ W &= \{e^{2\pi \mathbf{i} f_1 t}, \cdots, e^{2\pi \mathbf{i} f_{k-1} t}, e^{2\pi \mathbf{i} f_k t}, e^{2\pi \mathbf{i} f_{k+1} t}\} \end{aligned}$$

where $f_1, f_2, \cdots, f_k$ are original frequencies in x. The idea is to show that any vector in the linear subspace $\mathrm{span}\{V\}$ is close to some vector in the linear subspace $\mathrm{span}\{V'\}$.

For convenience, we use $\vec{u}^{\parallel}$ to denote the projection of vector $e^{2\pi \mathbf{i} f_k t}$ to the linear subspace $\mathrm{span}\{U\} = \mathrm{span}\{e^{2\pi \mathbf{i} f_1 t}, \cdots, e^{2\pi \mathbf{i} f_{k-1} t}\}$ and $\vec{w}^{\parallel}$ denote the projection of vector $e^{2\pi \mathbf{i} f_{k+1} t}$

to this linear subspace span$\{U\}$. Let $\vec{u}^{\perp} = e^{2\pi \mathbf{i} f_k t} - \vec{u}^{\parallel}$ and $\vec{w}^{\perp} = e^{2\pi \mathbf{i} f_{k+1} t} - \vec{w}^{\parallel}$ be their orthogonal part to span$\{U\}$.

From the definition $e^{2\pi \mathbf{i} f_k t} = \vec{u}^{\parallel} + \vec{u}^{\perp}$ and $\vec{u}^{\parallel} \in \text{span}\{U\} = \text{span}\{e^{2\pi \mathbf{i} f_1 t}, \cdots, e^{2\pi \mathbf{i} f_{k-1} t}\}$, we rewrite the linear combination

$$x(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t} = \sum_{j=1}^{k-1} \alpha_j e^{2\pi \mathbf{i} f_j t} + v_k \cdot \vec{u}^{\perp}$$

for some scalars $\alpha_1, \cdots, \alpha_{k-1}$.

We will substitute $\vec{u}^{\perp}$ by $\vec{w}^{\perp}$ in the above linear combination and find a set of new coefficients. Let $\vec{w}^{\perp} = \vec{w}_1 + \vec{w}_2$ where $\vec{w}_1 = \frac{\langle \vec{u}^{\perp}, \vec{w}^{\perp} \rangle}{\|\vec{u}^{\perp}\|_T^2} \vec{u}^{\perp}$ is the projection of $\vec{w}^{\perp}$ to $\vec{u}^{\perp}$. Therefore $\vec{w}_2$ is the orthogonal part of the vector $e^{2\pi \mathbf{i} f_{k+1} t}$ to span$\{V\} = \text{span}\{e^{2\pi \mathbf{i} f_1 t}, \cdots, e^{2\pi \mathbf{i} f_{k-1} t}, e^{2\pi \mathbf{i} f_k t}\}$. We use $\delta = \frac{\|\vec{w}_2\|_T}{\|\vec{w}^{\perp}\|_T}$ for convenience.

Notice that the $\min_{\beta \in \mathbb{C}} \frac{\|\vec{u}^{\perp} - \beta \cdot \vec{w}^{\perp}\|_T}{\|\vec{u}^{\perp}\|_T} = \delta$ and $\beta^* = \frac{\langle \vec{u}^{\perp}, \vec{w}^{\perp} \rangle}{\|\vec{w}^{\perp}\|_T^2}$ is the optimal choice. Therefore we set

$$x'(t) = \sum_{j=1}^{k-1} \beta_j e^{2\pi \mathbf{i} f_j t} + v_k \cdot \beta^* \cdot \vec{w}^{\perp} \in \text{span}\{e^{2\pi \mathbf{i} f_1 t}, \cdots, e^{2\pi \mathbf{i} f_{k-1} t}, e^{2\pi \mathbf{i} f_{k+1} t}\}$$

where the coefficients $\beta_1, \cdots, \beta_{k-1}$ guarantee that the projection of x' onto span$\{U\}$ is as same as the projection of x onto span$\{U\}$. From the choice of β^* and the definition of x',

$$\|x(t) - x'(t)\|_T^2 = \delta^2 \cdot |v_k|^2 \cdot \|\vec{u}^{\perp}\|_T^2 \leq \delta^2 \cdot \|x(t)\|_T^2.$$

Eventually, we show an upper bound for δ^2 from Claim 12.3.11.

$$\begin{aligned}
\delta^2 &= \frac{\|\vec{w}_2\|_T^2}{\|\vec{w}^{\perp}\|_T^2} \\
&= \frac{\det(\mathrm{Gram}_W)}{\det(\mathrm{Gram}_V)} \Big/ \frac{\det(\mathrm{Gram}_{V'})}{\det(\mathrm{Gram}_U)} \text{ by Claim 12.3.11} \\
&= \frac{\det(\mathrm{Gram}_W)}{\det(\mathrm{Gram}_V)} \cdot \frac{\det(\mathrm{Gram}_U)}{\det(\mathrm{Gram}_{V'})} \text{ by Corollary 12.8.3} \\
&\leq k^{4\alpha k^2} \cdot \frac{\prod_{i=1}^{k+1} \prod_{\substack{j=1 \\ j\neq i}}^{k+1} \min(|f_i - f_j|T, 1)}{\prod_{i=1}^{k} \prod_{\substack{j=1 \\ j\neq i}}^{k} \min(|f_i - f_j|T, 1)} \cdot \frac{\prod_{i=1}^{k-1} \prod_{\substack{j=1 \\ j\neq i}}^{k-1} \min(|f_i - f_j|T, 1)}{\prod_{i=1}^{k-1} \prod_{\substack{j=1 \\ j\neq i}}^{k-1} \min(|f_i - f_j|T, 1) \cdot \prod_{i=1}^{k-1} \min(|f_i - f_{k+1}|^2 T^2, 1)} \\
&= k^{4\alpha k^2} |f_k - f_{k+1}|^2 T^2
\end{aligned}$$

□

Lemma 12.8.5. *For any k frequencies $f_1 < f_2 < \cdots < f_k$, there exists k frequencies $f'_1, \cdots, f'_k$ such that $\min_{i\in[k-1]} f'_{i+1} - f'_i \geq \eta$ and for all $i \in [k]$, $|f'_i - f_i| \leq k\eta$.*

Proof. We define the new frequencies f'_i as follows: $f'_1 = f_1$ and $f'_i = \max\{f'_{i-1} + \eta, f_i\}$ for $i \in \{2, 3, \cdots, k\}$. □

12.8.4 Existence of nearby k-Fourier-sparse signal with frequency gap bounded away from zero

We combine the results in the above section to finish the proof of Lemma 12.2.3. We first prove that for any $x^*(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$, there always exists another k-Fourier-sparse signal x' close to $x^*(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$ such that the frequency gap in x' is at least $\eta \geq 2^{-\operatorname{poly}(k)}$. Then we show how to find a low degree polynomial $P(t)$ approximating $x'(t)$.

Lemma 12.2.1. There is a universal constant $C_1 > 0$ such that, for any $x^*(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$ and any $\delta > 0$, there always exist $\eta \geq \frac{\delta}{T} \cdot k^{-C_1 k^2}$ and $x'(t) = \sum_{j=1}^{k} v'_j e^{2\pi \mathbf{i} f'_j t}$ satisfying

$$\|x'(t) - x^*(t)\|_T \leq \delta \|x^*(t)\|_T$$

with $\min_{i \neq j} |f'_i - f'_j| \geq \eta$ and $\max_{j \in [k]} \{|f'_j - f_j|\} \leq k\eta$.

Proof. Using Lemma 12.8.5 on frequencies $f_1, \cdots, f_k$, we obtain k new frequencies $f'_1, \cdots, f'_k$ such that their gap is at least η and $\max_i |f_i - f'_i| \leq k\eta$. Next we use the hybrid argument to find x'.

Let $x^{(0)}(t) = x^*(t)$. For $i = 1, \cdots, t$, we apply Lemma 12.8.4 to shift f_i to f'_i and obtain

$$x^{(i)}(t) = \sum_{j=i+1}^{k} v_j^{(i)} e^{2\pi \mathbf{i} f_j t} + \sum_{j=1}^{i} v_j^{(i)} e^{2\pi \mathbf{i} f'_j t}.$$

From Lemma 12.8.4, we know $\|x^{(i)}(t) - x^{(i-1)}(t)\|_T \leq k^{C_0 k^2} (|f_i - f'_i| T) \|x^{(i-1)}\|_T$. Thus we obtain

$$\left(1 - k^{C_0 k^2} (k\eta T)\right)^i \|x^{(0)}(t)\|_T \leq \|x^{(i)}(t)\|_T \leq \left(1 + k^{C_0 k^2} (k\eta T)\right)^i \|x^{(0)}(t)\|_T,$$

which is between $\left[\left(1 - i \cdot k^{C_0 k^2}(k\eta T)\right)\|x^{(0)}(t)\|_T, \left(1 + 2i \cdot k^{C_0 k^2}(k\eta T)\right)\|x^{(0)}(t)\|_T\right]$ for $\eta \leq \frac{1}{5T} \cdot k^{-C_1 k^2}$ with some $C_1 > C_0$.

At last, we set $x'(t) = x^{(k)}(t)$ and bound the distance between $x'(t)$ and $x^*(t)$ by

$$\begin{aligned}
\|x^{(k)}(t) - x^{(0)}(t)\|_T &\leq \sum_{i=1}^{k} \|x^{(i)}(t) - x^{(i-1)}(t)\|_T && \text{by triangle inequality} \\
&\leq \sum_{i=1}^{k} k^{C_0 k^2}(|f_i - f_i'|T)\|x^{(i-1)}(t)\|_T && \text{by Lemma 12.8.4} \\
&\leq \sum_{i=1}^{k} 2k^{C_0 k^2}(k\eta T)\|x^{(i-1)}(t)\|_T && \text{by } \max_i |f_i - f_i'| \leq k\eta \\
&\leq k \cdot 2k^{C_0 k^2}(k\eta T)\|x^*(t)\|_T \\
&\leq \delta \|x^*(t)\|_T
\end{aligned}$$

where the last inequality follows by the sufficiently small η. □

12.8.5 Approximating k-Fourier-sparse signals by polynomials

For any k-Fourier-sparse signal with frequency gap bounded away from zero, we show that there exists a low degree polynomial which is close to the original k-Fourier-sparse signal in $\|\cdot\|_T$ distance.

Lemma 12.8.6 (Existence of low degree polynomial)**.** *Let* $x^*(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$*, where* $\forall j \in [k], |f_j| \leq \Delta$ *and* $\min_{i \neq j} |f_i - f_j| \geq \eta$*. There exists a polynomial* $Q(t)$ *of degree*

$$d = O\left(T\Delta + k \log 1/(\eta T) + k^2 \log k + k \log(1/\delta)\right)$$

such that,

$$\|Q(t) - x^*(t)\|_T^2 \leq \delta \|x^*(t)\|_T^2 \tag{12.25}$$

Proof. For each frequency f_j, let $Q_j(t) = \sum_{k=0}^{d-1} \frac{(2\pi \mathbf{i} f_j t)^k}{k!}$ be the first d terms in the Taylor Expansion of $e^{2\pi \mathbf{i} f_j t}$. For any $t \in [0, T]$, we know the difference between $Q_j(t)$ and $e^{2\pi \mathbf{i} f_j t}$ is at most

$$|Q_j(t) - e^{2\pi \mathbf{i} f_j t}| \leq |\frac{(2\pi \mathbf{i} f_j T)^d}{d!}| \leq (\frac{2\pi T \Delta \cdot e}{d})^d.$$

We define

$$Q(t) = \sum_{j=1}^{k} v_j Q_j(t)$$

and bound the distance between Q and x^* from the above estimation:

$$\begin{aligned}
\|Q(t) - x^*(t)\|_T^2 &= \frac{1}{T}\int_0^T |Q(t) - x^*(t)|^2 \mathrm{d}t \\
&= \frac{1}{T}\int_0^T |\sum_{j=1}^k v_j (Q_j(t) - e^{2\pi \mathbf{i} f_j t})|^2 \mathrm{d}t \\
&\leq 2k \sum_{j=1}^k \frac{1}{T}\int_0^T |v_j|^2 \cdot |Q_j(t) - e^{2\pi \mathbf{i} f_j t}|^2 \mathrm{d}t \qquad \text{by triangle inequality} \\
&\leq k \sum_{j=1}^k |v_j|^2 \cdot (\frac{2\pi T\Delta \cdot e}{d})^{2d} \qquad \text{by Taylor expansion}
\end{aligned}$$

On the other hand, from Lemma 12.2.2, we know

$$\|x^*(t)\|_T^2 \geq (\eta T)^{2k} \cdot k^{-ck^2} \sum_j |v_j|^2.$$

Because $d = 10 \cdot \pi e(T\Delta + k \log 1/(\eta T) + k^2 \log k + k \log(1/\delta))$ is large enough, we have $k(\frac{2\pi T\Delta \cdot e}{d})^{2d} \leq \delta(\eta T)^{2k} \cdot k^{-ck^2}$, which indicates that $\|Q(t) - x^*(t)\|_T^2 \leq \delta \|x^*\|_T^2$ from all discussion above. □

12.8.6 Transferring degree-d polynomial to (d+1)-Fourier-sparse signal

In this section, we show how to transfer a degree-d polynomial to (d+1)-Fourier-sparse signal.

Lemma 12.8.7. *For any degree-d polynomial $Q(t) = \sum_{j=0}^{d} c_j t^j$, any $T > 0$ and any $\epsilon > 0$, there always exist $\gamma > 0$ and*

$$x^*(t) = \sum_{i=1}^{d+1} \alpha_i e^{2\pi \mathbf{i}(\gamma i)t}$$

with some coefficients $\alpha_0, \cdots, \alpha_d$ such that

$$\forall t \in [0, T], |x^*(t) - Q(t)| \leq \epsilon.$$

Proof. We can rewrite $x^*(t)$,

$$\begin{aligned}
x^*(t) &= \sum_{i=1}^{d+1} \alpha_i e^{2\pi \mathbf{i}\gamma i t} \\
&= \sum_{i=1}^{d+1} \alpha_i \sum_{j=0}^{\infty} \frac{(2\pi \mathbf{i}\gamma i t)^j}{j!} \\
&= \sum_{j=0}^{\infty} \frac{(2\pi \mathbf{i}\gamma t)^j}{j!} \sum_{i=1}^{d+1} \alpha_i \cdot i^j \\
&= \sum_{j=0}^{d} \frac{(2\pi \mathbf{i}\gamma t)^j}{j!} \sum_{i=1}^{d+1} \alpha_i \cdot i^j + \sum_{j=d+1}^{\infty} \frac{(2\pi \mathbf{i}\gamma t)^j}{j!} \sum_{i=1}^{d+1} \alpha_i \cdot i^j \\
&= Q(t) + \underbrace{\left(\sum_{j=0}^{d} \frac{(2\pi \mathbf{i}\gamma t)^j}{j!} \sum_{i=1}^{d+1} \alpha_i \cdot i^j - Q(t) \right)}_{C_1} + \underbrace{\left(\sum_{j=d+1}^{\infty} \frac{(2\pi \mathbf{i}\gamma t)^j}{j!} \sum_{i=1}^{d+1} \alpha_i \cdot i^j \right)}_{C_2}.
\end{aligned}$$

Our goal is to show there exists some parameter γ and coefficients $\{\alpha_0, \alpha_1, \cdots, \alpha_d\}$ such that

the term $C_1 = 0$ and $|C_2| \leq \epsilon$. Let's consider C_1,

$$C_1 = \sum_{j=0}^{d} (\frac{t}{T})^j \left(\frac{(2\pi \mathbf{i}\gamma T)^j}{j!} \sum_{i=1}^{d+1} \alpha_i i^j - c_j \right)$$

To guarantee $C_1 = 0$, we need to solve a linear system with $d+1$ unknown variables and $d+1$ constraints,

$$\begin{aligned} \text{Find} \quad & \alpha_1, \alpha_2, \cdots \alpha_{d+1} \\ \text{s.t.} \quad & \frac{(2\pi \mathbf{i}\gamma T)^j}{j!} \sum_{i=1}^{d+1} \alpha_i i^j - c_j = 0, \forall j \in \{0, 1, \cdots, d\} \end{aligned}$$

Define $c'_j = c_j j!/(2\pi \mathbf{i}\gamma)^j$, let α and c' be the length-$(d+1)$ column vectors with α_i and c'_j. Let $A \in \mathbb{R}^{d+1 \times d+1}$ denote the Vandermonde matrix where $A_{i,j} = i^j, \forall i, j \in [d+1] \times \{0, 1, \cdots, d\}$. Then we need to guarantee $A\alpha = c'$. Using the definition of determinant, $\det(A) = \prod_{i<j} |i-j| \leq 2^{O(d^2 \log d)}$. Thus $\sigma_{\max}(A) \leq 2^{O(d^2 \log d)}$ and then

$$\sigma_{\min}(A) = \frac{\det(A)}{\prod_{i=1}^{d-1} \sigma_i} \geq 2^{-O(d^3 \log d)}.$$

We show how to upper bound $|\alpha_i|$,

$$\max_{i \in [d+1]} |\alpha_i| \leq \|\alpha\|_2 = \|A^\dagger c'\|_2 \leq \|A^\dagger\|_2 \cdot \|c'\|_2 \leq \frac{1}{\sigma_{\min}(A)} \sqrt{d+1} \max_{0 \leq j \leq d} \frac{|c_j| j!}{(2\pi\gamma T)^j}$$

Plugging the above equation into C_2, we have

$$\begin{aligned}
|C_2| &= \left| \sum_{j=d+1}^{\infty} \frac{(2\pi \mathbf{i}\gamma t)^j}{j!} \sum_{i=1}^{d+1} \alpha_i \cdot i^j \right| \\
&\leq \sum_{j=d+1}^{\infty} \frac{(2\pi\gamma t)^j}{j!} \sum_{i=1}^{d+1} |\alpha_i| \cdot i^j \\
&\leq \sum_{j=d+1}^{\infty} \frac{(2\pi\gamma t)^j}{j!} (d+1)^{d+1} \max_{i\in[d+1]} |\alpha_i| \\
&\leq \sum_{j=d+1}^{\infty} \frac{(2\pi\gamma t)^j}{j!} (d+1)^{d+2} \frac{1}{\sigma_{\min}(A)} \frac{d!}{(2\pi\gamma T)^d} \max_{0\leq j\leq d} |c_j| \\
&\leq \epsilon
\end{aligned}$$

where the last step follows by choosing sufficiently small

$$\gamma \lesssim \epsilon / \left(T 2^{\Theta(d^3 \log d)} \max_{0\leq j\leq d} |c_j| \right).$$

□

12.9 k-cluster Signal Recovery

12.9.1 Overview

In this section, we prove Lemma 12.9.1 as the main technical lemma to finish the proof of main Theorem 12.1.1, which shows how to learn $x^*(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$ with noise.

Lemma 12.9.1. *Let $x^*(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$ and $x(t) = x^*(t) + g(t)$ be our observation. For any $\delta > 0$ and $T > 0$, let $\mathcal{N}^2 := \frac{1}{T}\int_0^T |g(t)|^2 \mathrm{d}t + \delta \cdot \frac{1}{T}\int_0^T |x^*(t)|^2 \mathrm{d}t$. For $\Delta = \mathrm{poly}(k, \log(1/\delta))/T$, Procedure* SignalRecoveryKCluster$^+$ *in Algorithm 12.8 takes $l = O(k)$ frequencies $\widetilde{f}_1, \cdots, \widetilde{f}_l$ as input and finds l polynomials $Q_1, \cdots, Q_l$ of degree $d = O((T\Delta)^{1.5} + k^3 \log k + k \log 1/\delta)$ such that*

$$\widetilde{x}(t) = \sum_{j \in [l]} Q_j(t) e^{2\pi \mathbf{i} \widetilde{f}_j t} \text{ satisfies } \|\widetilde{x}(t) - x^*(t)\|_T^2 \lesssim \mathcal{N}^2. \tag{12.26}$$

The procedure succeeds with probability at least $1 - 2^{-\Omega(k)}$, uses $\mathrm{poly}(k, \log(1/\delta)) \cdot \log(FT)$ samples, and runs in $\mathrm{poly}(k, \log(1/\delta)) \cdot \log^2(FT)$ time.

For any set $W = \{t_1, \cdots, t_m\}$ where each $t_i \in [0, T]$, we use

$$\|\vec{v}\|_W = \sqrt{\frac{\sum_{i \in W} |\vec{v}(t_i)|^2}{|W|}} \text{ for any } \vec{v} : [0, T] \to \mathbb{C}$$

in this section. We first show that Procedure SignalRecoveryKCluster succeeds with constant probability, then prove that Procedure SignalRecoveryKCluster$^+$ succeeds with probability at least $1 - 2^{-\Omega(k)}$.

12.9.2 Heavy clusters separation

Recall the definition of "heavy" clusters.

Definition 12.2.4. Given $x^*(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$, any $\mathcal{N} > 0$, and a filter function $(H, \widehat{H})$ with bounded support in frequency domain. Let L_j denote the interval of $\mathrm{supp}(\widehat{e^{2\pi \mathbf{i} f_j t} \cdot H})$ for each $j \in [k]$.

Define an equivalence relation $\sim$ on the frequencies f_i by the transitive closure of the relation $f_i \sim f_j$ if $L_i \cap L_j \neq \emptyset$. Let $S_1, \ldots, S_n$ be the equivalence classes under this relation.

Define $C_i = \bigcup_{f \in S_i} L_i$ for each $i \in [n]$. We say C_i is a "heavy" cluster iff $\int_{C_i} |\widehat{H \cdot x^*}(f)|^2 \mathrm{d}f \geq T \cdot \mathcal{N}^2/k$.

By reordering C_i, we can assume $\{C_1, C_2, \cdots, C_l\}$ are heavy clusters, where $l \leq n \leq k$.

Claim 12.2.5. Given $x^*(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$ and any $\mathcal{N} > 0$, let H be the filter function defined in Section 12.12.1 and $C_1, \cdots, C_l$ be the heavy clusters from Definition 12.2.4. For

$$S = \left\{ j \in [k] \middle| f_j \in C_1 \cup \cdots C_l \right\},$$

we have $x^{(S)}(t) = \sum_{j \in S} v_j e^{2\pi \mathbf{i} f_j t}$ approximating x^* within distance $\|x^{(S)}(t) - x^*(t)\|_T^2 \lesssim \mathcal{N}^2$.

Proof. Let $x^{(\overline{S})}(t) = \sum_{j \in [k] \setminus S} v_j e^{2\pi \mathbf{i} f_j t}$. Notice that $\|x^* - x^{(S)}\|_T^2 = \|x^{(\overline{S})}\|_T^2$.

From the property VI of filter function $(H, \widehat{H})$ in Section 12.12.1, we have

$$\int_{-\infty}^{+\infty} |x^{(\overline{S})}(t) \cdot H(t)|^2 \mathrm{d}t \geq 0.9 \int_0^T |x^{(\overline{S})}(t)|^2 \mathrm{d}t = 0.9 \cdot T \|x^{\overline{S}}\|_T^2.$$

From Definition 12.2.4, we have

$$\begin{aligned}\int_{-\infty}^{+\infty} |x^{(\overline{S})}(t)\cdot H(t)|^2 \mathrm{d}t &= \int_{-\infty}^{+\infty} |\widehat{x^{(\overline{S})}\cdot H}(f)|^2 \mathrm{d}f \\ &= \int_{[-\infty,+\infty]\setminus C_1\cup\cdots\cup C_l} |\widehat{x^*\cdot H}(f)|^2 \mathrm{d}f \\ &\leq k\cdot T\mathcal{N}^2/k.\end{aligned}$$

Overall, we have $\|x^{(\overline{S})}\|_T^2 \lesssim \mathcal{N}^2$. □

From the guarantee of Theorem 12.2.6, for any $j\in S$, $\min_{i\in[l]}|f_j-\widetilde{f}_i|\leq \Delta\sqrt{\Delta T}$. From now on, we focus on the recovery of $x^{(S)}$, which is enough to approximate x^* from the above claim. Because we are looking for $\widetilde{x}$ approximating $x^{(S)}$ within distance $O(\mathcal{N}^2)$, from Lemma 12.2.1, we can assume there is a frequency gap $\eta\geq \frac{\delta}{10T}k^{-O(k^2)}$ among $x^{(S)}$.

12.9.3 Approximating clusters by polynomials

In this section, we show how to approximate $x^{(S)}$ by $x'(t) = \sum_{i\in[l]} e^{2\pi \mathbf{i}\widetilde{f}_i t} P_i(t)$ where $P_1, \cdots, P_l$ are low degree polynomials.

Claim 12.9.2. *For any $x^{(S)}(t) = \sum_{j\in S} v_j e^{2\pi \mathbf{i} f_j t}$ with a frequency gap $\eta = \min_{i\neq j}|f_i - f_j|$ and l frequencies $\widetilde{f}_1, \cdots, \widetilde{f}_l$ with the property $\forall j \in S, \min_{i\in[l]} |f_j - \widetilde{f}_i| \leq \Delta\sqrt{\Delta T}$, let*

$$d = 5\pi\left((T\Delta)^{1.5} + k^3 \log k + \log 1/\delta\right) \text{ and } V = \left\{t^j e^{2\pi \mathbf{i}\widetilde{f}_i t} | i \in [l], j \in \{0, \cdots, d\}\right\}.$$

There exists $x'(t) \in \text{span}\{V\}$ that approximates $x^{(S)}(t)$ as follows:

$$\forall t \in [0, T], |x'(t) - x^{(S)}(t)| \leq \delta \|x^{(S)}\|_T.$$

Proof. From Lemma 12.2.2, we know

$$\|x^{(S)}\|_T^2 \geq (\eta T)^{2k} \cdot k^{-ck^2} \sum_{j\in S} |v_j|^2.$$

For each frequency f_j, we use p_j to denote the index in $[l]$ such that $|f_j - \widetilde{f}_{p_j}| \leq \Delta\sqrt{\Delta T}$. We rewrite

$$x^{(S)}(t) = \sum_{i=1}^{l} e^{2\pi \mathbf{i}\widetilde{f}_i} \left(\sum_{j\in S: p_j = i} v_j e^{2\pi \mathbf{i}(f_j - \widetilde{f}_i)t}\right).$$

For $d = 5\pi((T\Delta)^{1.5} + k^3 \log k + \log 1/\delta)$ and each $e^{2\pi \mathbf{i}(f_j - \widetilde{f}_{p_j})t}$, let $Q_j(t) = \sum_{i=0}^{d-1} \frac{\left(2\pi \mathbf{i}(f_j - \widetilde{f}_{p_j})t\right)^i}{i!}$ be the first d terms in the Taylor Expansion of $e^{2\pi \mathbf{i}(f_j - \widetilde{f}_{p_j})t}$. For any $t \in [0, T]$, we know the difference between $Q_j(t)$ and $e^{2\pi \mathbf{i}(f_j - \widetilde{f}_{p_j})t}$ is at most

$$\forall t \in [0, T], |Q_j(t) - e^{2\pi \mathbf{i}(f_j - \widetilde{f}_{p_j})t}| \leq |\frac{(2\pi \mathbf{i}(f_j - \widetilde{f}_{p_j})T)^d}{d!}| \leq (\frac{8\pi(\Delta T)^{1.5}}{d})^d.$$

Let $x' = \sum_{i=1}^{l} e^{2\pi \mathbf{i} \widetilde{f}_i t} \left(\sum_{j \in S: p_j = i} v_j Q_j(t) \right)$. From all discussion above, we know for any $t \in [0, T]$,

$$\begin{aligned} |x'(t) - x^{(S)}(t)|^2 &\leq \left(\sum_{j \in S} |v_j| (\frac{8\pi (T\Delta)^{1.5}}{d})^d \right)^2 \\ &\leq k (\frac{8\pi (T\Delta)^{1.5}}{d})^{2d} \sum_j |v_j|^2 \\ &\leq \frac{k (\frac{8\pi (T\Delta)^{1.5}}{d})^{2d}}{(\eta T)^{2k} \cdot k^{-ck^2}} \|x^{(S)}\|_T^2 \\ &\leq \delta^2 \|x^{(S)}\|_T^2. \end{aligned}$$

□

We provide a property of functions in span$\{V\}$ such that we can use the Chernoff bound and the ϵ-net argument on vectors in span$\{V\}$.

Claim 12.2.7. For any $\vec{u} \in \text{span} \left\{ e^{2\pi \mathbf{i} \widetilde{f}_i t} \cdot t^j \middle| j \in \{0, \cdots, d\}, i \in [l] \right\}$, there exists some universal constants $C_1 \leq 4$ and $C_2 \leq 3$ such that

$$\max_{t \in [0,T]} \{|\vec{u}(t)|^2\} \lesssim (ld)^{C_1} \log^{C_2}(ld) \cdot \|\vec{u}\|_T^2$$

Proof. From Lemma 12.8.7, we can approximate each polynomial in $\vec{u}$ by a linear combination of $\{1, e^{2\pi \mathbf{i} \cdot \gamma t}, \cdots, e^{2\pi \mathbf{i} \cdot (\gamma d) t}\}$ such that we obtain $u^* \in \text{span} \left\{ e^{2\pi \mathbf{i} \cdot (\gamma j) t} \cdot e^{2\pi \mathbf{i} \widetilde{f}_i t} | i \in [l], j \in \{0, \cdots, d+1\} \right\}$ for some small γ such that $\forall t \in [0, T], |\vec{u}(t) - u^*(t)| \leq 0.01 \|\vec{u}\|_T$.

From Lemma 12.5.1, we know

$$\max_{t \in [0,T]} |u^*(t)|^2 \leq C \cdot \left((ld+1)^4 \cdot \log^3(ld+1) \right) \|u^*\|_T^2.$$

For some constant C', we have

$$\max_{t\in[0,T]} |\vec{u}(t)|^2 \leq C' \left((kd)^{C_1} \log^{C_2} d\right) \|\vec{u}\|_T^2.$$

□

12.9.4 Main result, with constant success probability

In this section, we show that the output $\widetilde{x}$ is close to x' with high probability using the ϵ-net argument, which is enough to prove $\|\widetilde{x}-x\|_T \lesssim \mathcal{N}^2$ from all discussion above. Because we can prove Lemma 12.9.6(which is the main goal of this section), then combining $\|x'-x^*\|_T \leq \|x'-x^{(S)}\|_T + \|x^{(S)}-x^*\|_T \lesssim \delta\|x^*\|_T$ and Lemma 12.9.6, we have $\|x^*-\widetilde{x}\|_T \lesssim \|g\|_T + \delta\|x^*\|_T$, which finishes the proof of Procedure SignalRecoveryKCluster in Algorithm 12.8 achieving the Equation (12.26) with constant success probability but not $1-2^{-\Omega(k)}$. We will boost the success probability in Section 12.9.5.

We first provide an ϵ-net $\mathcal{P}$ for the unit vectors $\mathcal{Q} = \{\vec{u} \in \mathrm{span}\{V\} \big| \|\vec{u}\|_T^2 = 1\}$ in the linear subspace $\mathrm{span}\{V\}$ where $V = \left\{ t^j \cdot e^{2\pi \mathbf{i} \widetilde{f}_i t} \big| j \in \{0,1,\cdots,d\}, i \in [l] \right\}$ from the above discussion. Notice that the dimension of $\mathrm{span}\{V\}$ is at most $l(d+1)$.

Claim 12.9.3. *There exists an ϵ-net $\mathcal{P} \subset \mathrm{span}\{V\}$ such that*

1. $\forall \vec{u} \in Q, \exists \vec{w} \in \mathcal{P}, \|\vec{u}-\vec{w}\|_T \leq \epsilon$.
2. $|\mathcal{P}| \leq \left(5\frac{l(d+1)}{\epsilon}\right)^{2l(d+1)}$.

Proof. Let $\mathcal{P}'$ be an $\frac{\epsilon}{l(d+1)}$-net in the unit circle of $\mathbb{C}$ with size at most $(4\frac{l(d+1)}{\epsilon}+1)^2$, i.e.,

$$\mathcal{P}' = \left\{ \frac{\epsilon}{2l(d+1)} j_1 + \mathbf{i}\frac{\epsilon}{2l(d+1)} j_2 \Big| j_1, j_2 \in \mathbb{Z}, |j_1| \leq \frac{2l(d+1)}{\epsilon}, |j_2| \leq \frac{2l(d+1)}{\epsilon} \right\}.$$

Observe that the dimension of $\mathrm{span}\{V\}$ is at most $l(d+1)$. Then we take an orthogonal basis $\vec{w}_1, \cdots, \vec{w}_{l(d+1)}$ in $\mathrm{span}\{V\}$ and set

$$P = \{ \sum_{i=1}^{l(d+1)} \alpha_i \vec{w}_i \big| \forall i \in [l(d+1)], \alpha_i \in \mathcal{P}' \}.$$

Therefore $\mathcal{P}$ is an ϵ-net for Q and $|\mathcal{P}| \leq \left(5\frac{l(d+1)}{\epsilon}\right)^{2l(d+1)}$. □

We first prove that W is a good estimation for all functions in the ϵ-net $\mathcal{P}$.

Claim 12.9.4. *For any $\epsilon > 0$, there exists a universal constant $C_3 \leq 5$ such that for a set S of i.i.d. samples chosen uniformly at random over $[0, T]$ of size $|S| \geq \frac{3(kd)^{C_3}\log^{C_3} d/\epsilon}{\epsilon^2}$,then with probability at least $1 - k^{-k}$, for all $\vec{w} \in \mathcal{P}$, we have*

$$\|\vec{w}\|_W \in \left[(1-\epsilon)\|\vec{w}\|_T, (1+\epsilon)\|\vec{w}\|_T\right].$$

Proof. From Claim 12.2.7 and Lemma 12.3.5, for each $\vec{w} \in \mathcal{P}$,

$$\Pr\left[\|\vec{w}(t)\|_W \notin \left[(1-\epsilon)\|\vec{w}\|_T, (1+\epsilon)\|\vec{w}\|_T\right]\right] \leq 2^{-\frac{|W|\epsilon^2}{3(kd)^{C_1}\log^{C_2+0.5} d}} \leq 2^{-kd\log^{1.5}\frac{d}{\epsilon}}.$$

From the union bound, $\|\vec{w}\|_W \in [(1-\epsilon)\|\vec{w}\|_T, (1+\epsilon)\|\vec{w}\|_T]$ for any $\vec{w} \in \mathcal{P}$ with probability at least $1 - (\frac{d}{\epsilon})^{-kd\log^{0.5} d} \cdot |\mathcal{P}| \geq 1 - d^{-d}$. □

Then We prove that W is a good estimation for all functions in $\text{span}\{V\}$ using the property of ϵ-nets.

Claim 12.9.5. *For any $\epsilon > 0$, there exists a universal constant $C_3 \leq 5$ such that for a set W of i.i.d. samples chosen uniformly at random over $[0, T]$ of size $|W| \geq \frac{3(kd)^{C_3}\log^{C_3} d/\epsilon}{\epsilon^2}$,then with probability at least $1 - d^{-d}$, for all $u \in \text{span}\{V\}$, we have*

$$\|\vec{u}\|_W \in \left[(1-3\epsilon)\|\vec{u}\|_T, (1+3\epsilon)\|\vec{u}\|_T\right]$$

Proof. We assume that the above claim is true for any $\vec{w} \in \mathcal{P}$. Without loss of generality, we consider $\vec{u} \in \Omega$ such that $\|\vec{u}\|_T = 1$.

Let $\vec{w}_0$ be the vector in $\mathcal{P}$ that minimizes $\|\vec{w}-\vec{u}\|_T$ for all $\vec{w} \in \mathcal{P}$, i.e., $\vec{w}_0 = \arg\min_{\vec{w}\in\mathcal{P}} \|\vec{w}-\vec{u}\|_T$. Define $\vec{u}_1 = \vec{u} - \vec{w}_0$ and notice that $\|\vec{u}_1\|_T \leq \epsilon$ because $\mathcal{P}$ is a ϵ-net. If $\|\vec{u}_1\|_T = 0$, then we skip the rest of this procedure. Otherwise, we define $\alpha_1 = \|\vec{u}_1\|_T$ and normalize $\widetilde{u}_1 = \vec{u}_1/\alpha_1$.

Then we choose $\vec{w}_1$ to be the vector in $\mathcal{P}$ that minimizes $\|\vec{w} - \widetilde{u}_1\|_T$ for all $\vec{w} \in \mathcal{P}$. Similarly, we set $\vec{u}_2 = \widetilde{u}_1 - \vec{w}_1$ and $\alpha_2 = \|\vec{u}_2\|_T$. Next we repeat this process for $\widetilde{u}_2 = \vec{u}_2/\alpha_2$ and so on. The recursive definition can be summarized in the following sense,

$$
\begin{aligned}
\text{initial}: \quad & \widetilde{u}_0 = \vec{u} \text{ and } m = 10\log_{1/\epsilon}(ld) + 1, \\
\text{For } i \in \{0,1,2,\cdots,m\}: \quad & \vec{w}_i = \arg\min_{\vec{w}\in\mathcal{P}} \|\vec{w} - \widetilde{u}_i\|_T, \\
& \vec{u}_{i+1} = \widetilde{u}_i - \vec{w}_i \text{ and } \alpha_{i+1} = \|\vec{u}_{i+1}\|_T, \\
& \text{if } \alpha_{i+1} = 0, \text{ stop.} \\
& \text{if } \alpha_{i+1} \neq 0, \widetilde{u}_{i+1} = \vec{u}_{i+1}/\alpha_{i+1} \text{ and continue,}
\end{aligned}
$$

Eventually, we have $\vec{u} = \vec{w}_0 + \alpha_1\vec{w}_1 + \alpha_1\alpha_2\vec{w}_2 + \cdots + \prod_{j=1}^{m}\alpha_j(\vec{w}_m + \vec{u}_{m+1})$ where each $|\alpha_i| \leq \epsilon$ and each $\vec{w}_i$ is in the ϵ-net $\mathcal{P}$. Notice that $\|\vec{u}_{m+1}\|_T \leq 1$ and $\|\vec{u}_{m+1}\|_W \leq (ld+1)^3 \cdot \|\vec{u}_{m+1}\|_T$ from Claim 12.2.7. We prove a lower bound for $\|\vec{u}\|_W$,

$$
\begin{aligned}
\|\vec{u}\|_W &= \|\vec{w}_0 + \alpha_1\vec{w}_1 + \alpha_1\alpha_2\vec{w}_2 + \cdots + \prod_{j=1}^{m}\alpha_j(\vec{w}_m + \vec{u}_{m+1})\|_W \\
&\geq \|\vec{w}_0\|_W - \|\alpha_1\vec{w}_1\|_W - \|\alpha_1\alpha_2\vec{w}_2\|_W - \cdots - \|\prod_{j=1}^{m}\alpha_j\vec{w}_m\|_W - \|\prod_{j=1}^{m}\alpha_j\vec{u}_{m+1}\|_W \\
&\geq (1-\epsilon) - \epsilon(1+\epsilon) - \epsilon^2(1+\epsilon) - \cdots - \epsilon^m(1+\epsilon) - \epsilon^m\|\vec{u}_{m+1}\|_W \\
&\geq 1 - \epsilon - \frac{(1+\epsilon)\epsilon}{1-\epsilon} - \epsilon^m \cdot (ld+1)^3 \geq 1 - 3\epsilon.
\end{aligned}
$$

Similarly, we have $\|\vec{u}\|_W \leq 1 + 3\epsilon$. □

Lemma 12.9.6. *With probability at least* 0.99 *over the* m *i.i.d samples in* W*,*

$$\|x'(t) - \widetilde{x}(t)\|_T \leq 2200 \left(\|g(t)\|_T + \|x^{(S)}(t) - x'(t)\|_T \right).$$

Proof. Let $g'(t) = g(t) + x^*(t) - x'(t)$ such that $x(t) = x'(t) + g'(t)$. Then we choose $\epsilon = 0.03$ and bound:

$$\begin{aligned}
&\|x'(t) - \widetilde{x}(t)\|_T \\
&\leq (1+3\epsilon)\|x'(t) - \widetilde{x}(t)\|_W && \text{with prob. } 1 - 2^{-\Omega(d \log d)} \text{ by Claim 12.9.5} \\
&= 1.09\|x'(t) - \widetilde{x}(t)\|_W && \text{by } \epsilon = 0.03 \\
&= 1.09\|x(t) - g'(t) - \widetilde{x}(t)\|_W && \text{by } x'(t) = x(t) - g'(t) \\
&\leq 1.09\|x(t) - \widetilde{x}(t)\|_W + 1.09\|g'(t)\|_W && \text{by triangle inequality} \\
&\leq 1.09\|x(t) - x'(t)\|_W + 1.09\|g'(t)\|_W && \text{by } \widetilde{x} = \operatorname*{arg\,min}_{y \in \text{span}\{V\}} \|x - y\|_W \\
&= 2.18\|g'(t)\|_W. && \text{by } x(t) - x'(t) = g(t)
\end{aligned}$$

From the fact that $\mathbb{E}_W[\|g'\|_W] = \|g'\|_T$, $\|g'\|_W \leq 1000\|g'\|_T$ with probability at least .999. It indicates $\|x'(t) - \widetilde{x}(t)\|_T \leq 2200\|g'\|_T$ with probability at least 0.99 from all discussion above. □

12.9.5 Boosting the success probability

In order to achieve $1 - 2^{-\Omega(k)}$ for the main theorem, we cannot combine Procedure SignalRecoveryKCluster with FrequencyRecoveryKCluster directly. However, using the similar proof technique in Theorem 12.4.5, we are able to boost the success probability by using Procedure SignalRecoveryKCluster$^+$ in Algorithm 12.8. It runs Procedure SignalRecoveryKCluster $R = O(k)$ times in parallel for independent fresh samples and report R different d-Fourier-sparse signals $\widetilde{x}_i(t)$. Then, taking $m = \mathrm{poly}(k)$ new locations $\{t_1, t_2, \cdots, t_m\}$, and computing $\widetilde{A}$ as before and $\widetilde{b}_j$ by taking the median of $\{\widetilde{x}_1(t_j), \cdots, \widetilde{x}_R(t_j)\}$. At the end, solving the linear regression for matrix $\widetilde{A}$ and vector $\widetilde{b}$. Thus, we complete the proof of Lemma 12.9.1.

Because we can transfer a degree-d polynomial to a d-Fourier-sparse signal by Lemma 12.8.7, the output of Procedure CFTKCluster in Algorithm 12.8 matches the main theorem,

Theorem 12.1.1. Let $x(t) = x^*(t) + g(t)$, where x^* is k-Fourier-sparse signal with frequencies in $[-F, F]$. Given samples of x over $[0, T]$ we can output $\widetilde{x}(t)$ such that with probability at least $1 - 2^{-\Omega(k)}$,

$$\|\widetilde{x} - x^*\|_T \lesssim \|g\|_T + \delta \|x^*\|_T .$$

Our algorithm uses $\mathrm{poly}(k, \log(1/\delta)) \cdot \log(FT)$ samples and $\mathrm{poly}(k, \log(1/\delta)) \cdot \log^2(FT)$ time. The output $\widetilde{x}$ is $\mathrm{poly}(k, \log(1/\delta))$-Fourier-sparse signal.

12.10 Technical Proofs

12.10.1 Proof of Theorem 12.8.2

We prove the following Theorem

Theorem 12.8.2. For real numbers $\xi_1, \ldots, \xi_k$, let $G_{\xi_1,\ldots,\xi_k}$ be the matrix whose (i,j)-entry is

$$\int_{-1}^{1} e^{2\pi \mathbf{i}(\xi_i - \xi_j)t} dt.$$

Then

$$\det(G_{\xi_1,\ldots,\xi_k}) = 2^{\widetilde{O}(k^2)} \prod_{i<j} \min(|\xi_i - \xi_j|^2, 1).$$

First, we note by the Cauchy-Binet formula that the determinant in question is equal to

$$\int_{-1}^{1}\int_{-1}^{1}\ldots\int_{-1}^{1} \left|\det([e^{2\pi i \xi_i t_j}]_{i,j})\right|^2 dt_1 dt_2 \ldots dt_k. \tag{12.27}$$

We next need to consider the integrand in the special case when $\sum |\xi_i| \leq 1/8$.

Lemma 12.10.1. *If $\xi_i \in R$ and $t_j \in \mathbb{R}$, $\sum_i |\xi_i|(\max_i |t_i|) \leq 1/8$ then*

$$|\det([e^{2\pi i \xi_i t_j}]_{i,j})| = \Theta\left(\frac{(2\pi)^{\binom{k}{2}} \prod_{i<j} |t_i - t_j||\xi_i - \xi_j|}{1!2!\cdots k!}\right).$$

Proof. Firstly, by adding a constant to all the t_j we can make them non-negative. This multiplies the determinant by a root of unity, and at most doubles $\sum_i |\xi_i|(\max_i |t_i|)$.

By continuity, it suffices to consider the t_i to all be multiples of $1/N$ for some large integer N. By multiplying all the t_j by N and all ξ_i by $1/N$, we may assume that all of the t_j are non-negative integers with $t_1 \leq t_2 \leq \ldots \leq t_k$.

Let $z_i = \exp(2\pi i \xi_i)$. Then our determinant is

$$\det\left(\left[z_i^{t_j}\right]_{i,j}\right),$$

which is equal to the Vandermonde determinant times the Schur polynomial $s_\lambda(z_i)$ where λ is the partition $\lambda_j = t_j - (j-1)$.

Therefore, this determinant equals

$$\prod_{i<j}(z_i - z_j) s_\lambda(z_1, z_2, \ldots, z_k).$$

The absolute value of

$$\prod_{i<j}(z_i - z_j)$$

is approximately $\prod_{i<j}(2\pi i)(\xi_i - \xi_j)$, which has absolute value $(2\pi)^{\binom{k}{2}} \prod_{i<j} |\xi_i - \xi_j|$. We have left to evaluate the size of the Schur polynomial.

By standard results, s_λ is a polynomial in the z_i with non-negative coefficients, and all exponents at most $\max_j |t_j|$ in each variable. Therefore, the monomials with non-zero coefficients will all have real part at least $1/2$ and absolute value 1 when evaluated at the z_i. Therefore,

$$|s_\lambda(z_1, \ldots, z_k)| = \Theta(|s_\lambda(1, 1, \ldots, 1)|).$$

On the other hand, by the Weyl character formula

$$s_\lambda(1, 1, \ldots, 1) = \prod_{i<j} \frac{t_j - t_i}{j - i} = \frac{\prod_{i<j} |t_i - t_j|}{1!2!\ldots k!}.$$

This completes the proof. □

Next we prove our Theorem when the ξ have small total variation.

Lemma 12.10.2. *If there exists a ξ_0 so that $\sum |\xi_i - \xi_0| < 1/8$, then*

$$\det(G_{\xi_1,\ldots,\xi_k}) = \Theta\left(\frac{2^{3k(k-1)/2}\pi^{k(k-1)}\prod_{i<j}|\xi_i - \xi_j|^2}{(k!)^3\prod_{n=0}^{k-1}(2n)!}\right).$$

Proof. By translating the ξ_i we can assume that $\xi_0 = 0$.

By the above we have

$$\Theta(\frac{(2\pi)^{k(k-1)}\prod_{i<j}|\xi_i - \xi_j|^2}{(1!2!\cdots k!)^2})\int_{-1}^{1}\cdots\int_{-1}^{1}\prod_{i<j}|t_i - t_j|^2 dt_1\ldots dt_k.$$

We note that by the Cauchy-Binet formula the latter term is the determinant of the matrix M with $M_{i,j} = \int_{-1}^{1} t^{i+j}dt$. This is the Graham matrix associated to the polynomials t^i for $0 \leq i \leq k-1$. Applying Graham-Schmidt (without the renormalization step) to this set yields the basis $P_n\alpha_n$ where $\alpha_n = \frac{2^n(n!)^2}{(2n)!}$ is the inverse of the leading term of P_n. This polynomial has norm $\alpha_n^2 2/(2n+1)$. Therefore, the integral over the t_i yields

$$\prod_{n=0}^{k-1}\frac{2^{n+1}(n!)^2}{(n+1)(2n)!}.$$

This completes the proof. □

Next we extend this result to the case that all the ξ are within poly(k) of each other.

Proposition 12.10.3. *If there exists a ξ_0 so that $|\xi_i - \xi_0| = \text{poly}(k)$ for all i, then*

$$\det(G_{\xi_1,\ldots,\xi_k}) = 2^{\widetilde{O}(k^2)}\prod_{i<j}\min(|\xi_i - \xi_j|^2, 1).$$

Proof. We begin by proving the lower bound. We note that for $0 < x < 1$,

$$\det(G_{\xi_1,\ldots,\xi_k}) \geq \int_{-x}^{x}\int_{-x}^{x}\cdots\int_{-1}^{1}\left|\det([e^{2\pi i\xi_i t_j}]_{i,j})\right|^2 dt_1 dt_2\ldots dt_k = x^k\det(G_{\xi_1/x,\xi_2/x,\ldots,\xi_k/k}).$$

Taking $x = 1/\operatorname{poly}(k)$, we may apply the above Lemma to compute the determinant on the right hand side, yielding an appropriate lower bound.

To prove the lower bound, we note that we can divide our ξ_i into clusters, $\mathcal{C}_i$, where for any i, j in the same cluster $|\xi_i - \xi_j| < 1/k$ and for i and j in different clusters $|\xi_i - \xi_j| \geq 1/k^2$. We then note as a property of Graham matrices that

$$\det(G_{\xi_1,\ldots,\xi_k}) \leq \prod_{\mathcal{C}_i} \det(G_{\{\xi_j \in \mathcal{C}_i\}}) = 2^{\widetilde{O}(k^2)} \prod_{i<j, \text{ in same cluster}} |\xi_i - \xi_j|^2 = 2^{\widetilde{O}(k^2)} \prod_{i<j} |\xi_i - \xi_j|^2.$$

This completes the proof. □

Finally, we are ready to prove our Theorem.

Proof. Let $I(t)$ be the indicator function of the interval $[-1, 1]$.

Recall that there is a function $h(t)$ so that for any function f that is a linear combination of at most k complex exponentials that $|h(t)f(t)|_2 = \Theta(|I(t)f(t)|_2)$ and so that $\widehat{h}$ is supported on an interval of length $\operatorname{poly}(k) < k^C$ about the origin.

Note that we can divide our ξ_i into clusters, $\mathcal{C}$, so that for i and j in a cluster $|\xi_i - \xi_j| < k^{C+1}$ and for i and j in different clusters $|\xi_i - \xi_j| > k^C$.

Let $\widetilde{G}_{\xi_1,\xi_2,\ldots,\xi'_k}$ be the matrix with (i,j)-entry $\int_{\mathbb{R}} |h(t)|^2 e^{(2\pi i)(\xi_i - \xi_j)t} dt$.

We claim that for any $k' \leq k$ that

$$\det(\widetilde{G}_{\xi_1,\xi_2,\ldots,\xi'_k}) = 2^{O(k')} \det(G_{\xi_1,\xi_2,\ldots,\xi'_k}).$$

This is because both are Graham determinants, one for the set of functions $I(t)\exp((2\pi i)\xi_j t)$ and the other for $h(t)\exp((2\pi i)\xi_j t)$. However since any linear combination of the former has

L^2 norm a constant multiple of that the same linear combination of the latter, we have that

$$\widetilde{G}_{\xi_1,\xi_2,\ldots,\xi_k'} = \Theta(G_{\xi_1,\xi_2,\ldots,\xi_k'})$$

as self-adjoint matrices. This implies the appropriate bound.

Therefore, we have that

$$\det(G_{\xi_1,\ldots,\xi_k}) = 2^{O(k)} \det(\widetilde{G}_{\xi_1,\ldots,\xi_k}).$$

However, note that by the Fourier support of h that

$$\int_{\mathbb{R}} |h(t)|^2 e^{(2\pi i)(\xi_i - \xi_j)t} dt = 0$$

if $|\xi_i - \xi_j| > k^C$, which happens if i and j are in different clusters. Therefore $\widetilde{G}$ is block diagonal and hence its determinant equals

$$\det(\widetilde{G}_{\xi_1,\ldots,\xi_k}) = \prod_{\mathfrak{C}} \det(\widetilde{G}_{\{\xi_j \in \mathfrak{C}_i\}}) = 2^{O(k)} \prod_{\mathfrak{C}} \det(G_{\{\xi_j \in \mathfrak{C}_i\}}).$$

However the Proposition above shows that

$$\prod_{\mathfrak{C}} \det(G_{\{\xi_j \in \mathfrak{C}_i\}}) = 2^{\widetilde{O}(k^2)} \prod_{i<j} \min(1, |\xi_i - \xi_j|^2).$$

This completes the proof. □

12.10.2 Proofs of Lemma 12.5.3 and Lemma 12.5.4

We fix $z_1, \cdots, z_k$ to be complex numbers on the unit circle and use $Q(z)$ to denote the degree-k polynomial $\prod_{i=1}^{k}(z - z_i)$.

Lemma 12.5.3. Let $Q(z)$ be a degree k polynomial, all of whose roots are complex numbers with absolute value 1. For any integer n, let $r_{n,k}(z) = \sum_{l=0}^{k-1} r_{n,k}^{(l)} \cdot z^l$ denote the residual polynomial of

$$r_{n,k}(z) \equiv z^n \pmod{Q(z)}.$$

Then, each coefficient of $r_{n,k}$ is bounded: $|r_{n,k}^{(l)}| \leq 2^k n^{k-1}$ for any l.

Proof. By definition, $r_{n,k}(z_i) = z_i^n$. From the polynomial interpolation, we have

$$r_{n,k}(z) = \sum_{i=1}^{k} \frac{\prod_{j \in [k] \setminus i}(z - z_j) z_i^n}{\prod_{j \in [k] \setminus i}(z_i - z_j)}.$$

Let $\mathrm{Sym}_{S,i}$ be the symmetry polynomial of $z_1, \cdots, z_k$ with degree i among subset $S \subseteq [k]$, i.e., $\mathrm{Sym}_{S,i} = \sum_{S' \subseteq \binom{S}{i}} \prod_{j \in S'} z_j$. Then

$$r_{n,k}^{(l)} = (-1)^{k-1-l} \sum_{i=1}^{k} \frac{\mathrm{Sym}_{[k] \setminus i, k-1-l} \cdot z_i^n}{\prod_{j \in [k] \setminus i}(z_i - z_j)}.$$

We omit $(-1)^{k-1-l}$ in the rest of proof and use induction on n, k, and l to prove $|r_{n,k}^{(l)}| \leq \binom{k-1}{l}\binom{n}{k-1}$.

Base Case of n: For any $n < k$, from the definition, $r(z) = z^n$ and $|r_{n,k}^{(l)}| \leq 1$.

Suppose it is true for any $n < n_0$. We consider $r_{n_0,k}^{l}$ from now on. When $k = 1$, $r_{n,0} = z_1^n$ is bounded by 1 because z_1 is on the unit circle of $\mathbb{C}$.

Given n_0, suppose the induction hypothesis is true for any $k < k_0$ and any $l < k$. For $k = k_0$, we first prove that $|r^{(k_0-1)}_{n_0,k_0}| \leq \binom{n_0}{k_0-1}$ then prove that $|r^{(l)}_{n_0,k_0}| \leq \binom{k_0-1}{l}\binom{n_0}{k_0-1}$ for $l = k_0 - 2, \cdots, 0$.

$$
\begin{aligned}
r^{(k_0-1)}_{n_0,k_0} &= \sum_{i=1}^{k_0} \frac{z_i^{n_0}}{\prod\limits_{j\in[k_0]\setminus i}(z_i - z_j)} \\
&= \sum_{i=1}^{k_0-1} \frac{z_i^{n_0}}{\prod\limits_{j\in[k_0]\setminus i}(z_i - z_j)} + \frac{z_{k_0}^{n_0}}{\prod\limits_{j\in[k_0]\setminus k_0}(z_{k_0} - z_j)} \\
&= \sum_{i=1}^{k_0-1} \frac{z_i^{n_0} - z_i^{n_0-1}z_{k_0} + z_i^{n_0-1}z_{k_0}}{\prod\limits_{j\in[k_0]\setminus i}(z_i - z_j)} + \frac{z_{k_0}^{n_0}}{\prod\limits_{j\in k_0\setminus k_0}(z_{k_0} - z_j)} \\
&= \sum_{i=1}^{k_0-1} \left(\frac{z_i^{n_0-1}}{\prod\limits_{j\in[k_0-1]\setminus i}(z_i - z_j)} + \frac{z_i^{n_0-1}z_{k_0}}{\prod\limits_{j\in k_0\setminus i}(z_i - z_j)} \right) + \frac{z_{k_0}^{n_0}}{\prod\limits_{j\in k_0\setminus k_0}(z_{k_0} - z_j)} \\
&= \left(\sum_{i=1}^{k_0-1} \frac{z_i^{n_0-1}}{\prod\limits_{j\in[k_0-1]\setminus i}(z_i - z_j)} \right) + \left(z_{k_0} \sum_{i=1}^{k_0} \frac{z_i^{n_0-1}}{\prod\limits_{j\in k_0\setminus i}(z_i - z_j)} \right) \\
&= r^{(k_0-2)}_{n_0-1,k_0-1} + z_{k_0} \cdot r^{(k_0-1)}_{n_0-1,k_0}
\end{aligned}
$$

Hence $|r^{(k_0-1)}_{n_0,k_0}| \le |r^{(k_0-2)}_{n_0-1,[k_0-1]}| + |r^{(k_0-1)}_{n_0-1,k_0}| \le \binom{n_0-2}{k_0-2} + \binom{n_0-2}{k_0-1} = \binom{n_0-1}{k_0-1}$. For $l < k_0 - 1$, we have

$$\begin{aligned}
r^{(l)}_{n_0,k_0} &= \sum_{i=1}^{k_0} \frac{\mathrm{Sym}_{[k_0]\setminus i,k_0-1-l} \cdot z_i^{n_0}}{\prod\limits_{j\in[k_0]\setminus i}(z_i - z_j)} \quad \text{let } l' = k_0 - 1 - l \\
&= \sum_{i=1}^{k_0-1} \frac{\left(\mathrm{Sym}_{[k_0-1]\setminus i,l'} + \mathrm{Sym}_{[k_0-1]\setminus i,l'-1} \cdot z_{k_0}\right) z_i^{n_0}}{\prod\limits_{j\in[k_0]\setminus i}(z_i - z_j)} + \frac{\mathrm{Sym}_{[k_0-1],l'} \cdot z_{k_0}^{n_0}}{\prod\limits_{j<k_0}(z_{k_0} - z_j)} \\
&= \sum_{i=1}^{k_0-1} \frac{\mathrm{Sym}_{[k_0-1]\setminus i,l'} \cdot (z_i - z_{k_0}) z_i^{n_0-1} + \mathrm{Sym}_{[k_0-1]\setminus i,l'} \cdot z_{k_0} z_i^{n_0-1} + \mathrm{Sym}_{[k_0-1]\setminus i,l'-1} \cdot z_{k_0} z_i^{n_0}}{\prod\limits_{j\in[k_0]\setminus i}(z_i - z_j)} \\
&\quad + \frac{\mathrm{Sym}_{[k_0-1],l'} \cdot z_{k_0}^{n_0}}{\prod\limits_{j<k_0}(z_{k_0} - z_j)} \\
&= \sum_{i=1}^{k_0-1} \frac{\mathrm{Sym}_{[k_0-1]\setminus i,l'} \cdot (z_i - z_{k_0}) z_i^{n_0-1} + \mathrm{Sym}_{[k_0-1],l'} \cdot z_{k_0} z_i^{n_0-1}}{\prod\limits_{j\in[k_0]\setminus i}(z_i - z_j)} + \frac{\mathrm{Sym}_{[k_0-1],l'} \cdot z_{k_0}^{n_0}}{\prod\limits_{j<k_0}(z_{k_0} - z_j)} \\
&= \sum_{i=1}^{k_0-1} \frac{\mathrm{Sym}_{[k_0-1]\setminus i,l'} \, z_i^{n_0-1}}{\prod\limits_{j\in[k_0-1]\setminus i}(z_i - z_j)} + \sum_{i=1}^{k_0-1} \frac{\mathrm{Sym}_{[k_0-1],l'} \cdot z_{k_0} z_i^{n_0-1}}{\prod\limits_{j\in[k_0]\setminus i}(z_i - z_j)} + \frac{\mathrm{Sym}_{[k_0-1],l'} \cdot z_{k_0}^{n_0}}{\prod\limits_{j<k_0}(z_{k_0} - z_j)} \\
&= r^{(l-1)}_{n_0-1,k_0-1} + \mathrm{Sym}_{[k_0-1],k_0-1-l} \cdot z_{k_0} \cdot r^{(k_0-1)}_{n_0-1,k_0}
\end{aligned}$$

By induction hypothesis, $|r^{(l)}_{n_0,k_0}| \le \binom{k_0-2}{l-1}\binom{n_0-1}{k_0-2} + \binom{k_0-1}{l}\binom{n_0-1}{k_0-1} \le \binom{k_0-1}{l}\binom{n_0}{k_0-1}$. □

Now we finish the proof of Lemma 12.5.4.

Lemma 12.5.4. For any $k \in \mathbb{Z}$ and any $z_1, \cdots, z_k$ on the unit circle of $\mathbb{C}$, there always exists a degree $m = O(k^2 \log k)$ polynomial $P(z) = \sum\limits_{j=0}^{m} c_j z^j$ with the following properties:

$$\begin{aligned}
&\text{Property I} && P(z_i) = 0, \forall i \in \{1, \cdots, k\}, \\
&\text{Property II} && c_0 = 1, \\
&\text{Property III} && |c_j| \le 11, \forall j \in \{1, \cdots, m\}.
\end{aligned}$$

Let $m = 10k^2 \log k$ and $\mathcal{P}$ denote a set of polynomials that has degree at most m, and all the coefficients are integers chosen from $\{-5, \cdots, -1, 0, 1, \cdots, 5\}$, i.e.,

$$\mathcal{P} := \left\{ P(z) = \sum_{i=0}^{m} \alpha_i z^i \mid \forall i \in \{0, 1, \cdots, m\}, |\alpha_i| \leq 2 \right\}.$$

Claim 12.10.4. *There exists $P^*(z) = \sum_{i=0}^{m} \alpha_i z^i$ with coefficient $|\alpha_i| \leq 10$ for any $i \in \{0, 1, \cdots, m\}$, such that every coefficient of $P^*(z) \mod Q(z)$ is bounded by 2^{-m}.*

Proof. For $P(z) = \sum_{i=0}^{m} \alpha_i z^i \in \mathcal{P}$, $P(z) \mod Q(z) \equiv \sum_{i=0}^{m} \alpha_i r_{n,k}(z)$ from the definition $r_{n,k}(z)$. Hence

$$P(z) \mod Q(z) = \sum_{i=0}^{m} \alpha_i \sum_{l=0}^{k-1} r_{i,k}^{(l)} z^l = \sum_{l=0}^{k-1} z^l \sum_{i=0}^{m} \alpha_i r_{i,k}^{(l)}.$$

Each coefficient in $P(z) \mod Q(z)$ is bounded by $|\sum_{i=0}^{m} \alpha_i r_{i,k}^{(l)}| \leq 5 \sum_{i=0}^{m} 2^k i^{k-1} \leq 2^k m^k$.

At the same time, $|\mathcal{P}| = 11^m$. From the pigeonhole principle and $\left(\frac{2^k m^k}{(2^{-m})^2}\right)^k < 11^m$, there exists $P_1, P_2 \in \mathcal{P}$ such that for $P^*(z) = P_1(z) - P_2(z)$, $P^*(z) \mod Q(z) = \sum_{i=0}^{k-1} \gamma_i z^i$ where each coefficient $|\gamma_i| \leq 2^{-m}$. □

Let $r(z) = \sum_{i=0}^{k-1} \gamma_i z^i = P^*(z) \mod Q(z)$ for convenience. If $P^*(0)$ (the constant term of P^*) is nonzero, then $|P^*(0) - r(0)| \geq 0.99$ from the above lemma. Therefore the polynomial $\frac{P^*(z) - r(z)}{P^*(0) - r(0)}$ satisfies the three properties in Lemma 12.5.4.

Otherwise, we assume z^l is the first term in $P^*(z)$ with a non-zero coefficient. Let

$$r_{-l,k}(z) = z^{-l} \mod Q(z) = \sum_{i=1}^{k} \frac{\prod_{j \in [k] \setminus i} (z - z_j) z_i^{-l}}{\prod_{j \in [k] \setminus i} (z_i - z_j)}.$$

For convenience, we use $z_S = \prod_{i \in S} z_i$ for any subset $S \subseteq [k]$. Notice that $z_i^{-l} = \frac{z_{[k]\setminus i}^l}{z_{[k]}^l}$. Hence $r_{-l,k}(z) = r'_{l,k}(z)/z_{[k]}^l$ where r' is the polynomial for k units roots $z_{[k]\setminus 1}, \cdots, z_{[k]\setminus k}$. So each coefficients of r is still bounded by $2^k l^k$, which is less than $2^{-m/2}$.

Eventually we choose $P^*(z)/z^l - r(z) \cdot r_{-l,k}(z)$ and renormalize it to satisfy the three properties in Lemma 12.5.4.

12.10.3 Proof of Lemma 12.4.3

Lemma 12.4.3. For any degree d polynomial $P(t) : \mathbb{R} \to \mathbb{C}$ with derivative $P'(t)$, we have,

$$\int_{-1}^{1} (1-t^2)|P'(t)|^2 \mathrm{d}t \le 2d^2 \int_{-1}^{1} |P(t)|^2 \mathrm{d}t. \tag{12.28}$$

Given a degree d polynomial $P(x)$, we rewrite $P(x)$ as a linear combination of the Legendre polynomials:

$$P(x) = \sum_{i=0}^{d} \alpha_i L_i(x).$$

We use $F_i(x) = (1-x^2)L_i'(x)$ for convenience. From the definition of the Legendre polynomials in the Equation (12.3), $F_i'(x) = -i(i+1) \cdot L_i(x)$ and $F_i''(x) = -i(i+1) \cdot L_i'(x)$.

Hence we have

$$\begin{aligned}
\int_{1}^{-1} (1-x^2)|P'(x)|^2 \mathrm{d}x = & \int_{1}^{-1} (1-x^2)P'(x) \cdot \overline{P'}(x) \mathrm{d}x \\
= & \int_{1}^{-1} \left(\sum_{i \in [d]} \alpha_i F_i(x) \right) \cdot \left(\sum_{i \in [d]} \overline{\alpha_i} \frac{-F_i''(x)}{i(i+1)} \right) \mathrm{d}x \\
= & \left(\sum_{i \in [d]} \alpha_i F_i(x) \right) \cdot \left(\sum_{i \in [d]} \overline{\alpha_i} \frac{-F_i'(x)}{i(i+1)} \right) \Bigg|_{-1}^{1} \\
+ & \int_{1}^{-1} \left(\sum_{i \in [d]} \alpha_i F_i'(x) \right) \cdot \left(\sum_{i \in [d]} \overline{\alpha_i} \frac{F_i'(x)}{i(i+1)} \right) \mathrm{d}x \\
= & \int_{1}^{-1} \left(\sum_{i \in [d]} \alpha_i \cdot i(i+1) \cdot L_i(x) \right) \cdot \left(\sum_{i \in [d]} \overline{\alpha_i} \frac{i(i+1) \cdot L_i(x)}{i(i+1)} \right) \mathrm{d}x \\
= & \sum_{i \in [d]} |\alpha_i|^2 i(i+1) \|L_i\|_T^2 \\
\le & d(d+1)\|P\|_T^2
\end{aligned}$$

12.10.4 Proof of Lemma 12.6.1

Lemma 12.6.1. $\widehat{P_{\sigma,a,b}x}(\sigma(f-b)) = \frac{1}{\sigma}e^{-2\pi\mathbf{i}\sigma af}\widehat{x}(f)$ and $\widehat{P_{\sigma,a,b}x}(f) = \frac{1}{\sigma}e^{-2\pi\mathbf{i}\sigma a(f/\sigma+b)}\widehat{x}(f/\sigma+b)$

Proof. Let's compute the Fourier Transform of $(P_{\sigma,a,b}x)(t)$,

$$
\begin{aligned}
&\widehat{P_{\sigma,a,b}x}(f) \\
=&\int_{-\infty}^{+\infty}(P_{\sigma,a,b}(x))(t)e^{-2\pi\mathbf{i}ft}\mathrm{d}t \\
=&\int_{-\infty}^{+\infty}x(\sigma(t-a))e^{-2\pi\mathbf{i}\sigma bt}e^{-2\pi\mathbf{i}ft}\mathrm{d}t \\
=&e^{-2\pi\mathbf{i}(\sigma ab+fa)}\int_{-\infty}^{+\infty}x(\sigma(t-a))e^{-2\pi\mathbf{i}\sigma b(t-a)}e^{-2\pi\mathbf{i}f(t-a)}\mathrm{d}t && \text{by shifting } t \text{ by } a \\
=&e^{-2\pi\mathbf{i}(\sigma ab+fa)}\int_{-\infty}^{+\infty}x(\sigma t)e^{-2\pi\mathbf{i}\sigma bt}e^{-2\pi\mathbf{i}ft}\mathrm{d}t && \text{by replacing } t-a \text{ by } t \\
=&\frac{1}{\sigma}e^{-2\pi\mathbf{i}(\sigma ab+fa)}\int_{-\infty}^{+\infty}x(\sigma t)e^{-2\pi\mathbf{i}b\sigma t}e^{-2\pi\mathbf{i}f\sigma t/\sigma}\mathrm{d}\sigma t \\
=&\frac{1}{\sigma}e^{-2\pi\mathbf{i}(\sigma ab+fa)}\int_{-\infty}^{+\infty}x(t)e^{-2\pi\mathbf{i}(b+f/\sigma)t}\mathrm{d}t && \text{by replacing } t\sigma \text{ by } t \\
=&\frac{1}{\sigma}e^{-2\pi\mathbf{i}a\sigma(f/\sigma+b)}\widehat{x}(f/\sigma+b) && \text{by definition of FT}
\end{aligned}
$$

The first result follows immediately by replacing $f/\sigma+b$ by f', which gives

$$\widehat{P_{\sigma,a,b}x}(\sigma(f'-b)) = \frac{1}{\sigma}e^{-2\pi\mathbf{i}a\sigma f'}\widehat{x}(f').$$

Thus, we complete the proof of this Lemma. □

12.10.5 Proof of Lemma 12.3.5

Lemma 12.3.5. Given any function $x(t) : \mathbb{R} \to \mathbb{C}$ with $\max_{t\in[0,T]} |x(t)|^2 \leq d\|x(t)\|_T^2$. Let S denote a set of points from 0 to T. If each point of S is chosen uniformly at random from $[0, T]$, we have

$$\Pr\left[\left|\frac{1}{|S|}\sum_{i\in S}|x(t_i)|^2 - \|x(t)\|_T^2]\right| \geq \epsilon\|x(t)\|_T^2\right] \quad \leq \quad e^{-\Omega(\epsilon^2|S|/d)}$$

Proof. Let M denote $\max_{t\in[0,T]} |x(t)|^2$. Replacing X_i by $\frac{|x(t_i)|^2}{M}$ and n by $|S|$ in Lemma A.1.1, we obtain that

$$\begin{aligned}
& \Pr[|X-\mu| > \epsilon\mu] \leq 2\exp(-\frac{\epsilon^2}{3}\mu) \\
\Longrightarrow \quad & \Pr\left[\left|\sum_{i\in S}\frac{|x(t_i)|^2}{M} - |S|\frac{\|x(t)\|_T^2}{M}\right| > \epsilon|S|\frac{\|x(t)\|_T^2}{M}\right] \leq 2\exp(-\frac{\epsilon^2}{3}\mu) \\
\Longrightarrow \quad & \Pr\left[\left|\frac{1}{|S|}\sum_{i\in S}|x(t_i)|^2 - \|x(t)\|_T^2\right| \geq \epsilon\|x(t)\|_T^2\right] \leq 2\exp(-\frac{\epsilon^2}{3}\mu) \\
\Longrightarrow \quad & \Pr\left[\left|\frac{1}{|S|}\sum_{i\in S}|x(t_i)|^2 - \|x(t)\|_T^2\right| \geq \epsilon\|x(t)\|_T^2\right] \leq 2\exp(-\frac{\epsilon^2}{3}|S|\frac{\|x(t)\|_T^2}{M})
\end{aligned}$$

which is less than $2\exp(-\frac{\epsilon^2}{3}|S|/d)$, thus completes the proof. □

12.10.6 Proof of Lemma 12.3.9

Lemma 12.3.9. For any polynomial $P(t)$ of degree at most d from R to $\mathbb{C}$, for any interval $[S,T]$,

$$\max_{t\in[S,T]} |P(t)|^2 \leq (d+1)^2 \cdot \frac{1}{T-S}\int_S^T |P(t)|^2 \mathrm{d}x.$$

Proof. Let $t^* = \arg\max_{t\in[S,T]} |P(t)|^2$. If $t^* \in (S,T)$, then it is enough to prove that

$$|P(t^*)|^2 \leq (d+1)^2 \frac{1}{t^*-S}\int_S^{t^*} |P(x)|^2 \mathrm{d}x \text{ and } |P(t^*)|^2 \leq (d+1)^2 \frac{1}{T-t^*}\int_{t^*}^T |P(x)|^2 \mathrm{d}x$$

on the two intervals $[S,t^*]$ and $[t^*,T]$ separately.

Without loss of generality, we will prove the inequality for $S=-1$ and $t^*=T=1$. We find the minimum $\|P(x)\|_T^2$ assuming $|P(1)|^2=1$. Because the first $(d+1)$ Legendre polynomials provide a basis of polynomials of degree at most d and their evaluation $L_n(1)=1$ for any n, we consider:

$$\begin{aligned} \min_{\alpha_0,\alpha_1,\cdots,\alpha_d\in\mathbb{C}} \quad & \int_{-1}^1 |P(x)|^2 \mathrm{d}x \\ \text{s.t.} \quad & P(x) = \sum_{i=0}^d \alpha_i L_i(x) \\ & |P(1)| = |\sum_{i=0}^d \alpha_i| = 1. \end{aligned}$$

We simplify the integration of $P(x)^2$ over $[-1,1]$ by the orthogonality of Legendre polyno-

mials:

$$\begin{aligned}\int_{-1}^{1}|P(x)|^2\mathrm{d}x &= \int_{-1}^{1}\left(\sum_{i=0}^{d}\alpha_i L_i(x)\right)\cdot\left(\sum_{j=0}^{d}\overline{\alpha_j}\overline{L_j}(x)\right)\mathrm{d}x \\ &= \int_{-1}^{1}\sum_{i=0}^{d}|\alpha_i|^2 L_i(x)^2+\sum_{i\neq j}\alpha_i\overline{\alpha_j}L_i(x)\overline{L_j}(x)\mathrm{d}x \\ &= \sum_{i=0}^{d}|\alpha_i|^2\frac{2}{2i+1} \text{ by Fact 12.3.8}\end{aligned}$$

Using $\int_{-1}^{1}|P(x)|^2\mathrm{d}x=\sum_{i=0}^{d}|\alpha_i|^2\frac{2}{2i+1}$, we simplify the optimization problem to

$$\begin{aligned}\min_{\alpha_0,\alpha_1,\cdots,\alpha_d\in\mathbb{C}} \quad & \sum_{i=0}^{d}|\alpha_i|^2\frac{2}{2i+1} \\ \text{s.t.} \quad & \left|\sum_{i=0}^{d}\alpha_i\right|=1\end{aligned}$$

From the Cauchy-Schwarz inequality, we have

$$\left|\sum_{i=0}^{d}\alpha_i\right|^2\leq\left(\sum_{i=0}^{d}|\alpha_i|^2\frac{2}{2i+1}\right)\left(\sum_{i=0}^{d}\frac{2i+1}{2}\right).$$

Therefore $\sum_{i=0}^{d}|\alpha_i|^2\frac{2}{2i+1}\geq\frac{2}{(d+1)^2}$ and $|P(1)|^2\leq(d+1)^2\cdot\frac{1}{2}\int_{-1}^{1}|P(x)|^2\mathrm{d}x$. □

Algorithm 12.1 Linear Regression Algorithms

procedure LINEARREGRESSION$(A, b,)$ — Fact 12.11.1
    $x' \leftarrow \arg\min_x \|Ax - b\|_2$.
    return x'
end procedure
procedure LINEARREGRESSIONW(A, b, w) — Fact 12.11.1
    $x' \leftarrow \arg\min_x \sum_{i=1}^{d} w_i |(Ax)_i - b_i|^2$.
    return x'
end procedure

12.11 Known Facts

This section provides a list of well-known facts existing in literature.

12.11.1 Linear regression

Given a linear subspace $\mathrm{span}\{\vec{v}_1, \cdots, \vec{v}_d\}$ and n points, we always use ℓ_2-regression to find a vector as the linear combination of $\vec{v}_1, \cdots, \vec{v}_d$ that minimizes the distance of this vector to those n points.

Fact 12.11.1. *Given an $n \times d$ matrix A and an $n \times 1$ column vector b , it takes $O(nd^{\omega-1})$ time to output an x' such that*

$$x' = \arg\min_x \|Ax - b\|_2.$$

where ω is the exponent of matrix multiplication[Wil12].

Notice that weighted linear regression can be solved by linear regression solver as a black-box.

Algorithm 12.2 Multipoint Evaluation of a Polynomial

1: **procedure** MULTIPOINTEVALUATION($P, \{t_1, t_2, \cdots, t_d\}$) — Fact 12.11.2
2: **return** $P(t_1), P(t_2), \cdots, P(t_d)$
3: **end procedure**

12.11.2 Multipoint evaluation of a polynomial

Given a degree-d polynomial, and n locations. The naive algorithm of computing the evaluations at those n locations takes $O(nd)$. However, the running time can be improved to $O(n \operatorname{poly}(\log d))$ by using this well-known result,

Fact 12.11.2 ([BS12]). *Let $c > 1$ denote some fixed constant. Given a degree-d polynomial $P(t)$, and a set of d locations $\{t_1, t_2, \cdots, t_d\}$. There exists an algorithm that takes $O(d \log^c d)$ time to output the evaluations*

$$\{P(t_1), P(t_2), \cdots, P(t_d)\}.$$

12.12 Analysis of Hash Functions and Filter Functions

12.12.1 Analysis of filter function $(H(t), \widehat{H}(f))$

We construct the Filter function $(H(t), \widehat{H}(f))$ in this section.

We fix the interval to be $\text{supp}(\text{rect}_1) = [-1/2, 1/2]$ instead of $[0, T]$ for convenience. We first define the filter function $H_1(t)$ which preserves the energy of a k-Fourier-sparse signal x^* on $[-1/2, 1/2]$ to the signal $H_1 \cdot x^*$ on $[-\infty, +\infty]$.

Definition 12.12.1. Let $s_1 = \Theta(k^4 \log^4 k)$, $\ell = \Omega(k \log k/\delta)$ be a even number, and $s_0 = C_0 s_1 \sqrt{\ell}$ for some constant C_0 that will normalize $H_1(0) = 1$. Recall that $\text{rect}_s(t) = 1$ iff $|t| \leq s/2$ and $\widehat{\text{rect}_s(f)} = \text{sinc}(fs) = \frac{\sin(\pi f s)}{\pi f s}$.

We define the filter function $H_1(t)$ and its Fourier transform $\widehat{H}_1(f)$ as follows:

$$\begin{aligned}
\widehat{H}_1(f) &= s_0 \cdot (\text{rect}_{s_1}(f))^{*\ell} \cdot \text{sinc}(f s_2), \\
&= s_0 \cdot \Big(\quad \Big)^{*\ell} \cdot \quad \text{(rect}_{s_1} \text{ with height 1, on } [-s_1/2, s_1/2]\text{)} \quad \text{(sinc}(f s_2) \text{ with height 1, on } [-1/s_2, 1/s_2]\text{)} \\
H_1(t) &= s_0 \cdot (\text{sinc}(s_1 t))^{\cdot \ell} * \text{rect}_{s_2}(t) \\
&= s_0 \cdot \Big(\quad \Big)^{\cdot \ell} * \quad \text{(sinc}(s_1 t) \text{ with height 1, on } [-1/s_1, 1/s_1]\text{)} \quad \text{(rect}_{s_2} \text{ with height 1, on } [-s_2/2, s_2/2]\text{)}
\end{aligned}$$

where s_0 is a fixed parameter s.t. $H_1(0) = 1$.

We provide some basic properties about our filter function. Notice that $\text{sinc}(t) = \frac{\sin(\pi t)}{\pi t}$ ($\text{sinc}(0)$ is defined to be 1) has the following properties (shown in Figure 12.4):

1. $\forall t \in \mathbb{R}, 1 - \frac{(\pi t)^2}{3!} \leq \text{sinc}(t) \leq 1$.

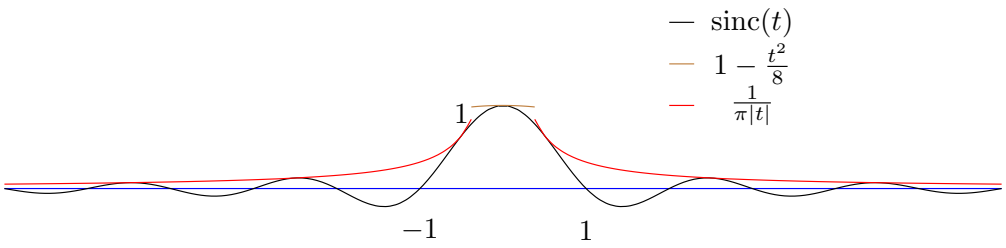

Figure 12.4: The Property of $\mathrm{sinc}(t)$.

2. $\forall |t| \leq 1.2/\pi, \mathrm{sinc}(t) \leq 1 - \frac{t^2}{8}$.

3. $\forall |t| > 1.2/\pi, |\mathrm{sinc}(t)| \leq \frac{1}{\pi|t|}$.

Claim 12.12.1. $\int_{-\frac{1.2}{\pi s_1}}^{\frac{1.2}{\pi s_1}} (\mathrm{sinc}(s_1 t))^\ell \mathrm{d}t \eqsim \frac{1}{s_1\sqrt{\ell}}$.

Proof. We use the above properties for the sinc function to prove the upper bound:

$$\begin{aligned}
\int_{-\frac{1.2}{\pi s_1}}^{+\frac{1.2}{\pi s_1}} (\mathrm{sinc}(s_1 t))^\ell \mathrm{d}t &= \frac{1}{s_1} \int_{-1.2/\pi}^{+1.2/\pi} (\mathrm{sinc}(t))^\ell \mathrm{d}t \\
&= \frac{2}{s_1} \left(\int_0^{\sqrt{8/\ell}} (\mathrm{sinc}\, t)^\ell \mathrm{d}t + \int_{\sqrt{8/\ell}}^{1.2/\pi} (\mathrm{sinc}(t))^\ell \mathrm{d}t \right) \\
&\leq \frac{2}{s_1} \left(\sqrt{8/\ell} + \sum_{i=1}^{\frac{1.2/\pi}{\sqrt{8/\ell}}-1} \int_{i\sqrt{8/\ell}}^{(i+1)\sqrt{8/\ell}} (1 - x^2/8)^\ell \mathrm{d}x \right) \\
&\leq \frac{2}{s_1} \left(\sqrt{8/\ell} + \sum_{i=1}^{\frac{1.2/\pi}{\sqrt{8/\ell}}-1} \sqrt{8/\ell} \cdot 2^{-i^2} \right) \\
&\lesssim \frac{1}{s_1\sqrt{\ell}}.
\end{aligned}$$

We prove the lower bound:

$$\begin{aligned}\int_{-\frac{1.2}{\pi s_1}}^{\frac{1.2}{\pi s_1}} (\mathrm{sinc}(s_1 t))^\ell \mathrm{d}t &= \frac{2}{s_1}\left(\int_0^{\sqrt{8/\ell}} (\mathrm{sinc}\, t)^\ell \mathrm{d}t + \int_{\sqrt{8/\ell}}^{1.2/\pi} (\mathrm{sinc}(t))^\ell \mathrm{d}t\right) \\ &\geq \frac{2}{s_1}\left(\int_0^{\sqrt{8/\ell}} (1-\frac{\pi^2 t^2}{6})^\ell \mathrm{d}t\right) \\ &\gtrsim \frac{1}{s_1\sqrt{\ell}}.\end{aligned}$$

□

We bound the integration outside $[-\frac{1.2}{\pi s_1}, \frac{1.2}{\pi s_1}]$ from the last property of the sinc function.

Claim 12.12.2. $\int_{\frac{1.2}{\pi s_1}}^{+\infty} (\mathrm{sinc}(s_1 t))^\ell \mathrm{d}t = O(1.2^{-\ell})$.

From these two claims, we have the existence of s_0.

Claim 12.12.3. *There exists a universal constant C_0 and $s_0 = C_0 s_1\sqrt{\ell}$ such that $H_1(0) = 1$.*

Proof. Because ℓ is a large even number, $\int_{\mathrm{rect}_{1-2/s_1}} \mathrm{sinc}(s_1 t)^\ell \mathrm{d}t \eqsim \frac{1}{s_1\sqrt{\ell}}$ from all discussion above. □

We show several useful properties about the Filter functions $\left(H_1(t), \widehat{H_1}(f)\right)$.

Lemma 12.12.4. *Given s_0, s_1, s_2, ℓ, where $\frac{s_2}{2} + \frac{1}{s_1} \leq 1/2$ and $s_0 = C_0 s_1\sqrt{\ell}$ for some constant*

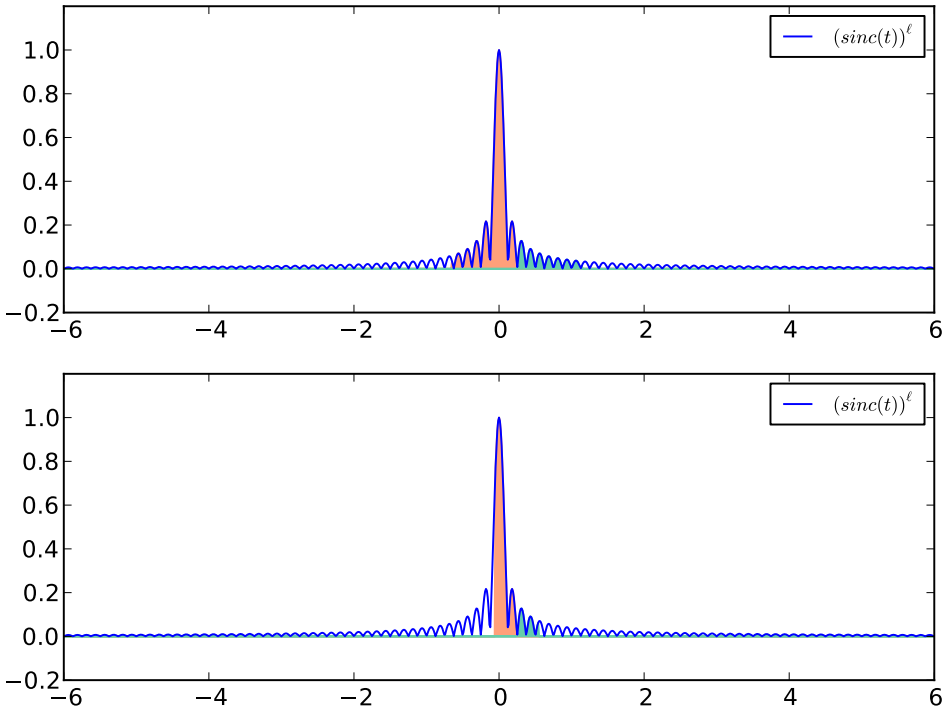

Figure 12.5: The light red area represents $\int_{(1/2-2/s_1)}^{(1/2-2/s_1)-t} s_0 \cdot \mathrm{sinc}\left(s_1(\tau)\right)^\ell \mathrm{d}\tau$ and the light green area represents $\int_{1/2-2/s_1}^{1/2-2/s_1+t} s_0 \cdot \mathrm{sinc}\left(s_1(\tau)\right)^\ell \mathrm{d}\tau$.

C_0. *The filter function* $(H_1(t), \widehat{H}_1(f))[s_0, s_1, s_2, \ell]$ *has the following properties,*

$$\begin{aligned}
\text{Property I}: &\quad H_1(t) \in [1 - \frac{s_0}{s_1} \cdot \frac{2\pi^{-\ell}}{\ell - 1}, 1], \ \textit{if } |t| \leq \frac{s_2}{2} - \frac{1}{s_1}. \\
\text{Property II}: &\quad H_1(t) \in [0, 1], \ \textit{if } \frac{s_2}{2} - \frac{1}{s_1} \leq |t| \leq \frac{1}{2} \\
\text{Property III}: &\quad H_1(t) \leq s_0 s_2 \left((s_1|t| - s_1 + 2)^2 + 1\right)^{-\ell}, \forall |t| > \frac{1}{2} \\
\text{Property IV}: &\quad \mathrm{supp}(\widehat{H}_1(f)) \subseteq [-\frac{s_1 \ell}{2}, \frac{s_1 \ell}{2}]
\end{aligned}$$

Proof of Property I. First, $H_1(0) = 1$ follows by definition of s_0, then we can prove the upper bound for $H_1(t)$ by showing for any $t > 0$, $H_1(0) - H_1(t) > 0$ always holds ,

By definition of sinc function, we know that $\text{sinc}(s_1 t)^\ell$ reaches 0 at all the points $\{\frac{1}{s_1} + i\frac{2}{s_1} | i \in \mathbb{N}\}$. By definition of s_1, we know that $\frac{1}{s_1} \ll \frac{1}{2} - \frac{1}{s_1}$. For any $t > 0$,

$$
\begin{aligned}
& H_1(0) - H_1(t) \\
= & \int s_0 \cdot \text{sinc}\left(s_1(\tau)\right)^\ell \cdot \text{rect}_{1-2/s_1}(0-\tau)\mathrm{d}\tau - \int s_0 \cdot \text{sinc}\left(s_1(\tau)\right)^\ell \cdot \text{rect}_{1-2/s_1}(t-\tau)\mathrm{d}\tau \\
= & \int_{-(1/2-2/s_1)}^{1/2-2/s_1} s_0 \cdot \text{sinc}\left(s_1(\tau)\right)^\ell \mathrm{d}\tau - \int_{-(1/2-2/s_1)+t}^{1/2-2/s_1+t} s_0 \cdot \text{sinc}\left(s_1(\tau)\right)^\ell \mathrm{d}\tau \\
= & \int_{-(1/2-2/s_1)}^{-(1/2-2/s_1)+t} s_0 \cdot \text{sinc}\left(s_1(\tau)\right)^\ell \mathrm{d}\tau - \int_{1/2-2/s_1}^{1/2-2/s_1+t} s_0 \cdot \text{sinc}\left(s_1(\tau)\right)^\ell \mathrm{d}\tau \\
\geq & 0,
\end{aligned}
$$

where the third step can be observed in Figure 12.5, and the last inequality follows by choosing s_1 to be an integer. Thus, we prove an upper bound for $H_1(t)$. Third, we show the lower bound for $H_1(t)$,

$$
\begin{aligned}
H_1(t) &= \int_{-\infty}^{+\infty} s_0 \cdot \text{sinc}(s_1\tau)^{\cdot\ell} \, \text{rect}_{s_2}(t-\tau)\mathrm{d}\tau \\
&= \int_{t-\frac{s_2}{2}}^{t+\frac{s_2}{2}} s_0 \cdot \text{sinc}(s_1\tau)^{\cdot\ell}\mathrm{d}\tau \\
&= 1 - \underbrace{\int_{t+\frac{s_2}{2}}^{+\infty} s_0 \cdot \text{sinc}(s_1\tau)^{\cdot\ell}\mathrm{d}\tau}_{A} - \underbrace{\int_{-\infty}^{t-\frac{s_2}{2}} s_0 \cdot \text{sinc}(s_1\tau)^{\cdot\ell}\mathrm{d}\tau}_{B}
\end{aligned}
$$

Thus, as long as we can upper bound the term A and B, then we will have a lower bound

for the $H_1(t)$, for any $|t| \leq \frac{s_2}{2} - \frac{1}{s_1}$.

$$\begin{aligned} A &= \int_{t+\frac{s_2}{2}}^{+\infty} s_0 \cdot \mathrm{sinc}(s_1\tau)^{\cdot\ell} \mathrm{d}\tau \\ &\leq \int_{\frac{1}{s_1}}^{+\infty} s_0 \cdot \mathrm{sinc}(s_1\tau)^{\cdot\ell} \mathrm{d}\tau \\ &\leq \int_{\frac{1}{s_1}}^{+\infty} s_0 \cdot (s_1\pi\tau)^{-\ell} \mathrm{d}\tau \\ &= s_0 \cdot (s_1\pi)^{-\ell} \frac{1}{\ell - 1} (1/s_1)^{-\ell+1} \\ &= \frac{s_0}{s_1} \cdot (\pi)^{-\ell} \frac{1}{\ell - 1} \end{aligned}$$

Similarly, we can bound the term B in the same way. □

Proof of Property II. In the proof of Property I, we already show that $\forall t$, $H_1(t) \leq 1$. Thus, the upper bound of Property II is also holding. The lower bound follows by both $\mathrm{sinc}(s_1 t)^{\cdot\ell}$ and $\mathrm{rect}_{s_2}(t)$ are always nonnegative, thus the convolution of these two functions has to be nonnegative. □

Proof of Property III. Let's prove the case when $t > 1$, since $H_1(t)$ is symmetric, then the case $t < -1$ will also hold. By definition of $(H_1(t), \widehat{H}_1(f))$, we have

$$\begin{aligned} H_1(t) &= s_0 \cdot \int_{-\infty}^{+\infty} \mathrm{sinc}(s_1(t-\tau))^{\cdot\ell} \, \mathrm{rect}_{s_2}(\tau) \mathrm{d}\tau \\ &= s_0 \cdot \int_{-\frac{s_2}{2}}^{\frac{s_2}{2}} \mathrm{sinc}(s_1(t-\tau))^{\cdot\ell} \mathrm{d}\tau \\ &= s_0 \cdot \int_{-\frac{s_2}{2}}^{\frac{s_2}{2}} \mathrm{sinc}(s_1(\tau-t))^{\cdot\ell} \mathrm{d}\tau \end{aligned}$$

We'd like to choose a middle point τ_0, and then separated the interval into two parts, one is $[-\frac{s_2}{2}, \tau_0]$ and the other is $[\tau_0, \frac{s_2}{2}]$. To choose a reasonable τ_0, we need to use the following simple facts,

$$\begin{aligned}(\frac{\sin(x)}{x})^\ell &\leq x^{-\ell} \text{ if } x \geq 1.2 \\ (\frac{\sin(x)}{x})^\ell &\leq (1 - \frac{x^2}{8})^\ell \text{ if } x < 1.2\end{aligned}$$

Thus, $|\pi s_1(\tau_0 - t)| = 1.2$, which implies that $\tau_0^+ = t + \frac{1.2}{\pi s_1}$ or $\tau_0^- = t - \frac{1.2}{\pi s_1}$. By relationship between s_1 and s_2, we know $\tau_0^- > \frac{1}{2} - \frac{1.2}{\pi s_1} > \frac{1}{2} - \frac{1}{s_1} \geq \frac{s_2}{2}$. Thus, we can use the case $x < 1.2$ to upper bound the $H_1(t)$,

$$\begin{aligned}& H_1(t) \\ \leq\ & s_0 \cdot s_2 \cdot \max_{\tau \in [-s_2/2, s_2/2]} \operatorname{sinc}(s_1(\tau - t))^\ell \\ \leq\ & s_0 \cdot s_2 \max_{\tau \in [-s_2/2, s_2/2]} (1 - \frac{(s_1\pi(\tau - t))^2}{8})^\ell \\ =\ & s_0 \cdot s_2 (1 - \frac{(s_1\pi(\frac{s_2}{2} - t))^2}{8})^\ell \\ \leq\ & s_0 \cdot s_2 \cdot (e^{-\frac{(s_1\pi(\frac{s_2}{2} - t))^2}{8}})^\ell && \text{by } 1 - x \leq e^{-x} \\ \leq\ & s_0 \cdot s_2 \cdot (e^{(s_1(t - s_2/2))^2})^{-\ell} && \text{by } 1 < \pi^2/8 \\ \leq\ & s_0 \cdot s_2 \cdot (1 + (s_1(t - s_2/2))^2)^{-\ell} && \text{by } 1 + x \leq e^x \\ \leq\ & s_0 \cdot (1 + (s_1(t - s_2/2))^2)^{-\ell} && \text{by } s_1 \leq 1.\end{aligned}$$

Thus, we complete the proof. □

Proof of Property IV. Because of the support of $\operatorname{rect}_{s_1}(f)$ is s_1, then the support of

$(\text{rect}_{s_1}(f))^{*\ell} = s_1\ell$. Since $\widehat{H}_1(f)$ is defined to be the $(\text{rect}_{s_1}(f))^{*\ell}$ multiplied by $\text{sinc}(fs_2)$, thus $\text{supp}(\widehat{H}_1(f)) \subseteq [-\frac{s_1\ell}{2}, \frac{s_1\ell}{2}]$. □

Definition 12.12.2. Given any $0 < s_3 < 1$, $0 < \delta < 1$, we define $(H(t), \widehat{H}(f))$ to be the filter function $(H_1(t), \widehat{H_1}(f))$ by doing the following operations

- Setting $\ell = \Theta(k \log(k/\delta))$,
- Setting $s_2 = 1 - \frac{2}{s_1}$,
- Shrinking by a factor s_3 in time domain,

$$H(t) = H_1(t/s_3) \tag{12.29}$$

$$\widehat{H}(f) = s_3\widehat{H_1}(s_3 f) \tag{12.30}$$

We call the "heavy cluster" around a frequency f_0 to be the support of $\delta_{f_0}(f) * \widehat{H}(f)$ in the frequency domain and use

$$\Delta_h = |\,\text{supp}(\widehat{H}(f))| = \frac{s_1 \cdot \ell}{s_3} \tag{12.31}$$

to denote the width of the cluster.

We show several useful properties about the Filter functions $\big(H(t), \widehat{H}(f)\big)$.

Lemma 12.6.4. Given $s_0, s_1, 0 < s_3 < 1, \ell > 1, 0 < \delta < 1$, where $\ell = \Theta(k \log(k/\delta))$.The filter

function $(H(t), \widehat{H}(f))$ has the following properties,

$$\begin{aligned}
\text{Property I}: &\quad H(t) \in [1-\delta, 1], \text{ when } |t| \leq (\frac{1}{2} - \frac{2}{s_1})s_3. \\
\text{Property II}: &\quad H(t) \in [0, 1], \text{ when } (\frac{1}{2} - \frac{2}{s_1})s_3 \leq |t| \leq \frac{1}{2}s_3. \\
\text{Property III}: &\quad H(t) \leq s_0 \cdot (s_1(\frac{|t|}{s_3} - \frac{1}{2}) + 2)^{-\ell}, \forall |t| > \frac{1}{2}s_3. \\
\text{Property IV}: &\quad \mathrm{supp}(\widehat{H}(f)) \subseteq [-\frac{s_1\ell}{2s_3}, \frac{s_1\ell}{2s_3}].
\end{aligned}$$

For any exact k-Fourier-sparse signal $x^*(t)$, we shift the interval from $[0, T]$ to $[-1/2, 1/2]$ and consider $x^*(t)$ for $t \in [-1/2, 1/2]$ to be our observation, which is also $x^*(t) \cdot \mathrm{rect}_1(t)$.

$$\begin{aligned}
\text{Property V}: &\quad \int_{-\infty}^{+\infty} \left|x^*(t) \cdot H(t) \cdot (1 - \mathrm{rect}_1(t))\right|^2 \mathrm{d}t < \delta \int_{-\infty}^{+\infty} |x^*(t) \cdot \mathrm{rect}_1(t)|^2 \mathrm{d}t. \\
\text{Property VI}: &\quad \int_{-\infty}^{+\infty} |x^*(t) \cdot H(t) \cdot \mathrm{rect}_1(t)|^2 \mathrm{d}t \in [1-\epsilon, 1] \cdot \int_{-\infty}^{+\infty} |x^*(t) \cdot \mathrm{rect}_1(t)|^2 \mathrm{d}t.
\end{aligned}$$

for arbitrarily small constant ϵ.

The Property I, II, III and IV follow by filter function $H(t), \widehat{H}(f)$ inheriting $H_1(t), \widehat{H}_1(f)$.

Proof of Property V. $\forall t \notin [-1/2, 1/2]$, we have,

$$\begin{aligned}
& |x^*(t) \cdot H(t)|^2 \\
\leq\ & |x^*(t)|^2 \cdot |H(t)|^2 \\
\leq\ & |x^*(t)|^2 \cdot (s_1(|t| - 1/2) + 2)^{-\ell} && \text{by Property III of } H_1(t) \\
\leq\ & k^7 \cdot (2kt)^{2.5k} \cdot \int_{-\infty}^{+\infty} |x^*(t) \cdot \mathrm{rect}_1(t)|^2 \mathrm{d}t \cdot (s_1(\frac{|t|}{s_3} - \frac{1}{2}) + 2)^{-\ell} && \text{by Lemma 12.5.5} \\
\leq\ & t^{O(k \log k)} \cdot \int_{-\infty}^{+\infty} |x^*(t) \cdot \mathrm{rect}_1(t)|^2 \mathrm{d}t \cdot (s_1(\frac{|t|}{s_3} - \frac{1}{2}) + 2)^{-\ell/2}. && (12.32)
\end{aligned}$$

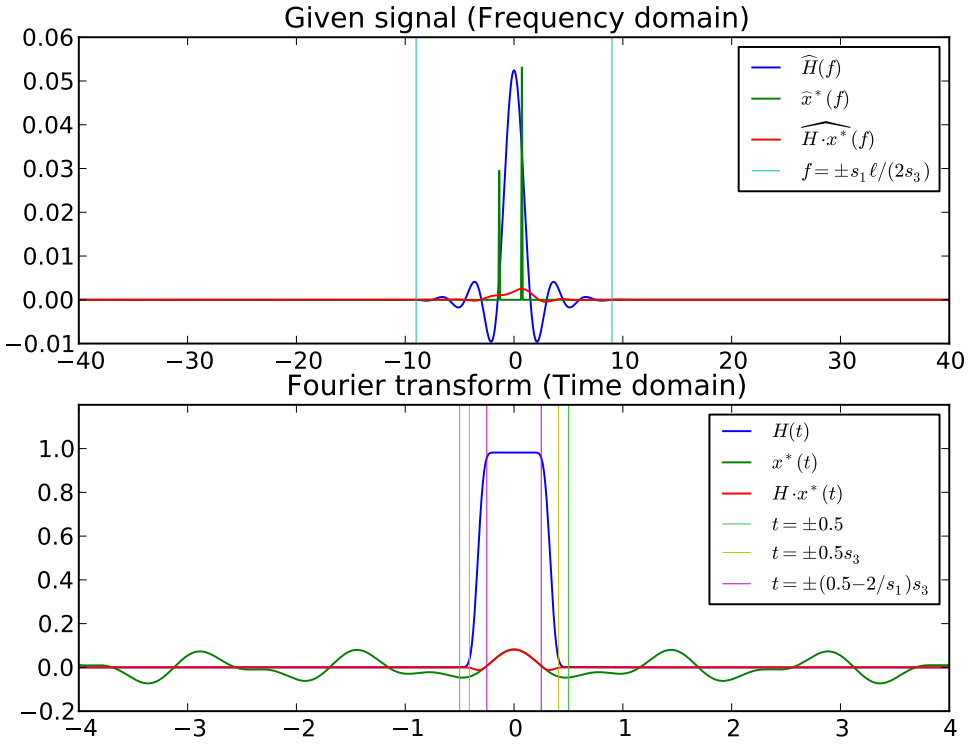

Figure 12.6: $\widehat{H \cdot x^*}(f)$ and $H \cdot x^*(t)$.

Thus taking the integral finishes the proof because $\ell \gtrsim k \log(k/\delta)$. □

Proof of Property VI. First, because of for any t, $|H_1(t)| \leq 1$, thus we prove the upper bound for LHS,

$$\int_{-\infty}^{+\infty} |x^*(t) \cdot H(t) \cdot \mathrm{rect}_1(t)|^2 \mathrm{d}t \leq \int_{-\infty}^{+\infty} |x^*(t) \cdot 1 \cdot \mathrm{rect}_1(t)|^2 \mathrm{d}t.$$

Second, as mentioned early, we need to prove the general case when $s_3 = 1 - 1/\operatorname{poly}(k)$. Define interval $S = [-s_3(\frac{1}{2} - \frac{1}{s_1}), s_3(\frac{1}{2} - \frac{1}{s_1})]$, by definition, $S \subset [-1/2, 1/2]$. Then define

$\overline{S} = [-1/2, 1/2] \setminus S$, which is $[-1/2, -s_3(\frac{1}{2} - \frac{1}{s_1})) \cup (s_3(\frac{1}{2} - \frac{1}{s_1}), 1/2]$. By Property I, we have

$$\int_S |x^*(t) \cdot H(t)|^2 \mathrm{d}t \geq (1-\delta)^2 \int_S |x^*(t)|^2 \mathrm{d}t \tag{12.33}$$

Then we can show

$$\begin{aligned}
&\int_{\overline{S}} |x^*(t)|^2 \mathrm{d}t \\
&\leq |\overline{S}| \cdot \max_{t \in [-1/2, 1/2]} |x^*(t)|^2 \\
&\leq (1 - s_3(1 - \frac{2}{s_1})) \cdot \widetilde{O}(k^4) \int_{-\frac{1}{2}}^{\frac{1}{2}} |x^*(t)|^2 \mathrm{d}t && \text{by Lemma 12.5.1} \\
&\lesssim \int_{-\frac{1}{2}}^{\frac{1}{2}} |x^*(t)|^2 \mathrm{d}t && \text{by } \min(\frac{1}{1-s_3}, s_1) \geq \widetilde{O}(k^4) \qquad (12.34)
\end{aligned}$$

Combining Equations (12.33) and (12.34) gives a lower bound for LHS,

$$\begin{aligned}
&\int_{-\infty}^{+\infty} |x^*(t) \cdot H(t) \cdot \mathrm{rect}_1(t)|^2 \mathrm{d}t \\
&\geq \int_S |x^*(t) H(t)|^2 \mathrm{d}t \\
&\geq (1-2\delta) \int_S |x^*(t)|^2 \mathrm{d}t && \text{by Equation (12.33)} \\
&\geq (1-2\delta) \int_{S \cup \overline{S}} |x^*(t)|^2 \mathrm{d}t - (1-2\delta) \int_{\overline{S}} |x^*(t)|^2 \mathrm{d}t \\
&\geq (1-2\delta) \int_{S \cup \overline{S}} |x^*(t)|^2 \mathrm{d}t - (1-2\delta)\epsilon \int_{S \cup \overline{S}} |x^*(t)|^2 \mathrm{d}t && \text{by Equation (12.34)} \\
&\geq (1-2\delta-\epsilon) \int_{-\frac{1}{2}}^{\frac{1}{2}} |x^*(t)|^2 \mathrm{d}t \\
&\geq (1-2\epsilon) \int_{-\infty}^{+\infty} |x^*(t) \cdot \mathrm{rect}_1(t)|^2 \mathrm{d}t && \text{by } \epsilon \gg \delta
\end{aligned}$$

□

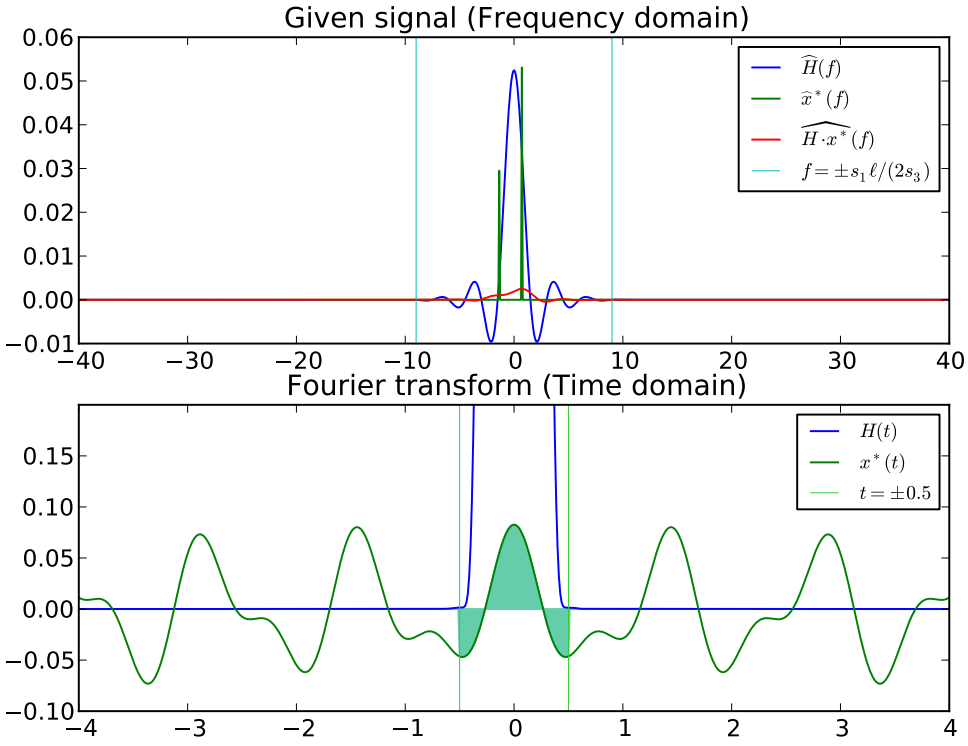

Figure 12.7: Property VI of filter function $H(t)$, first two figures of four figures. The light green area represents RHS(without scalar) of Property VI of filter H.

Remark 12.12.1. To match $(H(t), \widehat{H}(f))$ on $[-1/2, 1/2]$ with signal $x(t)$ on $[0, T]$, we will scale the time domain from $[-1/2, 1/2]$ to $[-T/2, T/2]$ and shift it to $[0, T]$. For example, the rectangle function in Property V and VI will be replaced by $\text{rect}_T(t - T/2)$. For the parameters $s_0, s_1, s_3, \delta, \ell$ in the definition of H, we always treat them as numbers. We assume T has seconds as unit and Δ_h has Hz as unit . For example, in time domain, the Property I becomes that given $T > 0$,

$$H(t) \in [1 - \delta, 1] \text{ if } |t - \frac{T}{2}| \leq (\frac{1}{2} - \frac{1}{s_1})s_3 \cdot T$$

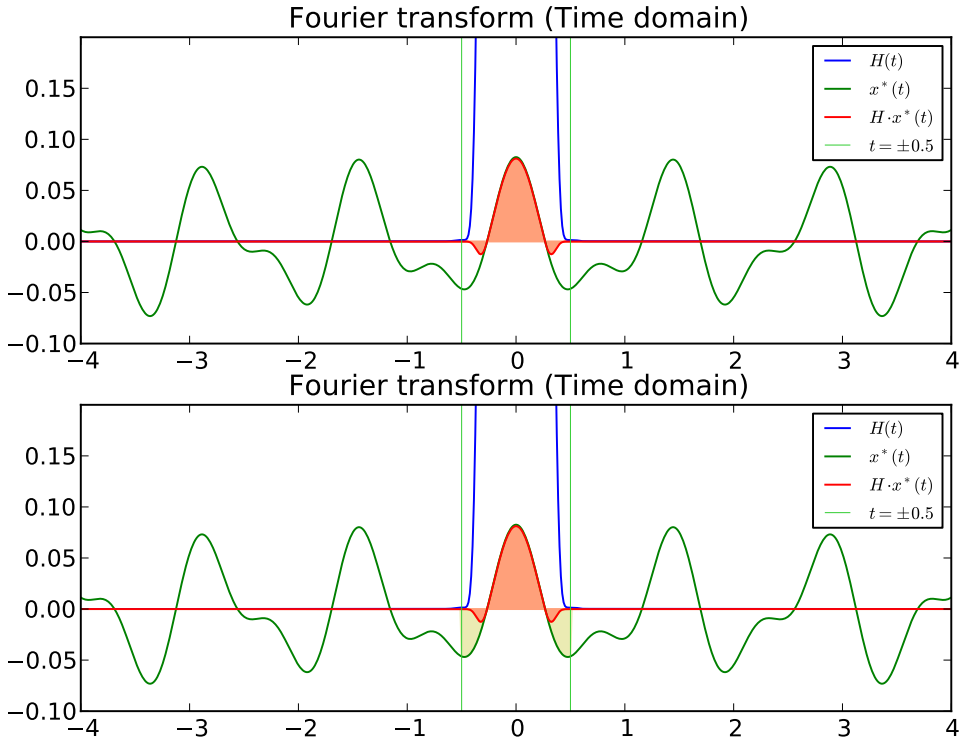

Figure 12.8: Property VI of filter function $H(t)$, last two figures of four figures. The light red area represents LHS of Property VI of filter H, the light yellow area represents the difference. Property VI says the light yellow area is only a small constant fraction of the light green area.

In frequency domain, the Property IV becomes

$$\mathrm{supp}(\widehat{H}(f)) \subseteq [-\frac{\Delta_h}{2}, \frac{\Delta_h}{2}], \text{ where } \Delta_h = \frac{s_1 \ell}{s_3 T}. \tag{12.35}$$

Lemma 12.12.5. *Let $H(t)$ denote the function defined in Definition 12.12.2. For any $t \in [-\frac{1}{2}, \frac{1}{2}]$, there exists an algorithm that takes $O(s_1 + \ell \log(s_1) + \log(1/\epsilon))$ time to output a*

value $\widetilde{H}(t)$ *such that*

$$(1-\epsilon)H(t) \leq \widetilde{H}(t) \leq (1+\epsilon)H(t).$$

Proof. We will show that using a low degree polynomial with sufficiently large degree is able to approximate the sinc function. By definition of filter function,

$$\begin{aligned}
H(t) &= s_0 \cdot \int_{-\infty}^{+\infty} \operatorname{sinc}(s_1\tau)^{\cdot \ell} \operatorname{rect}_{s_2}(t-\tau)\mathrm{d}\tau \\
&= s_0 \cdot \int_{t-\frac{s_2}{2}}^{t+\frac{s_2}{2}} (\frac{\sin(\pi s_1 \tau)}{\pi s_1 \tau})^{\ell}\mathrm{d}\tau \\
&= \frac{s_0}{\pi s_1} \int_{(t-\frac{s_2}{2})\pi s_1}^{(t+\frac{s_2}{2})\pi s_1} (\frac{\sin(\tau)}{\tau})^{\ell}\mathrm{d}\tau \\
&= \frac{s_0}{\pi s_1} \int_{(t-\frac{s_2}{2})\pi s_1}^{(t+\frac{s_2}{2})\pi s_1} \left(\sum_{i=0}^{\infty}(-1)^i \frac{\tau^{2i}}{(2i+1)!}\right)^{\ell} \mathrm{d}\tau \qquad \text{by Taylor expansion} \\
&= \frac{s_0}{\pi s_1} \int_{(t-\frac{s_2}{2})\pi s_1}^{(t+\frac{s_2}{2})\pi s_1} (A+B)^{\ell}\mathrm{d}\tau
\end{aligned}$$

where the last step follows by setting $A = \sum_{i=0}^{d}(-1)^i \frac{\tau^{2i}}{(2i+1)!}$, and $B = \sum_{i=d+1}^{\infty}(-1)^i \frac{\tau^{2i}}{(2i+1)!}$.

Denote $I^+ = (t+\frac{s_2}{2})\pi s_1$ and $I^- = (t-\frac{s_2}{2})\pi s_1$. Because of $t \in [-1/2, 1/2]$, then $\max(|I^+|, |I^-|) = O(s_1)$. The goal is to show that

$$(1-\epsilon)\int_{I^-}^{I^+}(A+B)^{\ell}\mathrm{d}\tau \leq \int_{I^-}^{I^+} A^{\ell}\mathrm{d}\tau \leq (1+\epsilon)\int_{I^-}^{I^+}(A+B)^{\ell}\mathrm{d}\tau$$

Let's prove an upper first,

$$
\begin{aligned}
&\int_{I^-}^{I^+} (A+B-B)^\ell \mathrm{d}\tau \\
=&\int_{I^-}^{I^+} (A+B)^\ell \mathrm{d}\tau + \sum_{j=1}^{\ell} \int_{I^-}^{I^+} \binom{\ell}{j} (A+B)^{\ell-j}(-B)^j \mathrm{d}\tau \\
\le&\int_{I^-}^{I^+} (A+B)^\ell \mathrm{d}\tau + \sum_{j=1}^{\ell} \int_{I^-}^{I^+} \binom{\ell}{j} |A+B|^{\ell-j}|B|^j \mathrm{d}\tau \\
\le&\int_{I^-}^{I^+} (A+B)^\ell \mathrm{d}\tau + \sum_{j=1}^{\ell} \int_{I^-}^{I^+} \binom{\ell}{j} |A+B|^{\ell-j}\mathrm{d}\tau \cdot \max_{\tau\in[I^-,I^+]} |B|^j \\
\le&\int_{I^-}^{I^+} (A+B)^\ell \mathrm{d}\tau + \ell 2^\ell \cdot \max_{\tau\in[I^-,I^+]} |B| && \text{by } |H(t)|\le 1 \text{ and } |B|^j \le |B| \\
\le&\int_{I^-}^{I^+} (A+B)^\ell \mathrm{d}\tau + \epsilon\cdot (s_1)^{-\Theta(\ell)} && \text{by Claim 12.12.6} \\
\le&(1+\epsilon)\int_{I^-}^{I^+} (A+B)^\ell \mathrm{d}\tau && \text{by Claim 12.12.7}
\end{aligned}
$$

where all the steps by setting $d \gtrsim s_1 + \ell\log(s_1) + \log(1/\epsilon)$. Similarly, we can prove a lower bound. □

Claim 12.12.6. *Let* $B(\tau) = \sum_{i=d+1}^{+\infty}(-1)\frac{\tau^{2i}}{(2i+1)!}$, *if* $d \gtrsim \tau + \ell\log(s_1) + \log(1/\epsilon)$ *then* $|B(\tau)| \le \epsilon(1/s_1)^{O(\ell)}$.

Proof. We first show, for any $i \ge d+1$,

$$
\begin{aligned}
&\frac{\tau^{2i}}{(2i+1)!} \\
\le&\frac{\tau^{2i}}{e((2i+1)/e)^{2i+1}} && \text{by } e(n/e)^n \le n! \\
\le&2^{-2i} && \text{by } i \gtrsim \tau \\
\le&\epsilon(1/s_1)^{O(\ell)} && \text{by } i \gtrsim \ell\log(s_1)+\log(1/\epsilon)
\end{aligned}
$$

Second, we can show that

$$\sum_{i=d+1}^{+\infty}(-1)\frac{\tau^{2i}}{(2i+1)!} \lesssim \frac{\tau^{2(d+1)}}{(2(d+1)+1)!} \leq \epsilon(1/s_1)^{O(\ell)}$$

Thus, we complete the proof. □

Claim 12.12.7. $\min_{t\in[-1/2,1/2]}|H(t)| \geq (s_1)^{-\Omega(\ell)}$.

Proof. By the property of $H(t)$,

$$\min_{\frac{1}{2}s_3<|t|\leq\frac{1}{2}} H(t) = \min_{|t|\leq\frac{1}{2}} H(t)$$

Thus, it suffices to prove a lower bound on $H(t)$ for any t such that $\frac{1}{2}s_3 < |t| \leq \frac{1}{2}$. Because of symmetric property, we only need to prove a lower bound for one side. Let's consider $t \in [\frac{1}{2}s_3, 1/2]$,

$$\begin{aligned}
H(t) &\geq \frac{s_0}{\pi s_1}\int_{(t-\frac{s_2}{2})\pi s_1}^{(t+\frac{s_2}{2})\pi s_1}(\frac{\sin(\tau)}{\tau})^{\ell}\mathrm{d}\tau \\
&\geq \frac{s_0}{\pi s_1}\int_{(t+\frac{s_2}{4})\pi s_1}^{(t+\frac{s_2}{2})\pi s_1}(\frac{\sin(\tau)}{\tau})^{\ell}\mathrm{d}\tau \\
&\geq \frac{s_0}{\pi s_1}\cdot\Theta((t+\frac{s_2}{2})s_1)\cdot\frac{1}{2}\cdot\pi\cdot\Theta((t+\frac{s_2}{2})\pi s_1)^{-\ell} \\
&\geq (s_1)^{-\Omega(\ell)}
\end{aligned}$$

□

12.12.2 Analysis of filter function $(G(t), \widehat{G}(f))$

We construct $(G(t), \widehat{G}(f))$ in a similar way of $(H_1(t), \widehat{H_1}(f))$ by switching the time domain and the frequency domain of $(H_1(t), \widehat{H_1}(f))$ and modify the parameters for the permutation hashing $P_{\sigma,a,b}$.

Definition 12.12.3. Given $B > 1$, $\delta > 0$, $\alpha > 0$, we construct $G(t), \widehat{G}(f)$ by doing the following operations,

- $s_2 = \frac{\pi}{2B}$,
- $s_1 = \frac{B}{\alpha\pi}$,
- $\ell = l = \Theta(\log(k/\delta))$.

Then $G(t), \widehat{G}(f)$ becomes

$$\begin{aligned} G(t) &= b_0 \cdot (\mathrm{rect}_{s_1}(t))^{*l} \cdot \mathrm{sinc}(ts_2) \\ &= b_0 \cdot (\mathrm{rect}_{\frac{B}{(\alpha\pi)}}(t))^{*l} \cdot \mathrm{sinc}(t\frac{\pi}{2B}), \\ \widehat{G}(f) &= b_0 \cdot (\mathrm{sinc}(s_1 f))^{\cdot l} * \mathrm{rect}_{s_2}(f) \\ &= b_0 \cdot (\mathrm{sinc}(\frac{B}{\alpha\pi} f))^{\cdot l} * \mathrm{rect}_{\frac{\pi}{2B}}(f). \end{aligned}$$

where the scalar $b_0 = \Theta(s_1\sqrt{l}) = \Theta(B\sqrt{l}/\alpha)$ satisfying $\widehat{G}(0) = 1$.

Lemma 12.6.5. Given $B > 1$, $\delta > 0$, $\alpha > 0$, we set $l = \Omega(\log(\delta/k))$. The filter function

$(G(t), \widehat{G}(f))[B, \delta, \alpha, l]$ satisfies the following properties,

$$\begin{aligned}
\text{Property I}: &\quad \widehat{G}(f) \in [1-\delta/k, 1], \text{ if } |f| \leq (1-\alpha)\frac{2\pi}{2B}. \\
\text{Property II}: &\quad \widehat{G}(f) \in [0, 1], \text{ if } (1-\alpha)\frac{2\pi}{2B} \leq |f| \leq \frac{2\pi}{2B}. \\
\text{Property III}: &\quad \widehat{G}(f) \in [-\delta/k, \delta/k], \text{ if } |f| > \frac{2\pi}{2B}. \\
\text{Property IV}: &\quad \mathrm{supp}(G(t)) \subset \Big[\frac{l}{2} \cdot \frac{-B}{\pi\alpha}, \frac{l}{2} \cdot \frac{B}{\pi\alpha}\Big]. \\
\text{Property V}: &\quad \max_t |G(t)| \lesssim \mathrm{poly}(B, l).
\end{aligned}$$

Proof. The first five Properties follows from Lemma 12.6.4 directly.

□

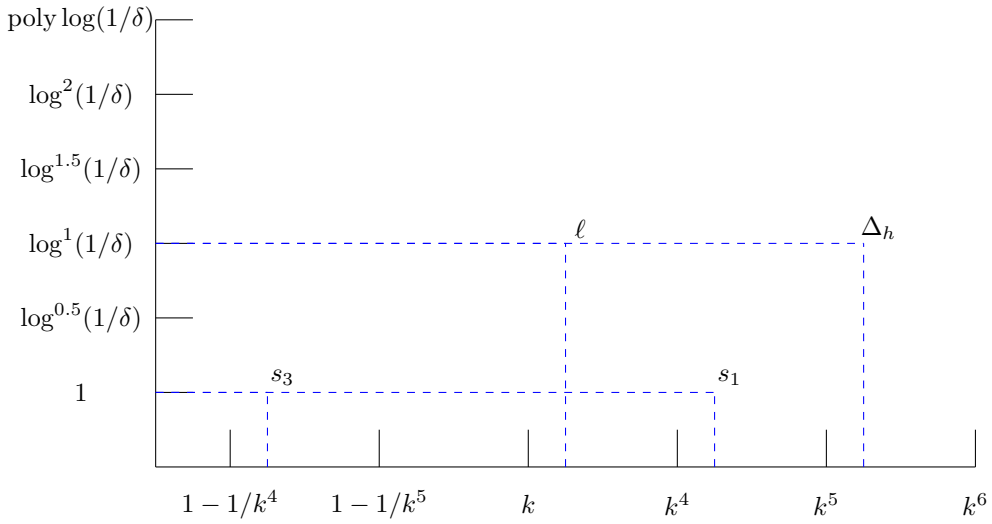

Figure 12.9: Parameters for s_1, s_3 and ℓ.

12.12.3 Parameters setting for filters

One-cluster Recovery. In one-cluster, we donot need filter function $(G(t), \widehat{G}(f))$.

In section 12.12.1, by Equation (12.34) in the proof of Property VI of filter function $(H(t), \widehat{H}(f))$, we need $\min(\frac{1}{1-s_3}, s_1) \geq \widetilde{O}(k^4)$.

In section 12.12.1, by Equation (12.32) in the proof of Property V of filter function $(H(t), \widehat{H}(f))$, we set $\ell \gtrsim k \log(k/\delta)$.

Δ_h is determined by the parameters of filter $(H(t), \widehat{H}(f))$ in Equation (12.35): $\Delta_h \approx \frac{s_1 \ell}{s_3 T}$ in section 12.12.1. Combining the setting of s_1, s_3 ℓ, we should set $\Delta_h \geq \widetilde{O}(k^5 \log(1/\delta))/T$.

k-cluster Recovery. Note that in the k-cluster recovery, we need to use filter function $(G(t), \widehat{G}(f))$. We choose $l = \log(k/\delta)$, $\alpha \approx 1$, $B \approx k$, and $D = l/\alpha$.

By proof of Property II of z in Lemma 12.7.18 from section 12.7.6, we need $T(1-s_3) >$

σBl. By the same reason in one-cluster recovery, $1-s_3 \leq \frac{1}{\widetilde{O}(k^4)}$. Combining $T(1-s_3) > \sigma Bl$ and $1-s_3 \leq \frac{1}{\widetilde{O}(k^4)}$, we obtain

$$\frac{T}{\widetilde{O}(k^4)} > \sigma Bl \tag{12.36}$$

Because in our algorithm, we will sample σ from $[\frac{1}{B\Delta_h}, \frac{2}{B\Delta_h}]$. Thus, plugging $\sigma = \Theta(\frac{1}{B\Delta_h})$ in Equation (12.36) we have

$$\frac{T}{\widetilde{O}(k^4)} > \frac{l}{\Delta_h}$$

which implies another lower bound for Δ_h,

$$\Delta_h \geq \widetilde{O}(k^4)l/T$$

Combining the above bound with previous lower bound in one-cluster recovery, we get

$$\Delta_h \geq \widetilde{O}(k^4 \log(1/\delta))/T + \widetilde{O}(k^5 \log(1/\delta))/T = \widetilde{O}(k^5 \log(1/\delta))/T$$

For s_1 and ℓ, we still choose the same setting as before, $s_1 \approx \widetilde{O}(k^4)$ and $\ell \approx O(k \log(k/\delta))$.

12.12.4 Analysis of HashToBins

In this section, we explain the correctness of Procedure HashToBins in Algorithm 12.6. Before giving the proof of that algorithm, we show how to connect CFT, DTFT and DFT.

Lemma 12.12.8. *For any signal $W : \mathbb{R} \to \mathbb{C}$, let $A : \mathbb{Z} \to \mathbb{C}$ and $B : [n] \to \mathbb{C}$ be defined as follows:*

$$A[i] = W(i), \forall i \in \mathbb{Z} \text{ and } B[i] = \sum_{j \in \mathbb{Z}} A[i + jn], \forall i \in [n].$$

Then we consider the Fourier transform on W, A, and B:

$$\begin{aligned} \text{CFT} \quad & \widehat{W} : \mathbb{R} \to \mathbb{C}, \\ \text{DTFT} \quad & \widehat{A} : [0, 1] \to \mathbb{C}, \\ \text{DFT} \quad & \widehat{B} : [n] \to \mathbb{C}. \end{aligned}$$

We have:

$$\forall f \in [0, 1), \widehat{A}(f) = \sum_{j \in \mathbb{Z}} \widehat{W}(f + j); \quad \forall i \in [n], \widehat{B}[i] = \sum_{j \in \mathbb{Z}} \widehat{W}(i/n + j).$$

Proof. Recall that $\mathrm{Comb}_s(t) = \sum_{j \in \mathbb{Z}} \delta_{js}(t)$. First, we show $\widehat{A}(f) = \sum_{j \in \mathbb{Z}} e^{2\pi \mathbf{i} j f} A[j]$ equals

to $\sum_{j\in\mathbb{Z}}\widehat{W}(f+j)$:

$$\begin{aligned}
\widehat{A}(f) = & \sum_{j\in\mathbb{Z}} e^{2\pi\mathbf{i}jf}W[j] && \text{by } A[j]=W(j)\\
= & \int_{-\infty}^{+\infty} e^{2\pi\mathbf{i}fj}W(j)\cdot \mathrm{Comb}_1(j)\mathrm{d}j\\
= & \widehat{W\cdot \mathrm{Comb}_1}(f)\\
= & (\widehat{W} * \widehat{\mathrm{Comb}_1})(f)\\
= & \sum_{j\in\mathbb{Z}} \widehat{W}(f+j). && (12.37)
\end{aligned}$$

Next, we prove that $\forall i\in[n], \widehat{B}[i]=\widehat{A}(i/n)$,

$$\begin{aligned}
\widehat{B}[i] = & \sum_{j=1}^{n} B[j]e^{\frac{2\pi\mathbf{i}}{n}ij} && \text{by DFT}\\
= & \sum_{j=1}^{n}(\sum_{k\in\mathbb{Z}} A[j+kn])e^{\frac{2\pi\mathbf{i}}{n}ij} && \text{by } B[j]=\sum_{k\in\mathbb{Z}}A[j+kn]\\
= & \sum_{j=1}^{n}\sum_{k\in\mathbb{Z}} A[j+kn]e^{\frac{2\pi\mathbf{i}}{n}i(j+kn)} && \text{by } e^{\frac{2\pi\mathbf{i}}{n}\cdot ikn}=1\\
= & \sum_{j\in\mathbb{Z}} A[j]e^{2\pi\mathbf{i}j\frac{i}{n}} = \widehat{A}(i/n) && \text{by DTFT.} \qquad (12.38)
\end{aligned}$$

Combining Equation (12.38) and Equation (12.37), we obtain that $\widehat{B}[j]=\widehat{A}(j/n)=\sum_{i\in\mathbb{Z}}\widehat{W}(j/n+i)$ for all $j\in[n]$. □

Claim 12.12.9. *Let $u\in\mathbb{C}^B$ and $V\in\mathbb{C}^{BD}$ such that for any $j\in B$, $u[j]=\sum_{i\in[D]}V[j+(i-1)B]$. Then*

$$\widehat{u}[j]=\widehat{V}[jD], \forall j\in[B].$$

Proof. We prove it through the definition of the Fourier transform:

$$\begin{aligned}
\widehat{V}[jD] = & \sum_{i=1}^{BD} V[i] \cdot e^{\frac{2\pi\mathbf{i}}{BD}\cdot i\cdot(jD)} && \text{by definition of DFT} \\
= & \sum_{i=1}^{B}\sum_{k=1}^{D} V[i+kB] e^{\frac{2\pi\mathbf{i}}{B}\cdot(i+kB)\cdot j} && \text{by replacing } i \text{ by } i+kB \\
= & \sum_{i=1}^{B} e^{\frac{2\pi\mathbf{i}}{B}\cdot j\cdot i}\sum_{k=1}^{D} V[i+(k-1)B] && \text{by } e^{2\pi\mathbf{i}jk}=1 \\
= & \sum_{i=1}^{B} e^{\frac{2\pi\mathbf{i}}{B}\cdot j\cdot i} u[i] = \widehat{u}[j] && \text{by definition of DFT on } u
\end{aligned}$$

□

We use Definition 12.6.1 and Lemma 12.6.1 to generalize Lemma 12.12.8,

Corollary 12.12.10. *If for all $j \in [n]$, $B[j] = \sum_{i\in\mathbb{Z}} W\big((j+in)\sigma - \sigma a\big)$, then $\forall j \in [n]$,*

$$\widehat{B}[j] = \sum_{i\in\mathbb{Z}} \widehat{W}\left((\frac{j}{n}+i)/\sigma\right)\cdot\frac{1}{\sigma}e^{-2\pi\mathbf{i}(\frac{j}{n}+i)a}.$$

If for all $j \in [n]$, $B[j] = \sum_{i\in\mathbb{Z}} W\big((j+in)\sigma - \sigma a\big)e^{-2\pi\mathbf{i}\sigma b(j+in)}$, then $\forall j \in [n]$,

$$\widehat{B}[j] = \sum_{i\in\mathbb{Z}} \widehat{W}\left((\frac{j}{n}+i)/\sigma + b\right)\cdot\frac{1}{\sigma}e^{-2\pi\mathbf{i}(\frac{j}{n}+i)a - 2\pi\mathbf{i}\sigma ab}.$$

Remark 12.12.2 (Samples of HashToBins). Procedure HashToBins in Algorithm 12.6 takes BD samples in $x(t)$:

$$x(\sigma(1-a)), x(\sigma(2-a)), \cdots, x(\sigma(BD-a)).$$

To analyze our algorithm, we use filter function $(G(t), \widehat{G}(f))$ and $\mathrm{Comb}_s(t) = \sum_{j\in\mathbb{Z}}\delta_{sj}(t)$ to define the discretization of G.

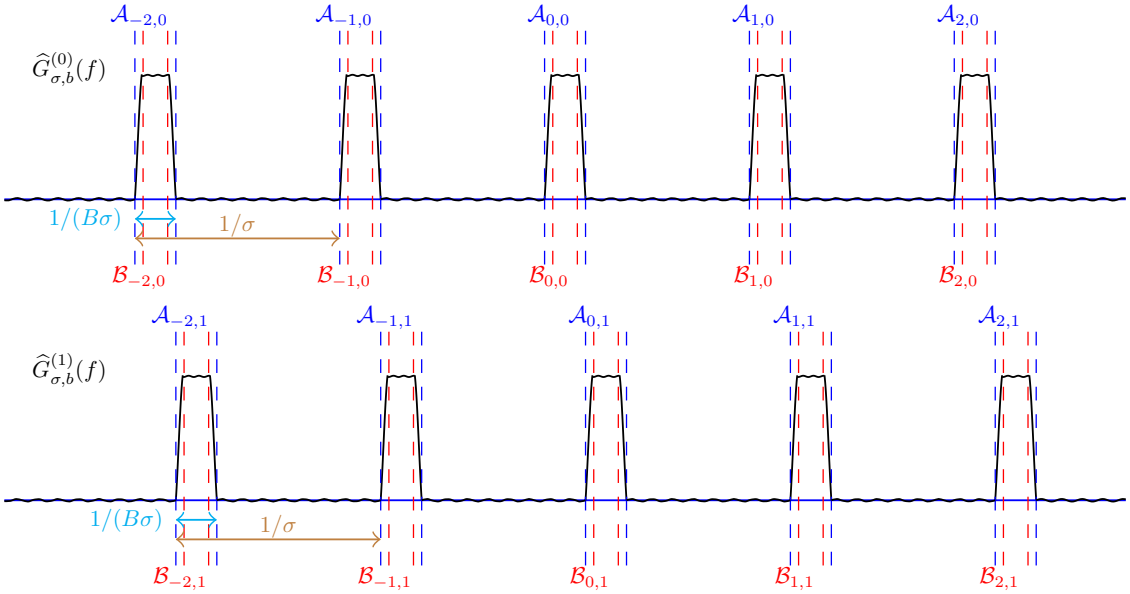

Figure 12.10: $\widehat{G}^{(j)}_{\sigma,b}(f)$ where the top one is $j = 0$ and the bottom one is $j = 1$, $\mathcal{A}_{i,j} = [\frac{1}{\sigma}(2\pi(i+\frac{j}{B}) - \frac{2\pi}{2B}), \frac{1}{\sigma}(2\pi(i+\frac{j}{B}) + \frac{2\pi}{2B})]$, $\mathcal{B}_{i,j} = [\frac{1}{\sigma}(2\pi(i+\frac{j}{B}) - \frac{2\pi(1-\alpha)}{2B}), \frac{1}{\sigma}(2\pi(i+\frac{j}{B}) + \frac{2\pi(1-\alpha)}{2B})]$

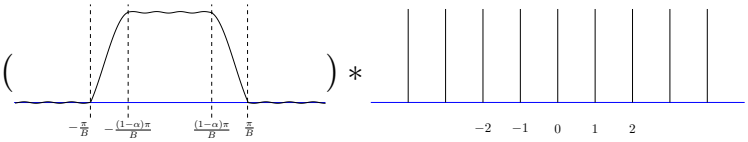
Definition 12.12.4. Define the discretization of $G(t)$ and $\widehat{G}(f)$,

$$
\begin{aligned}
G^{\text{dis}}(t) &= G(t) \cdot \text{Comb}_s(t) \\
\widehat{G}^{\text{dis}}(f) &= \frac{1}{s}(\widehat{G} * \text{Comb}_{1/s})(f) \\
&= (\widehat{G} * \text{Comb}_1)(f) \\
&= \Big(\quad \Big) * \quad
\end{aligned}
$$



where $|\text{supp}(G(t))| = \frac{lB}{\pi\alpha}$, $D = \frac{l}{\pi\alpha}$, $s = |\text{supp}(G(t))|/(BD) = l/(\pi\alpha D) = 1$.

Definition 12.6.6. $\forall \sigma > 0, b$ and $j \in [B]$. Define,

$$\begin{aligned} G^{(j)}_{\sigma,b}(t) &= \frac{1}{\sigma} G(t/\sigma) e^{2\pi \mathbf{i} t(j/B - \sigma b)/\sigma} \\ \widehat{G}^{(j)}_{\sigma,b}(f) &= \widehat{G}^{\mathrm{dis}}(\frac{j}{B} - \sigma f - \sigma b) = \sum_{i \in \mathbb{Z}} \widehat{G}(i + \frac{j}{B} - \sigma f - \sigma b) \end{aligned}$$

Lemma 12.6.7. Let $u \in \mathbb{C}^B$ be the result of HashToBins under permutation $P_{\sigma,a,b}$, and let $j \in [B]$. Define

$$\widehat{z} = \widehat{x \cdot H} \cdot \widehat{G}^{(j)}_{\sigma,b},$$

so

$$z = (x \cdot H) * G^{(j)}_{\sigma,b}.$$

Let vector $\widehat{u} \in \mathbb{C}^B$ denote the B-dimensional DFT of u, then $\forall j \in [B]$,

$$\widehat{u}[j] = z_{\sigma a}.$$

Proof. Recall B is the number of hash bins. $B \cdot D$ is the number of samples in time signal. Let $W(t) = x \cdot H(t)$, define vector $y \in \mathbb{C}^{BD}$, then $\forall j \in [BD]$, define

$$y[j] = W(\sigma(j - a)) e^{2\pi \mathbf{i} \sigma b j}$$

Recall $G(t)$ denote the $\mathrm{rect}^{*l}_{B/\alpha}(t) \cdot \mathrm{sinc}(t/B)$, then $|\mathrm{supp}(G(t))| = \frac{lB}{\alpha}$. Let vector $G' \in \mathbb{C}^{BD}$ is the discretization of $G(t)$, where $G'[i] = G(i)$. Then, $\forall j \in [B]$,

$$u[j] = \sum_{i \in [D]} V[j + iB]$$

where $V[j] = y[j] \cdot G'[j]$ and $G'[j]$ is the value at the jth nonzero point of $G^{\mathrm{dis}}(t)$. Applying Claim 12.12.9 with the definition of $u[j]$ and $V[j + iB]$, gives $\widehat{u}[j] = \widehat{V}[jD], \forall j \in [B]$.

Because of u is the result of HashToBins($x \cdot H, P_{\sigma,a,b}, G$) and $|\operatorname{supp}(G(t))| = BD$(choosing $D = l/\alpha$), then

$$u[j] = \sum_{i \in \mathbb{Z}} W(\sigma(j + iB - a))e^{-2\pi \mathbf{i}\sigma b(j+iB)}G(j + iB)$$

Then we define $G''(t) = G(t/\sigma + a)e^{-2\pi \mathbf{i}b\sigma(t/\sigma+a)}$ and $Y(t) = W(t) \cdot G''(t)$, then immediately, we have

$$\widehat{G''}(f) = \sigma\widehat{G}(\sigma(f - b))e^{2\pi \mathbf{i}a\sigma f} \quad \text{and} \quad \widehat{Y}(f) = \widehat{W}(f) * \widehat{G''}(f)$$

Thus, we can rewrite $u[j]$ in the following sense,

$$\begin{aligned}
& u[j] \\
= & \sum_{i \in \mathbb{Z}} W(\sigma(j + iB - a))e^{-2\pi \mathbf{i}\sigma b(j+iB)}G(j + iB) \\
= & \sum_{i \in \mathbb{Z}} W(\sigma(j + iB - a))G''(\sigma(j + iB - a)) && \text{by } G''(t) = G(t/\sigma + a)e^{-2\pi \mathbf{i}b\sigma(t/\sigma+a)} \\
= & \sum_{i \in \mathbb{Z}} Y(\sigma(j + iB - a)) && \text{by } Y(t) = W(t) \cdot G''(t)
\end{aligned}$$

Then

$$\begin{aligned}
&\widehat{u}[j] \\
=\ & \sum_{i\in\mathbb{Z}} \widehat{Y}((\frac{j}{B}+i)/\sigma)\cdot\frac{1}{\sigma}\cdot e^{-2\pi\mathbf{i}(\frac{j}{B}+i)a} && \text{by Corollary 12.12.10} \\
=\ & \sum_{i\in\mathbb{Z}} \int_{-\infty}^{+\infty} \widehat{W}(s)\cdot\widehat{G}''(\frac{j/B+i}{\sigma}-s)\cdot\frac{1}{\sigma}\cdot e^{-2\pi\mathbf{i}\cdot(j/B+i)a}\mathrm{d}s && \text{by } \widehat{Y}(f)=\widehat{W}(f)*\widehat{G}''(f) \\
=\ & \sum_{i\in\mathbb{Z}} \int_{-\infty}^{+\infty} \widehat{W}(s)\cdot\widehat{G}(j/B+i-\sigma s-\sigma b)\cdot e^{-2\pi\mathbf{i}\cdot(-\sigma s)a}\mathrm{d}s && \text{by } \widehat{G}''(f)=\sigma\widehat{G}(\sigma(f-b))e^{2\pi\mathbf{i}a\sigma f} \\
=\ & \int_{-\infty}^{+\infty} \widehat{W}(s)\cdot\sum_{i\in\mathbb{Z}}\widehat{G}((j/B+i)-\sigma s-\sigma b)e^{2\pi\mathbf{i}a\sigma s}\mathrm{d}s \\
=\ & \int_{-\infty}^{+\infty} \widehat{W}(s)\cdot\widehat{G}^{\mathrm{dis}}(\frac{j}{B}-\sigma s-\sigma b)e^{-2\pi\mathbf{i}a\sigma s}\mathrm{d}s && \text{by } \widehat{G}^{\mathrm{dis}}(f)=\sum_{i\in\mathbb{Z}}\widehat{G}(f+i)
\end{aligned}$$

By definition 12.12.4,

$$\widehat{G}^{(j)}_{\sigma,b}=\widehat{G}^{\mathrm{dis}}(\frac{j}{B}-\sigma s-\sigma b)=\sum_{i\in\mathbb{Z}}\widehat{G}(i+\frac{j}{B}-\sigma s-\sigma b)$$

By definition of $\widehat{z}$, we have

$$\widehat{z}(s)=\widehat{x\cdot H}(s)\cdot\widehat{G}^{(j)}(s)=\widehat{W}(s)\cdot\widehat{G}^{(j)}(s)$$

Then $\widehat{u}[j]$ is the $(a\sigma)^{th}$ inverse Fourier coefficients of $\widehat{z}$, basically,

$$\widehat{u}[j]=z_{a\sigma}=z(a\sigma)$$

Thus, we can conclude first computing vector $u\in\mathbb{C}^B$. Getting vector $\widehat{u}\in\mathbb{C}^B$ by using the Discrete Fourier transform $\widehat{u}=\mathrm{DFT}(u)$. This procedure allows us to sample from time domain to implicitly access the time signal's Fourier transform $\widehat{z}$. If z is one-cluster in frequency domain, then apply one-cluster recovery algorithm.

12.13 Algorithm

This section lists the pseudocode of our algorithms.

Algorithm 12.3 Get Empirical One Energy and Get Legal One Sample

procedure GetEmpirical1Energy(z, T, Δ) — Claim 12.7.10
  $R_{\text{est}} \leftarrow (T\Delta)^2$
  for $i = 1 \to R_{\text{est}}$ **do**
    Choose $\alpha_i \in [0, T]$ uniformly at random
    $z_{\text{emp}} \leftarrow z_{\text{emp}} + |z(\alpha_i)|^2$
  end for
  $z_{\text{emp}} \leftarrow \sqrt{z_{\text{emp}}/R_{\text{est}}}$
  return z_{emp}
end procedure
procedure GetLegal1Sample($z, \Delta, T, \beta, z_{\text{emp}}$) — Lemma 12.7.1
  $R_{\text{repeat}} \leftarrow (T\Delta)^3, S_{\text{heavy}} \leftarrow \emptyset$
  for $i = 1 \to R_{\text{repeat}}$ **do**
    Choose $\alpha_i \in [0, T]$ uniformly at random
    if $|z(\alpha_i)| \geq 0.5 \cdot z_{\text{emp}}$ **then**
      $S_{\text{heavy}} \leftarrow S_{\text{heavy}} \cup i$
    end if
  end for
  for $i \in S_{\text{heavy}}$ **do**
    $w(i) \leftarrow |z(\alpha_i)|^2 + |z(\alpha_i + \beta)|^2$
  end for
  $\alpha \leftarrow \alpha_i$ with probability $w(i) / \sum_{j \in S_{\text{heavy}}} w(j)$ for $i \in S_{\text{heavy}}$
  return α
end procedure

Algorithm 12.4 Locate One Signal, Locate One Inner, and Frequency Recovery One Cluster

procedure LOCATE1SIGNAL($z, T, F, \Delta, z_{\text{emp}}$) — Lemma 12.7.14
  Set $t \approx \log(FT)$, $t' = t/4$, $D_{\max} \approx \log_{t'}(FT)$, $R_{\text{loc}} \approx \log_{1/c}(tc)$, $L^{(1)} = 2F$
  for $i \in [D_{\max}]$ **do**
    $l \approx 2F/(t')^{i-1}\Delta$, $s \approx c$, $\widehat{\beta} = \frac{ts}{2\Delta l}$
    if $\widehat{\beta} \gtrsim T/(T\Delta)^{3/2}$ **then**
      break
    else
      $L^{(i)} \leftarrow$ LOCATE1INNER($z, \Delta, T, \widehat{\beta}, z_{\text{emp}}, L^{(i-1)}$)
    end if
  end for
  return $L^{(i)}$
end procedure
procedure LOCATE1INNER($z, \Delta, T, \widehat{\beta}, z_{\text{emp}}, \widetilde{L}$)
  Let $v_q \leftarrow 0$ for $q \in [t]$
  while $r = 1 \to R_{\text{loc}}$ **do**
    Choose $\beta \in [\frac{1}{2}\widehat{\beta}, \widehat{\beta}]$ uniformly at random
    $\gamma \leftarrow$ GETLEGAL1SAMPLE($z, \Delta, T, \beta, z_{\text{emp}}$)
    for $i \in [m]$ **do**

end procedure

Chapter 13

High Dimensional Fourier Transform

We consider the extensively studied problem of computing a k-sparse approximation to the d-dimensional Fourier transform of a length n signal. Our algorithm uses $O(k \log k \log n)$ samples, is dimension-free, operates for any universe size, and achieves the strongest ℓ_∞/ℓ_2 guarantee, while running in time comparable to the Fast Fourier Transform. All previous algorithms proceed either via the Restricted Isometry Property or via filter functions. Our approach totally departs from the aforementioned techniques, and we believe is a fresh look to the sparse Fourier transform problem.

13.1 Introduction

Initiated in discrete signal processing, compressed sensing/sparse recovery is an extensively studied branch of mathematics and algorithms, which postulates that a number of small linear measurements suffice to approximately reconstruct the best k-sparse approximation of a vector $x \in \mathbb{C}^n$ [CT06, CRT06b, Don06]. The literature on the subject is enormous, and has found applications in imaging, astronomy, seismology etc. One of the initial papers in the field, due to Candes, Romberg and Tao [CRT06a], counts almost $15,000$ references.

Probably the most important subtopic is the sparse Fourier transform, where one desires to reconstruct a k-sparse vector from Fourier measurements. In other words, measurements are not allowed to be generic, but have to belong to the so-called Fourier ensemble. In Optics imaging [Goo05, Voe11] and Magnetic resonance imaging (MRI) [ASSN08], the physics [Rey89] of the underlying device restricts us to the Fourier ensemble, where the sparse Fourier problem becomes highly relevant. In fact, one of the initial motivations of Candes, Romberg and Tao came out due to the aforementioned applications. The number of samples plays a crucial role: they determine the amount of radiation a patient receives in CT scans, and taking fewer samples can reduce the amount of time the patient needs to stay in the machine. The framework has found its way in practical life-changing applications. Software includes the Compressed Sensing GRAB-VIBE, CS SPACE, CS SEMAC and CS TOF by Siemens [Sie], as well as Compressed Sense by Phillips [Phi]. Its incorporation in the MRI technology allows faster acquisition rates, depiction of dynamic processes or moving organs, as well as acceleration of MRI scanning up to a factor of 40. On the webpage of SIEMENS Healthineers, for example, one can see the following, as well as numerous similar statements.

This allows bringing the advantages of Compressed Sensing GRASP-VIBE *to daily clinical routine.*

- *Perform push-button, free-breathing liver dynamics.*
- *Overcome timing challenges in dynamic imaging and respiratory artifacts.*
- *Expand the patient population eligible for abdominal* MRI.

The Fourier transform is in fact ubiquitous: image processing, audio processing, telecommunications, seismology, polynomial multiplication, SUBSET SUM and other textbook algorithms are a few of the examples where the Fast Fourier Transform finds applications. The Fast Fourier Transform by Cooley and Tukey [CT65] runs in $O(n \log n)$ time, and has far-reaching applications in all of the aforementioned cases. It is thus expected that algorithms which exploit sparsity assumptions about the input, and can outperform FFT in applications are of high practical value. Generally, the two most important parameters one would like to optimize are the sample complexity, i.e. the numbers needed to obtain from the time domain, as well as time needed to approximate the Fourier Transform.

Two different lines of research exist for the problem: the one focuses solely on sample complexity, while the other tries to achieve sublinear time while keeping the sample complexity as low as possible. The first line of research operates via the renowned Restricted Isometry Property (RIP), which proceeds by taking random samples and solving a linear/convex program, or an iterative thresholding procedure [CT06, DDTS06, TG07, BD08, DM08, RV08, BD09b, BD09a, NT09b, NV09, GK09, BD10, NV10, Fou11, Bou14, HR16]. The analysis of the algorithms is performed in the following way, in two steps. The first step ensures

that, after sampling an appropriate number of points from the time domain, the inverse DFT matrix restricted on the rows indexed by those points acts as a near isometry on the space of k-sparse vectors. All of the state of the art results [CT06, RV08, Bou14, HR16] employ chaining arguments to make the analysis of this sampling procedure as tight as possible. The second part is how to exploit the aforementioned near-isometry property to find the best k-sparse approximation to the signal. There the approaches either follow an iterative procedure which gradually denoise the signal [BD08, NT09b, NV09], or perform ℓ_1 minimization [CT06], a method that promotes sparsity of solutions.

The second line of research tries to implement arbitrary linear measurements via sampling Fourier coefficients [GL89, Man92, KM93, GGI+02, AGS03, GMS05, Iwe08, Iwe10, HIKP12a, HIKP12b, LWC13, Iwe13, PR14, IKP14, IK14, Kap16, Kap17, CI17, BZI17, MZIC17, LN19] and use sparse functions (in the time domain) which behave like bandpass filters in the frequency domain. The seminal work of Kapralov [Kap17] achieves $O(k \log n)$ samples and running time that is some log factors away from the sample complexity. This would be the end of the story, apart from the fact that this algorithm does not scale well with dimension, since it has an exponential dependence on d. Indeed, in many applications, one is interested in higher dimensions, rather than the one-dimensional case. The main reason[1] why this curse of dimensionality appears is due to the lack of dimension-independent ways to construct functions that approximate the ℓ_∞ ball and are sufficiently sparse in the time domain. A very nice work of Kapralov, Velingker and Zandieh [KVZ19] tries to remedy that by combining the standard execution of FFT with careful aliasing, but their algorithm

[1]But not the only one: pseudorandom permutations for sparse FT in high dimensions also incur an exponential loss, and it is not known whether this can be avoided.

works in a noiseless setting, and has a polynomial, rather than linear, dependence on k; the running time is polynomial in $k, \log n$ and the exponential dependence is avoided. It is an important and challenging question whether a robust and more efficient algorithm can be found.

We note that in many applications, such as MRI or computed tomography (CT), the main focus is the sample complexity; the algorithms that have found their way to industry are, to the best of our knowledge, not concerned with sublinear running time, but with the number of measurements, which determine the acquisition time, or in CT the radiation dose the patient receives. Lastly, we bring to the readers' attention the recent work on sparse Fourier transform in the continuous setting, see [Iwe10, Iwe13, Iwe13, BCG+12, PS15, CKPS16, AKM+19].

Our Contribution. We give a new algorithm for the sparse Fourier transform problem, which has $O(k \log n \log k)$ sample complexity for any dimension, and achieves the ℓ_∞/ℓ_2 guarantee[2], while running in time $\widetilde{O}(n)$. The previous state of the art algorithm that achieved such a guarantee is the work of Indyk and Kapralov [IK14], which has $2^{O(d \log d)} k \log n$ sample complexity; an exponentially worse dependence on d. The work of [HR16] obtains $O(k \log n \log^2 k)$ samples in any dimension, but has a much weaker guarantee, while their approach requires $\Omega(k \log n \log k)$ samples in high dimensions [Rao19]. Moreover, the algorithm in [IK14] operates when the universe size in each dimension is a power of 2, whereas there is no restriction in our work. To obtain our result, we introduce a set of new tech-

[2]This is the strongest guarantee in the sparse recovery literature. See also the caption of the table in Section 1.2

niques, deviating from previous work, which used the Restricted Isometry Property and/or filter functions.

13.1.1 Preliminaries

For any positive integer n, we use $[n]$ to denote $\{1, 2, \cdots, n\}$.

We assume that the universe size $n = p^d$ for any positive integer p. Our algorithm facilitates $n = \Pi_{j=1}^{d} p_j$ for any positive integers $p_1, \ldots, p_d$, but we decide to present the case $n = p^d$ for ease of exposition; the proof is exactly the same in the more general case. Let $\omega = e^{2\pi \mathbf{i}/p}$ where $\mathbf{i} = \sqrt{-1}$. We will work with the normalized d-dimensional Fourier transform

$$\widehat{x}_f = \frac{1}{\sqrt{n}} \sum_{t \in [p]^d} x_t \cdot \omega^{f^\top t}, \forall f \in [p]^d$$

and the inverse Fourier transform is

$$x_t = \frac{1}{\sqrt{n}} \sum_{f \in [p]^d} \widehat{x}_f \cdot \omega^{-f^\top t}, \forall t \in [p]^d.$$

For any vector x and integer k, we denote x_{-k} to be the vector obtained by zeroing out the largest (in absolute value) k coordinates from x.

13.1.2 Our result

Apart from being dimension-independent and working for any universe size, our algorithm satisfies ℓ_∞/ℓ_2, which is the strongest guarantee out of the standard guarantees considered in compressed sensing tasks. A guarantee G_1 is stronger than guarantee G_2 if for any k-sparse recovery algorithm that satisfies G_1 we can obtain a $\Omega(k)$-sparse recovery

algorithm that satisfies G_2. See also below for a comparison between ℓ_∞/ℓ_2 and ℓ_2/ℓ_2, the second stronger guarantee.

Previous work is summarized in Table 13.1. Our result is the following.

Theorem 13.1.1 (main result, informal version)**.** *Let $n = p^d$ where both p and d are positive integers. Let $x \in \mathbb{C}^{[p]^d}$. Let $k \in \{1, \ldots, n\}$. Assume that $R^* \geq \|\widehat{x}\|_\infty / \|\widehat{x}_{-k}\|_2$ where $\log R^* = O(\log n)$ (signal-to-noise ratio). There is an algorithm that takes $O(k \log k \log n)$ samples from x, runs in $\widetilde{O}(n)$ time, and outputs a $O(k)$-sparse vector y such that*

$$\|\widehat{x} - y\|_\infty \leq \frac{1}{\sqrt{k}} \|\widehat{x}_{-k}\|_2$$

holds with probability at least $1 - 1/\operatorname{poly}(n)$.

Comparison between ℓ_∞/ℓ_2 and ℓ_2/ℓ_2 (or ℓ_2/ℓ_1). For the sake of argument, we will consider only the ℓ_2/ℓ_2 guarantee which is stronger than ℓ_2/ℓ_1. The ℓ_2/ℓ_2 guarantee is the following: for $\widehat{x} \in \mathbb{C}^n$ one should output a z such that $\|\widehat{x} - z\|_2 \leq C\|\widehat{x}_{-k}\|_2$, where $C > 1$ is the approximation factor. Consider $C = 1.1$ [3], and think of the following signal: for a set S of size $0.05k$ we have $|\widehat{x}_i| = \frac{2}{\sqrt{k}} \|\widehat{x}_{\bar{S}}\|_2$. Then the all zeros vectors is a valid solution for the ℓ_2/ℓ_2 guarantee, since

$$\|\vec{0} - \widehat{x}\|_2^2 = \|\widehat{x}_S\|_2^2 + \|\widehat{x}_{\bar{S}}\|_2^2 = 0.05k \cdot \frac{4}{k} \|\widehat{x}_{\bar{S}}\|_2^2 + \|\widehat{x}_{\bar{S}}\|_2^2 = 1.2\|\widehat{x}_{\bar{S}}\|_2^2 < 1.1^2 \|\widehat{x}_{\bar{S}}\|_2^2.$$

[3] This is the case with the RIP based approaches, which obtain ℓ_2/ℓ_1. In fact many filter-based algorithms facilitate $(1 + \epsilon)$ on the right hand side, with the number of measurements being multiplied by ϵ^{-1}. By enabling the same dependence on ϵ^{-1} our algorithm facilitates a multiplicative ϵ factor on right hand side of the ℓ_∞/ℓ_2, which makes it much stronger. Thus, a similar argument can go through.

Table 13.1: $n = p^d$. We ignore the O for simplicity. The ℓ_∞/ℓ_2 is the strongest possible guarantee, with ℓ_2/ℓ_2 coming second, ℓ_2/ℓ_1 third and exactly k-sparse being the less strong. We note that [CT06, RV08, CGV13, Bou14, HR16] obtain a uniform guarantee, i.e. with $1 - 1/\text{poly}(n)$ they allow reconstruction of all vectors; ℓ_∞/ℓ_2 and ℓ_2/ℓ_2 are impossible in the uniform case [CDD09]. We also note that [RV08, CGV13, Bou14, HR16] give improved analysis of the Restricted Isometry property; the algorithm is suggested and analyzed (modulo the RIP property) in [BD08]. The work in [HIKP12a] does not explicitly state the extension to the d-dimensional case, but can easily be inferred from the arguments. [HIKP12a, IK14, Kap16, KVZ19] work when the universe size in each dimension are powers of 2. We also assume that the signal-to-noise ratio is bounded by a polynomial of n, which is a standard assumption in the sparse Fourier transform literature [HIKP12a, IK14, Kap16, Kap17, LN19].

It is clear that since $\vec{0}$ is a possible output, we may not recover any of the coordinates in S, which is the set of "interesting" coordinates. On the other hand, the ℓ_∞/ℓ_2 guarantee does allow the recovery of every coordinate in S. This is a difference of recovering all $0.05k$ versus 0 coordinates. From the above discussion, one can conclude in the case where there is too much noise, ℓ_2/ℓ_2 becomes much weaker than ℓ_∞/ℓ_2, and can be even meaningless. Thus, ℓ_∞/ℓ_2 is highly desirable, whenever it is possible. The same exact argument holds for

ℓ_2/ℓ_1.

13.1.3 Summary of previous Filter function based technique

One of the two ways to perform Fourier sparse recovery is by trying to implement arbitrary linear measurements, with algorithms similar to the ubiquitous CountSketch [CCF02]. In the general setting CountSketch hashes every coordinate to one of the $O(k)$ buckets, and repeats $O(\log n)$ times with fresh randomness. Then, it is guaranteed that every heavy coordinate will be isolated, and the contribution from non-heavy elements is small. To implement this in the Fourier setting becomes a highly non-trivial task however: one gets access only to the time-domain but not the frequency domain. One natural way to do this is to exploit the convolution theorem and find a function which is sparse in the time domain and approximates the indicator of an interval (rectangular pulse) in the frequency domain; these functions are called (bandpass) filters. Appropriate filters were designed in [HIKP12a, HIKP12b]: they were very good approximations of the rectangular pulse, i.e. the contribution from elements outside the passband zone contributed only by $1/\operatorname{poly}(n)$ their mass. These filters had an additional $\log n$ factor (in one dimension) in the sparsity of the time domain and they are sufficient for the purposes of [HIKP12a], but in high dimensions this factor becomes $\log^d n$. Filters based on the Dirichlet kernel give a better dependence in terms of sparsity and dimension (although still an exponential dependence on the latter), but the leak to subsequent buckets, i.e. coordinates outside the passband zone contribute a constant fraction of their mass, in contrast to the filter used in [HIKP12a]. Thus one should perform additional denoising, which is a non-trivial task. The seminal work of Indyk and Kapralov [IK14] was the first that showed how to perform sparse recovery with these

filters, and then Kapralov [Kap16, Kap17] extended this result to run in sublinear time. We note, that any filter-based approach with filters which approximate the ℓ_∞ box, suffers from the curse of dimensionality. [KVZ19] devised an algorithm which avoids the curse of dimensionality by using careful aliasing, but it works in the noiseless case and has a cubic dependence on k.

13.1.4 RIP property-based algorithms: a quick overview

We say the matrix $A \in \mathbb{C}^{m\times n}$ satisfies RIP (Restricted Isometry Property [CT05]) of order k if for all k-sparse vectors $x \in \mathbb{C}^n$ we have $\|Ax\|_2^2 \approx \|x\|_2^2$. A celebrated result of Candes and Tao [CT06] shows that Basis Pursuit (ℓ_1 minimization) suffices for sparse recovery, as long as the samples from the time domain satisfy RIP. In [CT06] it was also proved using generic chaining that random sampling with oversampling factor $O(\log^6 n)$ gives RIP property for any orthonormal matrix with bounded entries by $1/\sqrt{n}$. Then [RV08] improved the bound to $O(k\cdot\log^2 k\cdot\log(k\log n)\cdot\log n)$ and [CGV13] improved it to $O(k\cdot\log^3 k\cdot\log n)$. Subsequent improvement by Bourgain [Bou14] has lead to $O(k\log k\cdot\log^2 n)$ samples, improved by Haviv and Regev to $O(k\log^2 k\cdot\log n)$[HR16]. The fastest set of algorithms are iterative ones: for example Iterative Hard Thresholding [BD09a] or CoSaMP [NT09b] run $O(\log n)$ iterations[4] and each iteration takes $\widetilde{O}(n)$ time.

We note the very recent lower bound of [Rao19]: a subsampled Fourier matrix that satisfies the RIP properties should have $\Omega(k\log k\cdot d)$ rows[5]. This bound is particularly useful in high dimensions, since it deteriorates to a trivial bound in low dimensions. We still believe

[4] To be precise, their running time is logarithmic in the signal-to-noise ratio, but we assumed throughout the paper that this quantity is polynomial in n.

[5] [BLLM19] independently gives a similar bound for $d = \log n$.

though that a bound of $\Omega(k \log k \log n)$ should hold in all dimensions. Thus, what remains is to obtain the ℓ_2/ℓ_2 guarantee by giving a tighter analysis, and removing the one $\log k$ factor to match the lower bound, but our algorithm already allows Fourier sparse recovery with these number of samples, even with a stronger guarantee.

13.1.5 Overview of our technique

Let $x \in \mathbb{C}^{[p]^d}$ denote our input signal in the time domain. In the following we assume the knowledge of $\mu = \frac{1}{\sqrt{k}}\|\widehat{x}_{-k}\|_2$ and R^* which is an upper bound of $\|\widehat{x}\|_\infty/\mu$, and bounded by $\mathrm{poly}(n)$. These are standard assumption [HIKP12a, IK14, Kap16, Kap17, LN19] in the sparse Fourier transform literature. The bound on R^* is useful for bounding the running time (or the number of measurements in [HIKP12a]) and in any of [HIKP12a, IK14, Kap16, Kap17, LN19] a $\log n$ can be substituted by $\log R^*$ in the general case, which is also the case for our algorithm. We note that our algorithm will be correct with probability $1 - 1/\mathrm{poly}(n)$ whenever $R^* < 2^{n^{100}}$; this is fine for every reasonable application. We assumed the rounding errors in FFT computation to be negligible, similarly to Remark 3.4 in [IK14].

Consider the simplest scenario: $d = 1$, p is a prime number and a 1-sparse signal $\widehat{x}$ which is 1 on some frequency f^*. From a sample x_t in the time-domain what would be the most reasonable way to find f^*? For every $f \in [p]$ we would compute

$$\sqrt{n}\omega^{ft}x_t = \sqrt{n}\omega^{ft} \cdot \frac{1}{\sqrt{n}} \sum_{f' \in [p]} \omega^{-f't}\widehat{x}_{f'} = \omega^{(f-f^*)t},$$

and keep, for $t \neq 0$, the frequency that gives a real number. Since $(f - f^*)t$ will be zero only for $f = f^*$, we are guaranteed correct recovery. In the noisy and multi-dimensional case or p is an arbitrary integer, however, this argument will not work, because of the presence of

contribution from other elements and the fact that $(f - f^*)^\top t$ can be zero modulo p for other frequencies apart from f. However, we can take a number of samples t and average $\sqrt{n}\omega^{f^\top t}$, and hope that this will make the contribution from other frequencies small enough, so that we can infer whether f corresponds to a heavy coordinate or not. More specifically, we pick a list T of size $O(k)$ uniformly at random from $[p]^d$ and compute

$$\frac{\sqrt{n}}{|T|} \sum_{t \in T} \omega^{f^\top t} x_t$$

for all frequencies f. We show that if $|T| = O(k)$ our estimator is good on average (and later we will maintain $O(\log n)$ independent instances and take the median to make sure with probability $1 - 1/\operatorname{poly}(n)$ the estimators for all the frequencies are good), and in fact behaves like a crude filter, similarly to the ones used in [IK14], in the sense that every coordinate contributes a non-trivial amount to every other coordinate. However, these estimators do not suffer from the curse of dimensionality and our case is a little bit different, requiring a quite different handling. The main reason is that in contrast to the filters used in [IK14], there is not an easy way to formulate an isolation argument from heavy elements that would allow easy measurement re-use, like Definition 5.2 and Lemma 5.4 from [IK14]. Buckets induced by filter functions have a property of locality, since they correspond to approximate ℓ_∞ boxes (with a polynomial decay outside of the box) in $[p]^d$: the closer two buckets are the more contribute the elements of one into the other. Our estimators on the other side do not enjoy such a property. Thus, one has to go via a different route.

In what follows, we will discuss how to combine the above estimators with an iterative loop that performs denoising, i.e. removes the contribution of every heavy element to other heavy elements.

We first implement a procedure which takes $O(k \log n)$ uniform random measurements from x and has the guarantee that for any $\nu \geq \mu$ any $y \in \mathbb{C}^{[p]^d}$ where $\|\widehat{x} - y\|_\infty \leq 2\nu$ and y is independent from the randomness of the measurements, the procedure outputs a $O(k)$-sparse $z \in \mathbb{C}^{[p]^d}$ such that $\|\widehat{x} - y - z\|_\infty \leq \nu$ with probability $1 - 1/\operatorname{poly}(n)$.

Lemma 13.1.2 (LinfinityReduce procedure/data structure, informal)**.** *Let $\mu = \frac{1}{\sqrt{k}}\|\widehat{x}_{-k}\|_2$, and $\nu \geq \mu$. Let $\mathcal{T}^{(0)}$ be a list of $O(k \log n)$ i.i.d. elements in $[p]^d$. Let S be top $O(k)$ coordinates in $\widehat{x}$. There is a procedure that takes $\{x_t\}_{t \in \mathcal{T}}$, $y \in \mathbb{C}^{[p]^d}$ and ν as input, runs in $\widetilde{O}(n)$ time, and outputs $z \in \mathbb{C}^{[p]^d}$ so that if $\|\widehat{x} - y\|_\infty \leq 2\nu$, $\operatorname{supp}(y) \subseteq S$ and y is independent from the randomness of $\mathcal{T}^{(0)}$, then $\|\widehat{x} - y - z\|_\infty \leq \nu$ and $\operatorname{supp}(z) \subseteq S$ with probability $1 - 1/\operatorname{poly}(n)$ under the randomness of $\mathcal{T}^{(0)}$.*

Namely, we can take $O(k \log n)$ measurements and run the procedure in Lemma 13.1.2 to reduce (the upper bound of) the ℓ_∞ norm of the residual signal by half. We call the procedure in Lemma 13.1.2 LinfinityReduce procedure. More generally, we can take $O(H \cdot k \log n)$ measurements and run the LinfinityReduce procedure H times to reduce the ℓ_∞ norm of the residual signal to $1/2^H$ of its original magnitude, with failure probability at most $1/\operatorname{poly}(n)$. This is because if $\nu \geq 2^H \mu$ and $\|\widehat{x} - y\|_\infty \leq \nu$, then we can proceed in H iterations where in the h-th iteration ($h \in [H]$) we can take $O(k \log n)$ fresh measurements from x and run the LinfinityReduce procedure to make the ℓ_∞ norm of the residual signal at most $2^{-h}\nu$. Note that if we set $H = \log R^*$, we have already obtained a recovery algorithm taking $O(k \log n \log R^*)$ measurements, because we can drive down (the upper bound of) the ℓ_∞ norm of the residual signal from $\|\widehat{x}\|_\infty$ to μ in $\log R^*$ iterations.

13.1.5.1 $O(k \log n)$ measurements for $k = O(\log n)$

We first discuss a measurement reuse idea that leads us to a sparse recovery algorithm (Algorithm 13.1) taking $O(k \log n)$ measurements for $k = O(\log n)$. We set $H = 5$, and let $\mathcal{T} = \{\mathcal{T}^{(1)}, \ldots, \mathcal{T}^{(H)}\}$, where each $\mathcal{T}^{(h)}$ is a list of $O(k \log n)$ i.i.d. elements in $[p]^d$. Note that $\mathcal{T}^{(1)}, \ldots, \mathcal{T}^{(H)}$ are independent. In our sparse Fourier recovery algorithm, we will measure x_t for all $t \in \mathcal{T}$.

In a nutshell, our approach finely discretizes the space of possible trajectories the algorithm could evolve, and carefully argues about the correctness of the algorithm by avoiding the intractable union-bound over all trajectories.

Recovery algorithm. The recovery algorithm proceeds in $\log R^* - H + 1$ iterations, where each iteration (except the last iteration) the goal is to reduce the upper bound of ℓ_∞ norm of the residual signal by half. Initially, the upper bound is R^*. It is important to note that we use the same measurements $\mathcal{T} = \{\mathcal{T}^{(1)}, \ldots, \mathcal{T}^{(H)}\}$ in all of these $\log R^* - H + 1$ iterations.

In the following, we will describe one iteration of the recovery algorithm. Let $y \in \mathbb{C}^{[p]^d}$ denote the sparse vector recovered so far, and let the upper bound of $\|\widehat{x} - y\|_\infty$ be 2ν. Running the LinfinityReduce procedure H times where in the h-th time we use measurements in $\mathcal{T}^{(h)}$, we obtain a $O(k)$-sparse z such that with probability $1 - 1/\operatorname{poly}(n)$, $\|\widehat{x} - y - z\|_\infty \leq 2^{1-H}\nu \leq 0.1\nu$ (we call such z a desirable output by the LinfinityReduce procedure). Instead of taking $y + z$ as our newly recovered sparse signal, for each $f \in \operatorname{supp}(y + z)$, we project $y_f + z_f$ to the nearst points in $\mathcal{G}_{0.6\nu} := \{0.6\nu(x + y\mathbf{i}) : x, y \in \mathbb{Z}\}$ and assign to y'_f, where y' denotes our newly recovered sparse signal. For all $f \notin \operatorname{supp}(y + z)$, we let $y'_f = 0$.

Algorithm 13.1 Fourier Sparse Recovery by Projection, $O(k \log n)$ Measurements When $k = O(\log n)$

procedure FOURIERSPARSERECOVERYBYPROJECTION(x, n, k, μ, R^*) ▷ Section 13.1.5.1
  Require that $\mu = \frac{1}{\sqrt{k}}\|\widehat{x}_{-k}\|_2$ and $R^* \geq \|\widehat{x}\|_\infty / \mu$
  $H \leftarrow 5$, $\nu \leftarrow \mu R^*/2$, $y \leftarrow \vec{0}$ ▷ $y \in \mathbb{C}^{[p]^d}$ refers to the sparse vector recovered so far
  Let $\mathcal{T} = \{\mathcal{T}^{(1)}, \cdots, \mathcal{T}^{(H)}\}$ where each $\mathcal{T}^{(h)}$ is a list of i.i.d. uniform samples in $[p]^d$
  while true do
    $\nu' \leftarrow 2^{1-H}\nu$
    Use $\{x_t\}_{t \in \mathcal{T}}$ to run the LINFINITYREDUCE procedure (in Lemma 13.1.2) H times (use samples in $\mathcal{T}^{(h)}$ for each $h \in [H]$), and finally it finds z so that $\|\widehat{x} - y - z\|_\infty \leq \nu'$
    if $\nu' \leq \mu$ **then return** $y + z$ ▷ We found the solution
    $y' \leftarrow \vec{0}$
    for $f \in \mathrm{supp}(y + z)$ **do**
      $y'_f \leftarrow \Pi_{0.6\nu}(y_f + z_f)$ ▷ We want $\|\widehat{x} - y'\|_\infty \leq \nu$ and the dependence between y' and $\mathcal{T}$ is under control
    end for
    $y \leftarrow y'$, $\nu \leftarrow \nu/2$
  end while
end procedure

To simplify our exposition, here we introduce some notations. We call $\mathcal{G}_{0.6\nu}$ a grid of side length 0.6ν, and we generalize the definition to any side length. Namely, for any $r_g > 0$, let grid $\mathcal{G}_{r_g} := \{r_g(x + y\mathbf{i}) : x, y \in \mathbb{Z}\}$. Moreover, we define $\Pi_{r_g} : \mathbb{C} \to \mathcal{G}_{r_g}$ to be the mapping that maps any element in $\mathbb{C}$ to the nearest element in $\mathcal{G}_{r_g}$. Now we can write y' as

$$y'_f = \begin{cases} \Pi_{0.6\nu}(y_f + z_f), & \text{if } f \in \mathrm{supp}(y + z); \\ 0, & \text{if } f \notin \mathrm{supp}(y + z). \end{cases}$$

At the end of each iteration, we assign y' to y, and shrink ν by half. In the last iteration, we will not compute y', instead we output $y + z$. We present the algorithm in Algorithm 13.1.

Analysis. We analyze y' conditioned on the event that $\|\widehat{x} - y - z\|_\infty \leq 0.1\nu$ (i.e. z is a desirable output by the LinfinityReduce procedure, which happens with probability $1 - 1/\operatorname{poly}(n)$). We will prove that y' has two desirable properties: (1) $\|\widehat{x} - y'\|_\infty \leq \nu$; (2) the dependence between y' and our measurements $\mathcal{T}$ is under control so that after taking y' as newly recovered sparse signal, subsequent executions of the LinfinityReduce procedure with measurements $\mathcal{T}$ still work with good probability. Property (1) follows from triangle inequality and the fact that $\|\widehat{x} - (y+z)\|_\infty \leq 0.1\nu$ and $\|(y+z) - y'\|_\infty \leq 0.6\nu$. We now elaborate on property (2). We can prove that for any $f \in [p]^d$,

$$y'_f \in \left\{\Pi_{0.6\nu}(\widehat{x}_f + 0.1\nu(\alpha + \beta\mathbf{i})) : \alpha, \beta \in \{-1, 1\}\right\}.$$

Let S denote top $26k$ coordinates (in absolute value) of $\widehat{x}$. We can further prove that for any $f \in \overline{S}$, $y'_f = 0$. Therefore, the total number of possible y' is upper bounded by $4^{|S|} = 4^{O(k)}$. If $k = O(\log n)$, we can afford union bounding all $4^{O(k)} = \operatorname{poly}(n)$ possible y', and prove that with probability $1 - 1/\operatorname{poly}(n)$ for all possible value of y' if we take y' as our newly recovered sparse signal then in the next iteration the LinfinityReduce procedure with measurements $\mathcal{T}$ gives us a desirable output.

Sufficient event. More rigorously, we formulate the event that guarantees successful execution of Algorithm 13.1. Let $\mathcal{E}_1$ be the event that for all $O(\log R^*)$ possible values of $\nu \in \{\mu\frac{R^*}{2}, \mu\frac{R^*}{4}, \ldots, \mu 2^{H-1}\}$, for all possible vector y where $y_f = 0$ for $f \in \overline{S}$ and $y_f \in \{\Pi_{0.6\nu}(\widehat{x}_f + 0.1\nu(\alpha + \beta\mathbf{i})) : \alpha, \beta \in \{-1, 1\}\}$ for $f \in S$ (we also need to include the case that $y = \vec{0}$ for the success of the first iteration), running the LinfinityReduce procedure (in Lemma 13.1.2) H times (where in the h-th time measurements $\{x_t\}_{t \in \mathcal{T}^{(h)}}$ are used

to reduce the error from $2^{2-h}\nu$ to $2^{1-h}\nu$) finally gives z so that $\|\widehat{x}-y-z\|_\infty \le 2^{1-H}\nu$. The randomness of $\mathcal{E}_1$ comes from $\mathcal{T} = \{\mathcal{T}^{(1)}, \ldots, \mathcal{T}^{(H)}\}$.

First, event $\mathcal{E}_1$ happens with probability $1 - 1/\operatorname{poly}(n)$. This is because there are $4^{O(k)} \log R^*$ possible combinations of ν and y to union bound, and each has failure probability at most $1/\operatorname{poly}(n)$. For $k = O(\log n)$, and any $R^* < 2^{n^{100}}$ this gives the desired result. Second, conditioned on event $\mathcal{E}_1$ happens, Algorithm 13.1 gives correct output. This can be proved by a mathematical induction that in the t-th iteration of the while-true loop in Algorithm 13.1, $\|\widehat{x}-y\|_\infty \le 2^{-t}\mu R^*$.

13.1.5.2 $O(k \log k \log n)$ measurements for arbitrary k

Using random shift to reduce projection size. We remark that in the analysis of the previous recovery algorithm, if we can make sure that every $y_f + z_f$ has only one possible outcome when projecting to the grid $\mathcal{G}_{0.6\nu}$, then we no longer need to union bound $4^{O(k)}$ events. However, if $\widehat{x}_f$ is very close to a grid point in $\mathcal{G}_{0.6\nu}$ (or $\widehat{x}_f \in \mathcal{G}_{0.6\nu}$), then no matter how close $y_f + z_f$ and $\widehat{x}_f$ are, $\Pi_{0.6\nu}(y_f + z_f)$ will have 4 possible values.

To address this, we introduce random shift, whose property is captured by Lemma 13.1.3. To simplify notation, for any $r_b > 0$ and $c \in \mathbb{C}$ we define box $\mathcal{B}_\infty(c, r_b) := \{c + r_b(x + y\mathbf{i}) : x, y \in [-1, 1]\}$. For any $S \subseteq \mathbb{C}$, let $\Pi_{r_g}(S) = \{\Pi_{r_g}(c) : c \in S\}$.

Lemma 13.1.3 (property of a randomly shifted box, informal)**.** *If we take a box of side length $2r_b$ and shift it randomly by an offset in $\mathcal{B}_\infty(0, r_s)$ (or equivalently, $[-r_s, r_s] \times [-r_s, r_s]$) where $r_s \ge r_b$, and next we round every point inside that shifted box to the closest point in G_{r_g} where $r_g \ge 2r_s$, then with probability at least $(1 - r_b/r_s)^2$ everyone will be rounded to the same point.*

In the following, we present a sparse Fourier recovery algorithm that incorporates the random shift idea. The algorithm takes $O(k \log k \log n)$ measurements. We set $H = O(\log k)$ and take measurements of $\mathcal{T} = \{\mathcal{T}^{(1)}, \ldots, \mathcal{T}^{(H)}\}$, where $\mathcal{T}^{(h)}$ is a list of $O(k \log n)$ i.i.d elements in $[p]^d$. Note that $\mathcal{T}^{(1)}, \ldots, \mathcal{T}^{(H)}$ are independent, and the choice of H is different from Section 13.1.5.1.

In a nutshell, our approach finely discretizes the space of possible trajectories the algorithm could evolve; in contrast to the case of $k = O(\log n)$, the number of trajectories becomes much larger. For that, we perform random shifting after the samples are taken, such that the number of trajectories is pruned, and we need to argue for a much smaller collection of events. We note that we make the decoding algorithm be randomized: the randomness in previous algorithms was present only when taking samples, and the rest of the algorithm was deterministic. However, here we need randomness in both cases, and that helps us prune the number of possible trajectories. To the best of our knowledge, this is a novel argument and approach, and might be helpful for future progress in the field.

Recovery algorithm. Similar to the $k = O(\log n)$ case (Section 13.1.5.1), we assume that we have already obtained a $O(k)$-sparse $y \in \mathbb{C}^{[p]^d}$ such that $\|\widehat{x} - y\|_\infty \leq 2\nu$ and y is "almost" independent from $\mathcal{T}$. We show how to obtain $y' \in \mathbb{C}^{[p]^d}$ such that $\|\widehat{x} - y'\|_\infty \leq \nu$ with probability $1 - 1/\operatorname{poly}(n)$ and y' is "almost" independent from $\mathcal{T}$. The main idea is we first run LinfinityReduce procedure $H = O(\log k)$ times to get an $O(k)$-sparse $z \in \mathbb{C}^{[p]^d}$ such that $\|\widehat{x} - y - z\|_\infty \leq \frac{1}{2^{20}k}\nu$. Then we repeatedly sample a uniform random shift $s \in \mathbb{C}$ (where $\|s\|_\infty \leq 10^{-3}\nu$; here we consider complex numbers as 2D vectors) until for every $f \in \operatorname{supp}(y + z)$, all the points (or complex numbers) of the form $y_f + z_f + s + a + b\mathbf{i}$ where

    repeat
      Pick $s \in \mathcal{B}_\infty(0, 10^{-3}\nu)$ uniformly at random
    until $\forall f \in \mathrm{supp}(y+z), |\Pi_{0.04\nu}(\mathcal{B}_\infty(y_f + z_f + s, \nu'))| = 1$
    $y' \leftarrow \vec{0}$
    for $f \in \mathrm{supp}(y+z)$ **do**
      $y'_f \leftarrow \Pi_{0.04\nu}(y_f + z_f + s)$ ▷ We want $\|\widehat{x} - y'\|_\infty \leq \nu$ and the dependence between y' and $\mathcal{T}$ is under control
    end for
    $y \leftarrow y'$, $\nu \leftarrow \nu/2$
  end while
end procedure

$a, b \in [-\frac{\nu}{2^{20}k}, \frac{\nu}{2^{20}k}]$ round to the same grid point in $\mathcal{G}_{0.04\nu}$. Finally, for every $f \in \mathrm{supp}(y+z)$, we assign $\Pi_{0.04\nu}(y_f + z_f + s)$ to y'_f; all remaining coordinates in y' will be assigned to 0. We present an informal version of our algorithm in Algorithm 13.2, and defer its formal version to the appendix.

Analysis. Now we analyze the above approach. First, we have the guarantee that $\|\widehat{x} - y'\|_\infty \leq \nu$. Moreover, note that by our choice of s, for every $f \in \mathrm{supp}(y+z)$, $y_f + z_f + s$ and $\widehat{x}_f + s$ round to the same grid point in $\mathcal{G}_{0.04\nu}$. Therefore, for the new vector y' we

have recovered, we "hide" the randomness in $\mathcal{T}$, and the randomness only leaks from failed attempts of the shifts. In the following, we show that each attempt of shift succeeds with probability $\frac{1}{2}$.

We can restate the procedure of choosing s to be:

repeatedly sample $s \sim \mathcal{B}_\infty(0, 10^{-3}\nu)$,

until for all $f \in \mathrm{supp}(y+z)$, $\left|\Pi_{0.04\nu}\left(\mathcal{B}_\infty\left(y_f + z_f + s, \frac{\nu}{2^{20}k}\right)\right)\right| = 1$.

Note that $|\mathrm{supp}(y+z)| = O(k)$. Let us say that we can always guarantee that $|\mathrm{supp}(y+z)| \le 50k$. By Lemma 13.1.3 where we let $r_b = \frac{\nu}{2^{20}k}$, $r_s = 10^{-3}\nu$ and $r_g = 0.04\nu$, for $f \in \mathrm{supp}(y+z)$,

$$\Pr\left[\left|\Pi_{0.04\nu}\left(\mathcal{B}_\infty\left(y_f + z_f + s, \frac{\nu}{2^{20}k}\right)\right)\right| = 1\right] \ge (1 - \frac{r_b}{r_s})^2 \ge 1 - \frac{1}{100k}.$$

By a union bound over $f \in \mathrm{supp}(y+z)$, the probability is at least $\frac{1}{2}$ that for all $f \in \mathrm{supp}(y+z)$, $|\Pi_{0.04\nu}(\mathcal{B}_\infty(y_f + z_f + s, \frac{\nu}{2^{20}k}))| = 1$.

Therefore, with probability $1 - 1/\mathrm{poly}(n)$, we will only try $O(\log n)$ shifts. We can apply a union bound over $O(\log n)$ possible shifts, and prove that with probability $1 - 1/\mathrm{poly}(n)$ if taking y' as our new y, and shrinking ν by half, the LinfinityReduce procedure will work as desired as if there is no dependence issue.

Sufficient event. Let S be top $O(k)$ coordinates in $\widehat{x}$. Let $L = O(\log R^*)$ denote the number of iterations in Algorithm 13.2. For $\ell \in [L]$, let $\nu_\ell = 2^{-\ell}\mu R^*$. For $\ell \in [L-1]$, let $s_\ell^{(a)}$ be the a-th uniform randomly sampled from $\mathcal{B}_\infty(0, 10^{-3}\nu_\ell)$ as appeared on Line 10 in Algorithm 13.2. For the sake of analysis, we assume that Algorithm 13.2 actually produces an infinite sequence of shifts $s_\ell^{(1)}, s_\ell^{(2)}, \ldots$. We formulate the event that guarantees successful

execution of Algorithm 13.2. We define event $\mathcal{E}_2$ to be all of the following events hold.

1. For all $\ell \in [L-1]$, there exists $a \in [10 \log n]$ so that for all $f \in S$,

$$\left| \Pi_{0.04\nu_\ell} \left(\mathcal{B}_\infty(\widehat{x}_f + s_\ell^{(a)}, \frac{1}{100k}\nu_\ell) \right) \right| = 1.$$

2. For $\ell = 1$, if we run the LinfinityReduce procedure H times with $y = \vec{0}$ and measurements in $\mathcal{T}$, we get z such that $\|\widehat{x} - z\|_\infty \leq 2^{1-H}\nu_1$ and $\text{supp}(z) \subseteq S$.

3. For all $\ell \in \{2, \ldots, L\}$, for all $a \in [10 \log n]$, if we run the LinfinityReduce procedure H times with $y = \xi$ where

$$\xi_f = \begin{cases} \Pi_{0.04\nu_\ell}(\widehat{x}_f + s_{\ell-1}^{(a)}), & \text{if } f \in S; \\ 0, & \text{if } f \in \overline{S}. \end{cases}$$

then we get z such that $\|\widehat{x} - y - z\|_\infty \leq 2^{1-H}\nu_\ell$ and $\text{supp}(y + z) \subseteq S$.

We can prove that event $\mathcal{E}_2$ happens with probability $1 - 1/\text{poly}(n)$. Moreover, we can prove that conditioned on event $\mathcal{E}_2$ Algorithm 13.2 gives correct output. We defer both proofs in the appendix.

13.2 Algorithm for d-dimensional Sparse Fourier Transform

In this section, we will give a Fourier sparse recovery algorithm that takes $O(k \log k \log n)$ measurements with "ℓ_∞/ℓ_2" guarantee. We assume the knowledge of $\mu = \frac{1}{\sqrt{k}}\|\widehat{x}_{-k}\|_2$. In fact, a constant factor approximation suffices, but we prefer to assume exact knowledge of it in order to simplify exposition. All of the arguments go through in the other case, with minor changes in constants. We also assume we know R^* so that $R^* \geq \|\widehat{x}\|_\infty / \mu$. We assume that $\log R^* = O(\log n)$. For larger $\log R^* = O(\mathrm{poly}(n))$, our algorithm will still work, but the decoding time will be worse by a factor of $\frac{\log R^*}{\log n}$. Note that our assumptions on μ and R^* are standard. For example, [IK14] make the same assumption. We assume that we can measure the signal x in the time domain, and we want to recover the signal $\widehat{x}$ in the frequency domain.

In our algorithm, we will use μ as a threshold for noise, and we will perform $\log R^*$ iterations, where in each iteration the upper bound of ℓ_∞ norm of the residual signal (in the frequency domain) shrinks by half. In Section 13.2.1, we give some definitions that will be used in the algorithm. Then we present our new algorithm for d-dimension Fourier sparse recovery in Section 13.2.2. In Section 13.2.3, we prove the correctness of the proposed algorithm.

13.2.1 Notations

For a subset of samples (or measurements) $\{x_t\}_{t \in T}$ from the time domain, where T is a list of elements in $[p]^d$, we define $\widehat{x}^{[T]}$ in Definition 13.2.1 as our estimation to $\widehat{x}$.

Definition 13.2.1 (Fourier transform of a subset of samples)**.** Let $x \in \mathbb{C}^{[p]^d}$. For any T

which is a list of elements in $[p]^d$, for any $f \in [p]^d$, we define

$$\widehat{x}_f^{[T]} = \frac{\sqrt{n}}{|T|} \sum_{t \in T} \omega^{f^\top t} x_t.$$

In order to reuse samples across different iterations where we drive down the upper bound of the residual signal by half, in each iteration after we obtain estimations to heavy hitters (or equivalently large coordinates), instead of subtracting the estimates directly, we need to "hide" the randomness leaked by the samples. We interpret each estimate (which is a complex number) as a point on a 2-dimension plane, and hide the randomness by rounding the estimate to the nearest grid point (where the side length of the grid is chosen to be a small constant fraction of the target ℓ_∞ norm of the residual signal in the frequency domain), which we call "projection onto grid". In Definition 13.2.2, we formally define box and grid, and in Definition 13.2.3 we define projection to grid. We illustrate these two definitions in Figure 13.1.

Definition 13.2.2 (box and grid)**.** For any $c \in \mathbb{C}$ and $r \geq 0$, we define box $\mathcal{B}_\infty(c, r) \subseteq \mathbb{C}$ as

$$\mathcal{B}_\infty(c, r) = \{c + x + y\mathbf{i} : x, y \in [-r, r]\}.$$

Namely, if we consider complex numbers as points on 2D plane, box $\mathcal{B}_\infty(c, r)$ refers to ℓ_∞ ball with radius r centered at c.

For any $r > 0$, we define grid $\mathcal{G}_r \subseteq \mathbb{C}$ as

$$\mathcal{G}_r = \{xr + yr\mathbf{i} : x, y \in \mathbb{Z}\}.$$

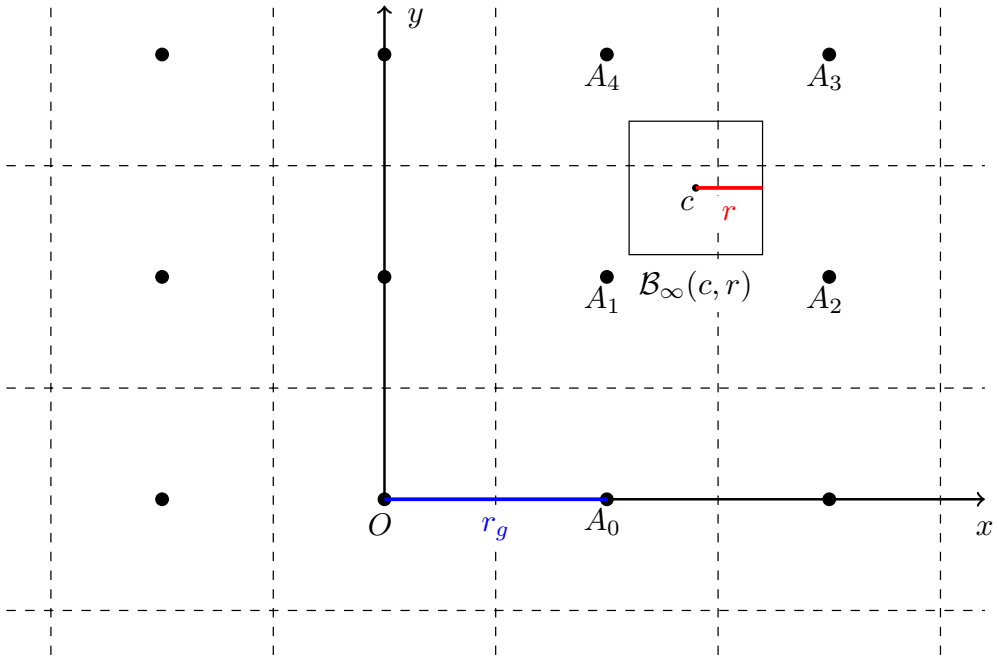

Figure 13.1: Illustration of box $\mathcal{B}_\infty(c,r)$ and grid $\mathcal{G}_{r_g}$. Box $\mathcal{B}_\infty(c,r)$ refers to all the points in the square centered at c with side length $2r$. Grid $\mathcal{G}_{r_g}$ refers to all the solid round points, and the distance between origin O and A_0 is r_g. Note that the dashed lines are decision boundaries of the projection Π_{r_g}, and all the points inside a minimum cell separated by the dashed lines are mapped (by Π_{r_g}) to the same grid point in $\mathcal{G}_{r_g}$ (which is the center of the cell). We have $\Pi_{r_g}(c) = A_1$ and $\Pi_{r_g}(\mathcal{B}_\infty(c,r)) = \{A_1, A_2, A_3, A_4\}$.

Definition 13.2.3 (projection onto grid)**.** For any $r > 0$, we define Π_r to be a maping from $\mathbb{C}$ to $\mathcal{G}_r$, so that for any $c \in \mathbb{C}$,

$$\Pi_r(c) = \arg\min_{c' \in \mathcal{G}_r} |c - c'|,$$

where we break the tie by choosing the one with minimum $|c'|$. As a natural generalization, For $C \subseteq \mathbb{C}$, we define

$$\Pi_r(C) = \{\Pi_r(c) : c \in C\}.$$

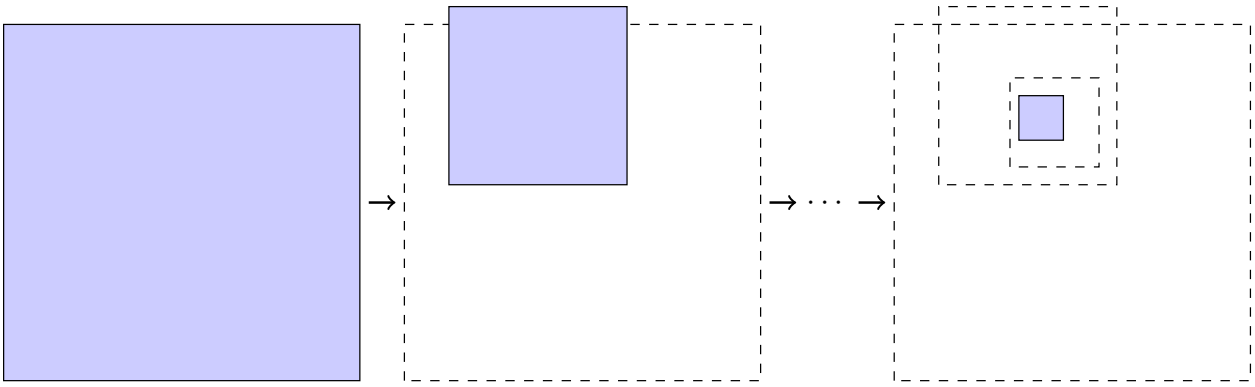
13.2.2 Algorithm

We present our new sparse Fourier recovery algorithm in Algorithm 13.3. Its auxiliary function LINFINITYREDUCE is in Algorithm 13.4. Important constants are summarized in Table 13.2.

In Algorithm 13.3, we define "bucket size" $B = O(k)$ and number of repetitions $R = O(\log n)$. For each $r \in [R]$, we choose $\mathcal{T}_r$ to be a list of B independent and uniformly random elements in $[p]^d$. We will measure x_t for all $t \in \cup_{r\in[R]}\mathcal{T}_r$, and use LINFINITYREDUCE in Algorithm 13.4 to locate and estimate all the "heavy hitters" of the residual signal so that if we substract them then the ℓ_∞ norm of the new residual signal shrinks by half. The input to LINFINITYREDUCE is a signal $x \in \mathbb{C}^{[p]^d}$ in the time domain (but we can only get access to x_t where $t \in \cup_{r\in[R]}\mathcal{T}_r$), a sparse vector $y \in \mathbb{C}^{[p]^d}$ in the frequency domain that we have recovered so far, and $\nu \geq \mu$ such that $\|\widehat{x}-y\|_\infty \leq 2\nu$ where we will refer $\widehat{x}-y$ as the currect residual signal (in the frequency domain). It is guaranteed that LINFINITYREDUCE$(x, n, y, \{\mathcal{T}_r\}_{r=1}^R, \nu)$ returns a $O(k)$-sparse z so that $\|\widehat{x} - y - z\| \leq \nu$ with probability $1 - 1/\operatorname{poly}(n)$.

Algorithm 13.3 in total maintains $H = O(\log k)$ independent copies of such error-reduce data structures, where in the h-th copy it measures $\mathcal{T}^{(h)} = \{\mathcal{T}_r^{(h)}\}_{r\in[R]}$ for $h \in [H]$. We denote $\mathcal{T} = \{\mathcal{T}^{(h)}\}_{r\in[R]}$. If $\log R^* \leq H$, then we can simply use different $\mathcal{T}^{(h)}$ in different iterations. In that case $L = 1$ and $H = \log R^*$ in Algorithm 13.3. We will get $z^{(1)}$ on Line 20 such that $\|\widehat{x} - y^{(0)} - z^{(1)}\|_\infty \leq \mu$ (we will prove in the analysis this holds with probability $1 - 1/\operatorname{poly}(n)$) where $y^{(0)} = 0$, and return $z^{(1)} + y^{(0)}$ on Line 22.

If $\log R^* > H$, we have to reuse the samples. We proceed in L iterations (in the loop between Line 14 and Line 33 in Algorithm 13.3), where $L = \log R^* - H + 1$. For $\ell \in [L]$,

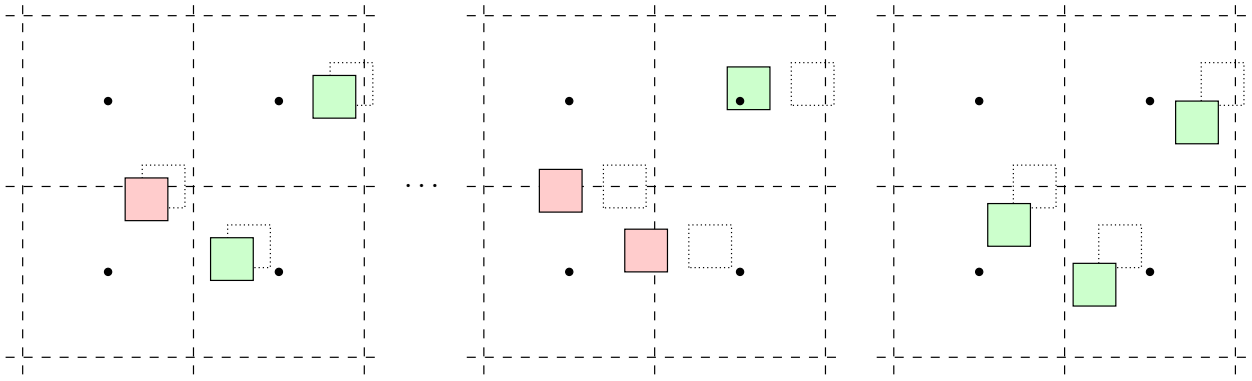


(a) $h = 0$ (b) $h = 1$ (c) $h = H$

Figure 13.2: Illustration of the behavior of Line 16 to Line 20 in Algorithm 13.3. For any $f \in [p]^d$, we draw box $\mathcal{B}_\infty(y_f^{(\ell-1)} + z_f, 2^{1-h}\nu_\ell)$ after h iterations of the for loop between Line 17 and Line 19 in Algorithm 13.3, where $h \in \{0, 1, \ldots, H\}$. Conditioned on LINFINITYREDUCE is correct, for every $h \in \{0, 1, \ldots, H\}$, after h-th iteration we have $\widehat{x}_f \in \mathcal{B}_\infty(y_f^{(\ell-1)} + z_f, 2^{1-h}\nu_\ell)$. When $h = 0$, i.e. before the loop between Line 17 and Line 19 starts, we know that $\widehat{x}_f \in \mathcal{B}_\infty(y_f^{(\ell-1)}, 2\nu_\ell)$ as depicted by (a). After each iteration in h, the radius of the box shrinks by half (and its center might change). Finally after H iterations, as depicted by (c), we obtain $z^{(\ell-1)}$ such that $\widehat{x}_f \in \mathcal{B}_\infty(y_f^{(\ell-1)} + z_f^{(\ell)}, 2^{1-H}\nu_\ell)$.

as defined in Line 15, $\nu_\ell = 2^{-\ell}\mu R^*$ refers to the target ℓ_∞ of the residual signal in the ℓ-th iteration (namely, for $\ell \in [L-1]$ we want to obtain $y^{(\ell)}$ so that $\|\widehat{x} - y^{(\ell)}\|_\infty \le \nu_\ell$). In the ℓ-th iteration where $\ell \in [L]$, by using the samples in $\mathcal{T} = \{\mathcal{T}^{(h)}\}_{h \in H}$ (Line 16 to Line 20), the algorithm tries to get $z^{(\ell)}$ so that $\|\widehat{x} - y^{(\ell-1)} - z^{(\ell)}\|_\infty \le 2^{1-H}\nu_\ell$. The intuition on the behavior of Line 16 to Line 20 is depicted in Figure 13.2.

If $\ell = L$ the algorithm will return $y^{(L-1)} + z^{(L)}$ as in Line 22; otherwise, the algorithm will try to compute $y^{(\ell)}$ based on $y^{(\ell-1)} + z^{(\ell)}$. In Line 25 to Line 28, the algorithm repeatedly samples a uniform random shift $s_\ell \in \mathcal{B}_\infty(0, \alpha\nu_\ell)$ (where $\alpha \in (0, 1)$ is a small constant chosen in Table 13.2) until the shift is good, where shift s_ℓ is good if and only if for each $f \in \mathrm{supp}(y^{(\ell-1)} + z^{(\ell)})$, all the points in $\mathcal{B}_\infty(y^{(\ell-1)} + z^{(\ell)} + s_\ell, 2^{1-H}\nu_\ell)$ (i.e. the box obtained by



(a) a failed attempt (b) another failed attempt (c) a successful attempt

Figure 13.3: Illustration of the iteration between Line 25 and Line 28 in Algorithm 13.3. The round solid points represent grid points in $\mathcal{G}_{\beta\nu}$, and the dashed lines represent decision boundaries of $\Pi_{\beta\nu_\ell}$. In this example we have $|\operatorname{supp}(y^{(\ell-1)}+z^{(\ell)})| = 3$, and the dotted squares represent boxes $\mathcal{B}_\infty(y_f^{(\ell-1)}+z_f^{(\ell)}, 2^{1-H}\nu_\ell)$ for $f \in \operatorname{supp}(y^{(\ell-1)}+z^{(\ell)})$. The algorithm repeatedly samples a random shift $s \sim \mathcal{B}_\infty(0, \alpha\nu_\ell)$, until all the shifted boxes $\{\mathcal{B}_\infty(y_f^{(\ell-1)}+z_f^{(\ell)}, 2^{1-H}\nu_\ell)+s\}_{f\in\operatorname{supp}(y^{(\ell-1)}+z^{(\ell)})}$ do not intersect with the dashed lines (i.e. decision boundaries of $\Pi_{\beta\nu_\ell}$). In the figure, we color a shifted box in green if it does not intersect with dashed lines, and color in red otherwise. After a series of failed attempts from (a) to (b), we finally have a successful attempt in (c).

applying shift s_ℓ to the box $\mathcal{B}_\infty(y^{(\ell-1)}+z^{(\ell)}, 2^{1-H}\nu_\ell))$ project to the same grid point in $\mathcal{G}_{\beta\nu_\ell}$. We depict the process of obtaining the shift s_ℓ in Figure 13.3. It is crucial to note that if the shift s_ℓ is good and the vector $z^{(\ell)}$ we get is desirable (namely $\|\widehat{x}-y^{(\ell-1)}-z^{(\ell)}\|_\infty \le 2^{1-H}\nu_\ell$), then for each $f \in \operatorname{supp}(y^{(\ell-1)}+z^{(\ell)})$, $\Pi_{\beta\nu_\ell}(y_f^{(\ell-1)}+z_f^{(\ell)}+s_\ell) = \Pi_{\beta\nu_\ell}(\widehat{x}_f+s_\ell)$.

On Line 31, we assign $\Pi_{\beta\nu_\ell}(y_f^{(\ell-1)}+z_f^{(\ell)}+s_\ell)$ to $y_f^{(\ell)}$. Because β is a small constant, we still have the guarantee that $\|\widehat{x}-y^{(\ell)}\|_\infty \le \nu_\ell$. Moreover, by assigning $\Pi_{\beta\nu_\ell}(y_f^{(\ell-1)}+z_f^{(\ell)}+s_\ell) = \Pi_{\beta\nu_\ell}(\widehat{x}_f+s_\ell)$ to $y_f^{(\ell)}$, we "hide" the randomness in $\mathcal{T} = \{\mathcal{T}^{(h)}\}_{h\in[H]}$. Now the randomness in $\mathcal{T}$ only leaks from failed attempts of the shifts. For analysis purpose, we maintain a counter a_ℓ for $\ell \in [L-1]$ recording the number of attempts until we have sampled a good

one. By our choice of parameters, we can prove that with high probability $a_\ell \le 10 \log n$ for each $\ell \in [L-1]$. Thus intuitively the leaked randomness is under control, and we can formally apply a union bound to prove that with good probability all possible invocations of LinfinityReduce by our FourierSparseRecovery produce desirable output.

13.2.3 Analysis

In order to analyze the algorithm, let $S \subseteq [n]$ be top $C_S k$ coordinates of $\widehat{x}$ where $C_S = 26$, and let $\overline{S} = [n] \setminus S$. In order to analyze the performance of LinfinityReduce in Algorithm 13.4, we need the following definition.

Definition 13.2.4 (uniform sample)**.** We say t is sampled from $[p]^d$ uniformly at random if for each $i \in [d]$, we independently sample t_i from $[p]$ uniformly at random. We use $t \sim [p]^d$ to denote it.

Fact 13.2.1. *Let $\omega = e^{2\pi \mathbf{i}/p}$ where p is any positive integer. For a fixed $f \in [p]^d \setminus \{\vec{0}\}$, $\mathbb{E}_{t \sim [p]^d}[\omega^{f^\top t}] = 0$.*

Proof. Note that $\mathbb{E}_{t \sim [p]^d}[\omega^{f^\top t}] = \prod_{i \in [d]} \mathbb{E}_{t_i \sim [p]}[\omega^{f_i t_i}]$ by the fact that $t_1, \ldots, t_d$ are independent. Because $f \neq \vec{0}$, there exists $i \in [d]$ so that $f_i \neq 0$. We have

$$\begin{aligned} \mathop{\mathbb{E}}_{t_i \sim [p]}[\omega^{f_i t_i}] &= \frac{1}{p} \sum_{j=0}^{p-1} (\omega^{f_i})^j \\ &= \frac{1}{p} \cdot \frac{(\omega^{f_i})^0 (1 - (\omega^{f_i})^p)}{1 - \omega^{f_i}} \\ &= 0, \end{aligned}$$

where the second step follows from the sum of geometry series where $\omega^{f_i} \neq 1$, adn the third step follow from $(\omega^{f_i})^p = e^{2\pi \mathbf{i} f_i} = 1$. Therefore, $\mathbb{E}_{t \sim [p]^d}[\omega^{f^\top t}] = 0$.

Let T be a list of i.i.d. samples from $[p]^d$, then the coeffcients $c_f^{[T]}$ defined in Definition 13.2.5 have the following property.

Lemma 13.2.3 (properties of coeffcient c)**.** *Let T be a list of B independent and uniform random elements in $[p]^d$. Then we have*

1. $c_0^{[T]} = 1$.

2. *For any* $f \in [p]^d \setminus \{0\}$, $\mathbb{E}_T\left[|c_f^{[T]}|^2\right] = \frac{1}{B}$.
3. *For any* $f, f' \in [p]^d$, $f \neq f'$, $\mathbb{E}_T\left[c_f^{[T]} \cdot \overline{c_{f'}^{[T]}}\right] = 0$.

Proof. **Part 1.** By definition of $c_0^{[T]}$,

$$c_0^{[T]} = \frac{1}{|T|}\sum_{t\in T}\omega^{0\cdot t} = 1.$$

Part 2. Let $T = \{t_1, \ldots, t_B\}$, where t_i is independently and uniformly chosen from $[p]^d$. For any $f \in [p]^d \setminus \{0\}$,

$$\begin{aligned}
\mathop{\mathbb{E}}_T\left[|c_f^{[T]}|^2\right] &= \mathop{\mathbb{E}}_T\left[c_f^{[T]} \cdot \overline{c_f^{[T]}}\right] \\
&= \frac{1}{|T|^2}\mathop{\mathbb{E}}_T\left[\sum_{i,j\in[B]}\omega^{f^\top(t_i-t_j)}\right] \\
&= \frac{1}{|T|^2}\left(|T| + \mathop{\mathbb{E}}_T\left[\sum_{i,j\in[B],i\neq j}\omega^{f^\top(t_i-t_j)}\right]\right) \\
&= \frac{1}{|T|} + \frac{1}{|T|^2}\sum_{i,j\in[B],i\neq j}\mathop{\mathbb{E}}_T\left[\omega^{f^\top(t_i-t_j)}\right] \\
&= \frac{1}{|T|} - \frac{1}{|T|^2}\cdot 0 \\
&= \frac{1}{|T|} = \frac{1}{B},
\end{aligned}$$

where the forth step follows by $\mathbb{E}_T[\omega^{f^\top(t_i-t_j)}] = \mathbb{E}_{t\sim[p]^d}[\omega^{f^\top t}] = 0$, in which $\mathbb{E}_T[\omega^{f^\top(t_i-t_j)}] = \mathbb{E}_{t\sim[p]^d}[\omega^{f^\top t}]$ because $i \neq j$, t_i, t_j are independent and uniformly random distributed in $[p]^d$, $t_i - t_j \sim [p]^d$; $\mathbb{E}_{t\sim[p]^d}[\omega^{f^\top t}] = 0$ follows by by Fact 13.2.1 and f is not a zero vector.

Part 3. For any $f, f' \in [p]^d$, $f \neq f'$,

$$\begin{aligned}
\mathop{\mathbb{E}}_{T}\left[c_f^{[T]} \cdot \overline{c_{f'}^{[T]}}\right] &= \frac{1}{|T|^2} \mathop{\mathbb{E}}_{T}\left[\sum_{i,j\in[B]} \omega^{f^\top t_i - f'^\top t_j}\right] \\
&= \frac{1}{|T|^2}\left(\sum_{i,j\in[B],i\neq j} \mathop{\mathbb{E}}_{T}\left[\omega^{f^\top t_i - f'^\top t_j}\right] + \sum_{i\in[B]} \mathop{\mathbb{E}}_{T}\left[\omega^{(f-f')^\top t_i}\right]\right) \\
&= \frac{1}{|T|^2}\left(\sum_{i,j\in[B],i\neq j} \mathop{\mathbb{E}}_{t_i\sim[p]^d}\left[\omega^{f^\top t_i}\right] \mathop{\mathbb{E}}_{t_j\sim[p]^d}\left[\omega^{-f'^\top t_j}\right] + \sum_{i\in[B]} \mathop{\mathbb{E}}_{t_i\sim[p]^d}\left[\omega^{(f-f')^\top t_i}\right]\right) \\
&= 0,
\end{aligned}$$

where the second step follows from separating diagonal term and off-diagonal terms, the third step follows from t_i and t_j are independent, the last step follows from Fact 13.2.1 where $f - f' \neq \vec{0}$, and at least one of f and f' is not $\vec{0}$.

□

Let T be a list of independent and uniformly random elements from $[p]^d$. We are going to measure x_t for $t \in T$, and take $\widehat{x}_f^{[T]}$ (recall its definition in Definition 13.2.1) as estimate to $\widehat{x}_f$. By Lemma 13.2.2, $\widehat{x}_f^{[T]} = \sum_{f'\in[p]^d} c_{f-f'}^{[T]} \widehat{x}_{f'}$. The following lemma bounds the contribution of coordinates from V where $V \subseteq [p]^d \setminus \{f\}$, namely $|\sum_{f'\in V} c_{f-f'}^{[T]} \widehat{x}_{f'}|$. When analyzing the quality of $\widehat{x}_f^{[T]}$ as an approximation to $\widehat{x}_f$, we consider coordinates in V as noise, and we usually set $V = [p]^d \setminus \{f\}$.

Lemma 13.2.4 (noise bound)**.** *For any $f \in [p]^d$, T which is a list of B i.i.d. samples from $[p]^d$ and $V \subseteq [n]$ such that $f \notin V$,*

$$\Pr_{T}\left[\left|\sum_{f'\in V} c_{f-f'}^{[T]} \widehat{x}_{f'}\right| \geq \frac{10}{\sqrt{B}} \|\widehat{x}_V\|_2\right] \leq \frac{1}{100}.$$

Proof. First, we can prove that $\mathbb{E}_T\left[\left|\sum_{f'\in V} c^{[T]}_{f-f'}\widehat{x}_{f'}\right|^2\right] = \frac{1}{B}\|\widehat{x}_V\|_2^2$, because

$$\begin{aligned}
\mathop{\mathbb{E}}_{T}\left[\left|\sum_{f'\in V} c^{[T]}_{f-f'}\widehat{x}_{f'}\right|^2\right] &= \mathop{\mathbb{E}}_{T}\left[\sum_{f_1,f_2\in V}(c^{[T]}_{f-f_1}\widehat{x}_{f_1})\overline{(c^{[T]}_{f-f_2}\widehat{x}_{f_2})}\right] \\
&= \sum_{f_1,f_2\in V}\mathop{\mathbb{E}}_{T}\left[c^{[T]}_{f-f_1}\overline{c^{[T]}_{f-f_2}}\right]\widehat{x}_{f_1}\overline{\widehat{x}_{f_2}} \\
&= \sum_{f'\in V}\mathop{\mathbb{E}}_{T}\left[\left|c^{[T]}_{f-f'}\right|^2\right]|\widehat{x}_{f'}|^2 \\
&= \frac{1}{B}\|\widehat{x}_V\|_2^2,
\end{aligned}$$

where the third step follows from Lemma 13.2.3 that for $f-f_1 \neq f-f_2$, $\mathbb{E}_T\left[c^{[T]}_{f-f_1}\overline{c^{[T]}_{f-f_2}}\right] = 0$, and the last step follows from $\mathbb{E}_T\left[\left|c^{[T]}_{f-f'}\right|^2\right] = 1/B$ in Lemma 13.2.3.

Then the lemma follows from Chebyshev Inequality and the fact that

$$\mathop{\mathbb{V}}_{T}\left[\left|\sum_{f'\in V} c^{[T]}_{f-f'}\widehat{x}_{f'}\right|\right] \leq \mathop{\mathbb{E}}_{T}\left[\left|\sum_{f'\in V} c^{[T]}_{f-f'}\widehat{x}_{f'}\right|^2\right] = \frac{1}{B}\|\widehat{x}_V\|_2^2.$$

□

In the next lemma, we show the guarantee of LinfinityReduce in Algorithm 13.4.

Lemma 13.2.5 (guarantee of LinfinityReduce in Algorithm 13.4)**.** *Let $x \in \mathbb{C}^{[p]^d}$, and $n = p^d$. Let $R = C_R \log n$, and $B = C_B k$. Let $C_B \geq 10^6$ and $C_R \geq 10^3$. Let $\mu = \frac{1}{\sqrt{k}}\|\widehat{x}_{-k}\|_2$, and $\nu \geq \mu$. For $r \in [R]$, let $\mathcal{T}_r$ be a list of B i.i.d. elements in $[p]^d$. Let $z \in \mathbb{C}^n$ denote the output of*

$$\textsc{LinfinityReduce}(x, n, y, \{\mathcal{T}_r\}_{r=1}^R, \nu).$$

Algorithm 13.4 Procedure for Reducing ℓ_∞-norm of the Residual Signal

1: **procedure** LINFINITYREDUCE($x, n, y, \{\mathcal{T}_r\}_{r=1}^R, \nu$) ▷ Lemma 13.2.5
2: **Require** that $\|\widehat{x} - y\|_\infty \le 2\nu$
3: Let w be inverse Fourier transform of y ▷ We have $\widehat{w} = y$
4: **for** $r = 1 \to R$ **do**
5: **for** $f = 1 \to n$ **do** ▷ Implemented by FFT which takes $O(n \log n)$ time
6: $u_{f,r} \leftarrow \frac{\sqrt{n}}{|\mathcal{T}_r|} \sum_{t \in \mathcal{T}_r} \omega^{f^\top t}(x_t - w_t)$ ▷ $\omega = e^{2\pi \mathbf{i}/p}, u_{f,r} = \widehat{(x-w)}_f^{[\mathcal{T}_r]}$
7: **end for**
8: **end for**
9: **for** $f = 1 \to n$ **do**
10: $\eta = \mathrm{median}_{r \in [R]}\{u_{f,r}\}$ ▷ Take the median coordinate-wise
11: **if** $|\eta| \le \nu/2$ **then**
12: $z_f \leftarrow \eta$
13: **else**
14: $z_f \leftarrow 0$
15: **end if**
16: **end for**
17: **return** z ▷ Guarantee $\|\widehat{x} - y - z\|_\infty \le \nu$
18: **end procedure**

Let S be top $C_S k$ coordinates in $\widehat{x}$, where $C_S = 26$. If $\|\widehat{x} - y\|_\infty \le 2\nu$, $\mathrm{supp}(y) \subseteq S$ and y is independent from the randomness of $\{\mathcal{T}_r\}_{r=1}^R$, then with probability $1 - 1/\mathrm{poly}(n)$ under the randomness of $\{\mathcal{T}_r\}_{r=1}^R$, $\|\widehat{x} - y - z\|_\infty \le \nu$ and $\mathrm{supp}(z) \subseteq S$. Moreover, the running time of LINFINITYREDUCE *is $O(n \log^2 n)$.*

Proof. Note that $\forall f \in \overline{S}$,

$$|\widehat{x}_f| \le \sqrt{\frac{\|\widehat{x}_{-k}\|_2^2}{C_S k - k}} = \frac{1}{5}\mu,$$

where the last step follows from choice of C_S.

Let w denote the inverse Fourier transform of y. Note that on Line 6 in Algo-

rithm 13.4, for any $f \in [p]^d$ and $r \in [R]$,

$$\begin{aligned} u_{f,r} &= \frac{\sqrt{n}}{|\mathcal{T}_r|} \sum_{t \in \mathcal{T}_r} \omega^{f^\top t}(x_t - w_t) \\ &= \widehat{(x-w)}_f^{[\mathcal{T}_r]} \\ &= \sum_{f' \in [n]} c_{f-f'}^{[\mathcal{T}_r]} (\widehat{x}_{f'} - y_{f'}), \end{aligned}$$

where the second step follows by the notation in Definition 13.2.1, and the third step follows by Lemma 13.2.2. Therefore,

$$\widehat{x}_f - y_f = u_{f,r} - \sum_{f' \in [p]^d \setminus \{f\}} c_{f-f'}^{[\mathcal{T}_r]} (\widehat{x}_{f'} - y_{f'}), \tag{13.1}$$

By Lemma 13.2.4,

$$\Pr_{\mathcal{T}_r} \left[\left| \sum_{f' \in [p]^d \setminus \{f\}} c_{f-f'}^{[\mathcal{T}_r]} (\widehat{x}_{f'} - y_{f'}) \right| \geq \frac{10}{\sqrt{B}} \|(\widehat{x} - y)_{[p]^d \setminus \{f\}}\|_2 \right] \leq \frac{1}{100}. \tag{13.2}$$

We have

$$\begin{aligned} \frac{10}{\sqrt{B}} \|(\widehat{x} - y)_{[p]^d \setminus \{f\}}\|_2 &\leq \frac{10}{\sqrt{B}} \left(\|(\widehat{x} - y)_{S \setminus \{f\}}\|_2 + \|(\widehat{x} - y)_{\overline{S} \setminus \{f\}}\|_2 \right) \\ &\leq \frac{10}{\sqrt{B}} \left(\|\widehat{x} - y\|_\infty \cdot \sqrt{|S|} + \|\widehat{x}_{\overline{S} \setminus \{f\}}\|_2 \right) \\ &\leq \frac{10}{\sqrt{B}} \left(2\nu \cdot \sqrt{26k} + \sqrt{k}\mu \right) \\ &\leq \frac{1}{100\sqrt{k}} \left(2\nu \cdot \sqrt{26k} + \sqrt{k}\mu \right) \\ &< 0.12\nu, \end{aligned} \tag{13.3}$$

where the first step following by triangle inequality, the second step follows by the assumption that $\mathrm{supp}(y) \subseteq S$, the forth step follows by $C_B \geq 10^6$, the last step follows by $\mu \leq \nu$.

Therefore,

$$\begin{aligned}
\Pr_{\mathcal{T}_r}[|u_{f,r} - (\widehat{x}_f - y_f)| \le 0.12\nu] &= \Pr_{\mathcal{T}_r}\left[\left|\sum_{f' \in [p]^d \setminus \{f\}} c_{f-f'}^{[\mathcal{T}_r]}(\widehat{x}_{f'} - y_{f'})\right| \le 0.12\nu\right] \\
&= 1 - \Pr_{\mathcal{T}_r}\left[\left|\sum_{f' \in [p]^d \setminus \{f\}} c_{f-f'}^{[\mathcal{T}_r]}(\widehat{x}_{f'} - y_{f'})\right| > 0.12\nu\right] \\
&\ge 1 - \Pr_{\mathcal{T}_r}\left[\left|\sum_{f' \in [p]^d \setminus \{f\}} c_{f-f'}^{[\mathcal{T}_r]}(\widehat{x}_{f'} - y_{f'})\right| \ge \frac{10}{\sqrt{B}}\|(\widehat{x} - y)_{[p]^d \setminus \{f\}}\|_2\right] \\
&\ge 1 - \frac{1}{100},
\end{aligned}$$

where the first step follows by (13.1), the third step follows by (13.3), and the last step follows by (13.2).

Thus we have

$$\Pr_{\mathcal{T}_r}[u_{f,r} \in \mathcal{B}_\infty(\widehat{x}_f - y_f, 0.12\nu)] \ge \Pr_{\mathcal{T}_r}[|u_{f,r} - (\widehat{x}_f - y_f)| \le 0.12\nu] \ge 1 - \frac{1}{100}.$$

Let $\eta_f = \text{median}_{r \in [R]} u_{f,r}$ as on Line 10 in Algorithm 13.4. By Chernoff bound, with probability $1 - 1/\operatorname{poly}(n)$, more than $\frac{1}{2}R$ elements in $\{u_{f,r}\}_{r=1}^R$ are contained in box $\mathcal{B}_\infty(\widehat{x}_f - y_f, 0.12\nu)$, so that $\eta_f \in \mathcal{B}_\infty(\widehat{x}_f - y_f, 0.12\nu)$.

Therefore, we have

$$\Pr[|\eta_f - (\widehat{x}_f - y_f)| \le 0.17\nu] \ge \Pr[|\eta_f - (\widehat{x}_f - y_f)| \le \sqrt{2} \cdot 0.12\nu] \ge 1 - 1/\operatorname{poly}(n).$$

Let E be the event that for all $f \in [p]^d$, $|\eta_f - (\widehat{x}_f - y_f)| \le 0.17\nu$. By a union bound over $f \in [p]^d$, event E happens with probability $1 - 1/\operatorname{poly}(n)$. In the rest of the proof, we condition on event E.

(**Case 1**) For $f \in \overline{S}$, note that

$$|\eta_f| \le 0.17\nu + |\widehat{x}_f - y_f| = 0.17\nu + |\widehat{x}_f| \le 0.17\nu + 0.2\nu = 0.37\nu.$$

According to the if statement between Line 11 and Line 15 in Algorithm 13.4, z_f will be assigned to 0. Thus $\mathrm{supp}(z) \subseteq S$. In addition, $|\widehat{x}_f - y_f - z_f| = |\widehat{x}_f| \le \mu \le \nu$.

(**Case 2**) For $f \in S$, we have two cases. We prove that $|(\widehat{x}_f - y_f) - z_f| \le \nu$ for both cases.

(**Case 2.1**) $|\eta_f| \le 0.5\nu$. z_f is assigned as 0. Because

$$|\eta_f - (\widehat{x}_f - y_f)| \le 0.17\nu, \quad |\widehat{x}_f - y_f| \le |\eta_f| + 0.17\nu \le 0.67\nu.$$

Therefore,

$$|(\widehat{x}_f - y_f) - z_f| \le 0.67\nu \le \nu.$$

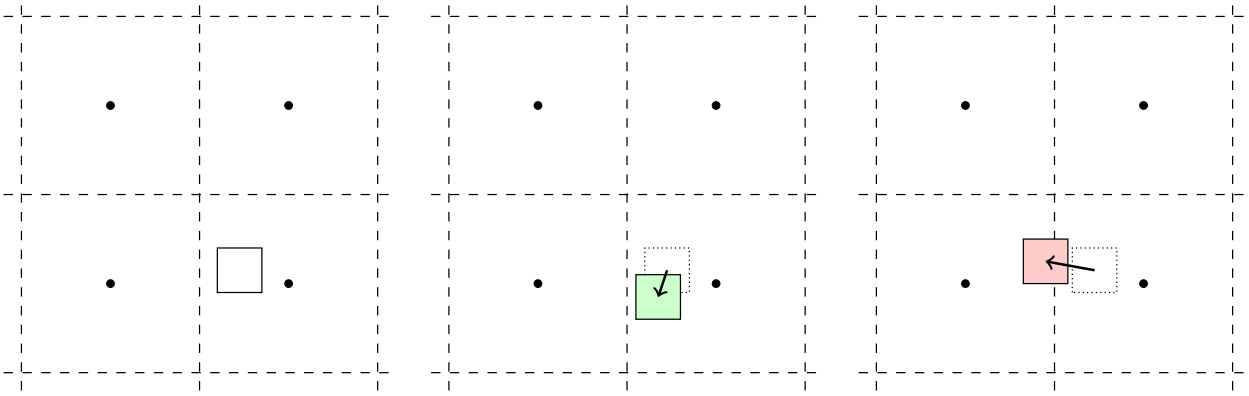
(**Case 2.2**) $|\eta_f| > 0.5\nu$. z_f is assigned as η_f. We have

$$|(\widehat{x}_f - y_f) - z_f| = |(\widehat{x}_f - y_f) - \eta_f| \le 0.17\nu \le \nu.$$

We thus have obtained that with probability $1 - 1/\operatorname{poly}(n)$, $\|(\widehat{x} - y) - z\|_\infty \le \nu$ and $\mathrm{supp}(z) \subseteq S$.

The running time of LinfinityReduce is dominated by the loop between Line 4 and Line 8, which takes $O(R \cdot n \log n) = O(n \log^2 n)$ by FFT. □

For a given box $\mathcal{B}_\infty(c, r)$ and grid $\mathcal{G}_{r_g}$, we say a shift $s \in \mathbb{C}$ is good if after applying the shift, all the points in the shifted box $\mathcal{B}_\infty(c, r) + s$ are mapped to the same point by



(a) a box and grid (b) a good shift (c) a bad shift

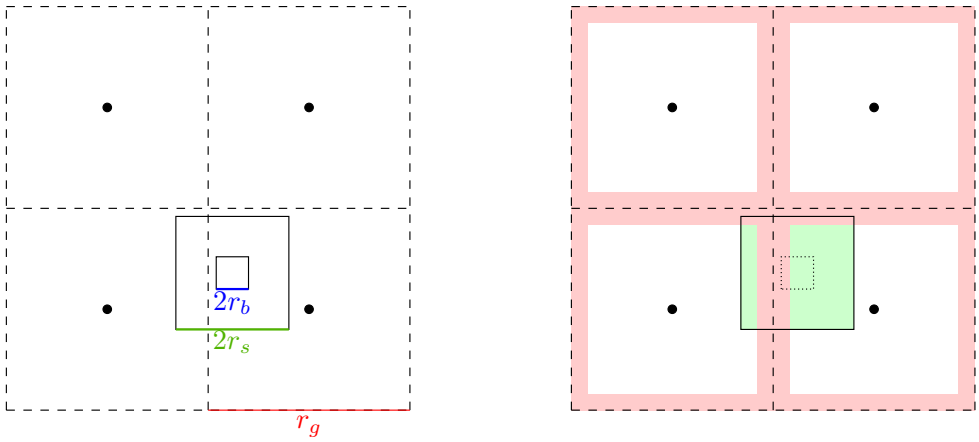
Figure 13.4: Illustration of good and bad shifts in Definition 13.2.6. In (a), the small square represents box $\mathcal{B}_\infty(c, r_b)$, and the dashed lines represent the decision boundary of Π_{r_g}. The arrows in (b) and (c) represent two different shifts, where the shift in (b) is an example of good shift, since the shifted box does not intersect with the decision boundaries of Π_{r_g}, while the shift in (c) is an example of bad shift, since the shifted box intersects with the decision boundaries of Π_{r_g}.

Π_{r_g} (recall that Π_{r_g} projects any point to the nearst grid point in $\mathcal{G}_{r_g}$). We formulate the notation of a good shift in the following definition, and illustrate in Figure 13.4.

Definition 13.2.6 (good shift)**.** For any r_g, r_b, and any $c \in \mathbb{C}$, we say shift $s \in \mathbb{C}$ is a good shift if

$$\left|\Pi_{r_g}(\mathcal{B}_\infty(c, r_b) + s)\right| = 1.$$

The following lemma intuitively states that if we take a box of radius r_b (or equivalently, side length $2r_b$) and shift it randomly by an offset in $\mathcal{B}_\infty(0, r_s)$ (or equivalently, $[-r_s, r_s] \times [-r_s, r_s]$) where $r_s \geq r_b$, and next we round everyone inside that shifted box to the closest point in G_{r_g} where $r_g \geq 2r_s$, then with probability at least $(1 - r_b/r_s)^2$ everyone will be rounded to the same point. In other words, let $s \sim \mathcal{B}_\infty(0, r_s)$, for box $\mathcal{B}_\infty(c, r_b)$ and



(a) $r_g \geq 2r_s \geq 2r_b$ (b) partition of good and bad shifts

Figure 13.5: Illustration of Lemma 13.2.6. In (a) the smallest square represents box $\mathcal{B}_\infty(c, r_b)$, the medium-sized square represents $\mathcal{B}_\infty(c, r_s)$, and the dashed lines represent decision boundaries of Π_{r_g}. Note that for $s \sim \mathcal{B}_\infty(0, r_s)$, the center of the shifted box $s+\mathcal{B}_\infty(c, r_b)$ is $s + c \sim \mathcal{B}_\infty(c, r_s)$. Shift s is good (recall in Definition 13.2.6) for box $\mathcal{B}_\infty(c, r_b)$ and grid $\mathcal{G}_{r_g}$ if and only if the distance between $s+c$ and decision boundaries of Π_{r_g} is greater than r_b. In (b), we draw in red the set of points which are within distance at most r_b to the decision boundaries of Π_{r_g}. Then in (b) the red part inside $\mathcal{B}_\infty(c, r_s)$ corresponds to bad shifts (plus c), and the green part corresponds to good shifts (plus c). Intuitively, the fraction of the green part is at least $(1 - r_b/r_s)^2$ because the vertical red strips can cover a width of at most $2r_b$ on the x-axis of $\mathcal{B}_\infty(c, r_s)$ (whose side length is $2r_s$), and the horizontal red strips can cover a width of at most $2r_b$ on the y-axis.

grid $\mathcal{G}_{r_g}$, s is a good shift with probability at least $(1 - r_b/r_s)^2$. We illustrate the lemma in Figure 13.5.

Lemma 13.2.6 (property of a randomly shifted box)**.** *For any r_g, r_s, r_b so that $r_g/2 \geq r_s \geq r_b > 0$ and any $c \in \mathbb{C}$, let $s \in \mathbb{C}$ be uniform randomly chosen in $\mathcal{B}_\infty(0, r_s)$, then*

$$\Pr_{s \sim \mathcal{B}_\infty(0, r_s)} \left[\left| \Pi_{r_g}(\mathcal{B}_\infty(c, r_b) + s) \right| = 1 \right] \geq \left(1 - \frac{r_b}{r_s}\right)^2,$$

where we refer r_g, r_s, r_b as the radius of grid, shift and box respectively, and we use notation $C + s$ to refer to $\{c + s : c \in C\}$.

Proof. We consider complex numbers as points in 2D plane, where the real part is the coordinate on x-axis, and the imaginary part is the coordinate on y-axis. Note that the "decision boundary" of projection Π_{r_g} from $\mathbb{C}$ onto grid $\mathcal{G}_{r_g}$ consists of verticle lines of form $x = (m+\frac{1}{2})r_g$ and horizontal lines of form $y = (m+\frac{1}{2})r_g$, where $m \in \mathbb{Z}$. $\left|\Pi_{r_g}(\mathcal{B}_\infty(c, r_b) + s)\right| = 1$ if and only if the shifted box $\mathcal{B}_\infty(c, r_b) + s$ does not intersect with the "decision boundary".

Let $s = s_x + s_y\mathbf{i}$ and $c = c_x + c_y\mathbf{i}$. Then the shifted box does not intersect with the "decision boundary" if and only if both the interval

$$[c_x - r_b + s_x, c_x + r_b + s_x] \text{ and } [c_y - r_b + s_y, c_y + r_b + s_y]$$

do not intersect with $\{(m + \frac{1}{2})r_g : m \in \mathbb{Z}\}$. The probability of each one is at least $1 - \frac{r_b}{r_s}$, and two events are independent. Therefore, we get the claimed result. □

In the following, we define event $\mathcal{E}$, which is a sufficient condition for the correctness of Algorithm 13.3. Event $\mathcal{E}$ consists of three parts. Part 1 of $\mathcal{E}$ is used to prove that $a_\ell \le 10 \log n$ for $\ell \in [L-1]$ on Line 29 in Algorithm 13.3. Part 2 and Part 3 of $\mathcal{E}$ are used to prove that Line 15 to Line 20 in Algorithm 13.3 give a desirable $z^{(\ell)}$ for $\ell \in [L]$.

Definition 13.2.7 (sufficient condition for the correctness of Algorithm 13.3)**.** For input signal $x \in \mathbb{C}^n$, let $\mu = \frac{1}{\sqrt{k}}\|\widehat{x}_{-k}\|_2$ and R^* is an upper bound of $\|\widehat{x}\|_\infty/\mu$. Let S be top $C_S k$ coordinates in $\widehat{x}$. Let $H = \min\{\log k + C_H, \log R^*\}$, and $L = \log R^* - H + 1$. For $\ell \in [L]$, let $\nu_\ell = 2^{-\ell}\mu R^*$. For $\ell \in [L-1]$, let $s_\ell^{(a)}$ be the a-th uniform randomly sampled from $\mathcal{B}_\infty(0, \alpha\nu_\ell)$ as appeared on Line 26 in Algorithm 13.3 (i.e. $s_\ell^{(1)}, \ldots, s_\ell^{(a_\ell)}$ are sampled, and $s_\ell^{(a_\ell)}$ is the first that satisfies the condition on Line 28). For the sake of analysis, we assume that Algorithm 13.3 actually produces an infinite sequence of shifts $s_\ell^{(1)}, s_\ell^{(2)}, \ldots$, and

chooses the smallest a_ℓ so that $s_\ell^{(a_\ell)}$ satisfies $\forall f \in \mathrm{supp}(y^{(\ell-1)} + z^{(\ell)}), |\Pi_{\beta\nu_\ell}(\mathcal{B}_\infty(y_f^{(\ell-1)} + z_f^{(\ell)} + s_\ell^{(a_\ell)}, 2^{1-H}\nu_\ell))| = 1$ on Line 28.

For $\ell \in [L-1]$, we define random variable a'_ℓ to be the smallest a' such that for all $f \in S$,

$$\left|\Pi_{\beta\nu_\ell}\left(\mathcal{B}_\infty(\widehat{x}_f + s_\ell^{(a')}, 2^{3-H}\nu_\ell)\right)\right| = 1.$$

We define event $\mathcal{E}$ to be all of the following events hold.

1. For all $\ell \in [L-1]$, $a'_\ell \leq 10 \log n$.
2. For $\ell = 1$, if we execute Line 15 to Line 20 in Algorithm 13.3 with $y^{(0)} = 0$, we get $z^{(1)}$ such that $\|\widehat{x} - z^{(1)}\|_\infty \leq 2^{1-H}\nu_1$ and $\mathrm{supp}(z^{(1)}) \subseteq S$.
3. For all $\ell \in \{2, \ldots, L\}$, for all $a \in [10 \log n]$, if we execute Line 15 to Line 20 in Algorithm 13.3 with $y^{(\ell-1)} = \xi$ where

$$\xi_f = \begin{cases} \Pi_{\beta\nu_\ell}(\widehat{x}_f + s_{\ell-1}^{(a)}), & \text{if } f \in S; \\ 0, & \text{if } f \in \overline{S}. \end{cases}$$

then we get $z^{(\ell)}$ such that $\|\widehat{x} - y^{(\ell-1)} - z^{(\ell)}\|_\infty \leq 2^{1-H}\nu_\ell$ and $\mathrm{supp}(y^{(\ell-1)} + z^{(\ell)}) \subseteq S$.

In the following, we will prove that for fixed x, under the randomness of $\{s_\ell^{(a)}\}_{\ell\in[L-1],a\in\{1,\ldots\}}$ and $\mathcal{T} = \{\mathcal{T}^{(h)}\}_{h\in[H]}$, event $\mathcal{E}$ (defined in Definition 13.2.7) happens with probability at least $1 - 1/\mathrm{poly}(n)$. Moreover, we will prove that event $\mathcal{E}$ is a sufficient condition for the correctness of Algorithm 13.3. Namely, conditioned on event $\mathcal{E}$, Algorithm 13.3 gives a desirable output.

Lemma 13.2.7 (event $\mathcal{E}$ happens with high probability)**.** *Let $\mathcal{E}$ in Definition 13.2.7. For any fixed $x \in \mathbb{C}^n$, under the randomness of shifts $\{s_\ell^{(a)}\}_{\ell\in[L-1],a\in\{1,\ldots\}}$ and $\mathcal{T} = \{\mathcal{T}^{(h)}\}_{h\in[H]}$,*

$$\Pr[\mathcal{E}] \geq 1 - 1/\mathrm{poly}(n).$$

Proof. We bound the failure probability of each parts in event $\mathcal{E}$ respectively as follows, and $\Pr[\mathcal{E}] \geq 1 - 1/\operatorname{poly}(n)$ follows by a union bound.

Part 1. If $H = \log R^*$, then $L = 1$ and it is trivially true that "for all $\ell \in [L-1], a'_\ell \leq 10 \log n$". Otherwise, we have $H = \log k + C_H$. By Lemma 13.2.6, for any $\ell \in [L-1]$, for any $f \in S$,

$$\Pr_{s \sim \mathcal{B}_\infty(0, \alpha\nu_\ell)} \left[\left| \Pi_{\beta\nu_\ell} \left(\mathcal{B}_\infty \left(\widehat{x}_f, 2^{3-H}\nu_\ell \right) + s \right) \right| = 1 \right] \geq \left(1 - \frac{2^{3-H}\nu_\ell}{\alpha\nu_\ell} \right)^2 = \left(1 - \frac{2^{3-H}}{\alpha} \right)^2,$$

where $(1 - 2^{3-H}/\alpha)^2 \geq 1 - 2^{4-C_H - \log k}/\alpha \geq 1 - \frac{1}{100k}$ by our choice of α and C_H in Table 13.2.

For each $\ell \in [L-1]$, by a union bound over all f in S, the probability is at least $1 - \frac{C_S k}{100k} = 1 - \frac{26k}{100k} \geq \frac{1}{2}$ that for all $f \in S$, $|\Pi_{\beta\nu_\ell}(\mathcal{B}_\infty(\widehat{x}_f + s, 2^{3-H}\nu_\ell))| = 1$ where $s \sim \mathcal{B}_\infty(0, \alpha\nu_\ell)$. Formally, we get

$$\Pr_{s \sim \mathcal{B}_\infty(0, \alpha\nu_\ell)} \left[\left| \Pi_{\beta\nu_\ell} \left(\mathcal{B}_\infty \left(\widehat{x}_f, 2^{3-H}\nu_\ell \right) + s \right) \right| = 1, \forall f \in S \right] \geq 1/2.$$

Therefore, by definition of a'_ℓ in Definition 13.2.7,

$$\Pr[a'_\ell \leq 10 \log n] \geq 1 - (1/2)^{10 \log n} = 1 - 1/n^{10}.$$

By a union bound over all $\ell \in [L-1]$, the probability is at least $1 - L/n^{10} = 1 - 1/\operatorname{poly}(n)$ that for all $\ell \in [L-1]$, $a'_\ell \leq 10 \log n$.

Part 2. By Lemma 13.2.5 and a union bound over all $h \in [H]$, the failure probability is at most $H/\operatorname{poly}(n) = 1/\operatorname{poly}(n)$, where $H = O(\log k)$ and so $H/\operatorname{poly}(n)$ is still $1/\operatorname{poly}(n)$.

Part 3. For each $\ell \in \{2, \ldots, L\}$ and $a \in [10 \log n]$, similar to the above argument, each has failure probability at most $1/\operatorname{poly}(n)$. By a union bound, the failure probability is

at most

$$(L-1)\cdot(10\log n)/\operatorname{poly}(n) = 1/\operatorname{poly}(n).$$

□

In the following lemma, we show that if event $\mathcal{E}$ (defined in Definition 13.2.7) happens, then Algorithm 13.3 gives a desirable output.

Lemma 13.2.8 (correctness of Algorithm 13.3 conditioned on $\mathcal{E}$)**.** *Let $n = p^d$, and let $k \in [n]$. Let $x \in \mathbb{C}^n$ be input signal. Let $\mu = \frac{1}{\sqrt{k}}\|\widehat{x}_{-k}\|_2$. Let $R^* \geq \|\widehat{x}\|_\infty / \mu$ and R^* is a power of 2. Let $H = \min\{\log k + C_H, \log R^*\}$. Let $L = \log R^* - H + 1$. For $\ell \in [L-1]$, let $y^{(\ell)}$ be the vector obtained on Line 31 of Algorithm 13.3. For $\ell \in [L]$, let $z^{(\ell)}$ be the vector obtained on Line 20. Note that $y^{(0)} = 0$, and $y^{(L-1)} + z^{(L)}$ is the output of* FourierSparseRecovery(x, n, k, R^*, μ) *in Algorithm 13.3. Conditioned on the event $\mathcal{E}$ (defined in Definition 13.2.7) happens, we have*

$$\|\widehat{x} - y^{(L-1)} - z^{(L)}\|_\infty \leq \frac{1}{\sqrt{k}}\|\widehat{x}_{-k}\|_2.$$

Proof. We first discuss the case that $H = \log R^*$. In that case, $L = 1$. Conditioned on the event $\mathcal{E}$ (Part 2 of $\mathcal{E}$), $z^{(1)}$ obtained through Line 15 to Line 20 in Algorithm 13.3 satisfies $\|\widehat{x} - z^{(1)}\|_\infty \leq 2^{1-H}\nu_1 = 2^{1-H}(2^{-1}\mu R^*) = \mu$.

In the rest of the proof, we discuss the case that $H > \log R^*$. For $\ell \in [L]$, let $\nu_\ell = 2^{-\ell}\mu R^*$. For $\ell \in [L-1]$, let $s_\ell^{(a_\ell)} \in \mathcal{B}_\infty(0, \alpha\nu_\ell)$ denote the first $s_\ell^{(a)}$ on Line 26 in Algorithm 13.3 such that for all $f \in \operatorname{supp}(y^{(\ell-1)} + z^{(\ell)})$,

$$\left|\Pi_{\beta\nu_\ell}\left(\mathcal{B}_\infty\left(y_f^{(\ell-1)} + z_f^{(\ell)} + s_\ell^{(a)}, 2^{1-H}\nu_\ell\right)\right)\right| = 1.$$

For $\ell \in [L-1]$, we define $\xi^{(\ell)} \in \mathbb{C}^{[p]^d}$ as follows

$$\xi_f^{(\ell)} = \begin{cases} \Pi_{\beta\nu_\ell}(\widehat{x}_f + s_\ell^{(a_\ell)}), & \text{if } f \in S; \\ 0, & \text{if } f \in \overline{S}. \end{cases}$$

We also define $\xi^{(0)} = 0$, $s_0^{(a)} = 0$ for $a \in \{1, \ldots\}$ and $a_0 = 1$.

(**Goal: Inductive Hypothesis**) We are going to prove that conditioned on event $\mathcal{E}$ (defined in Definition 13.2.7), for all $\ell \in \{0, \ldots, L-1\}$,

$$y^{(\ell)} = \xi^{(\ell)} \quad \text{and} \quad a_\ell \le 10 \log n.$$

(**Base case**) Note that $y^{(0)} = \xi^{(0)} = 0$ and $a_0 = 1 \le 10 \log n$.

(**Inductive step**) We will prove that conditioned on event $\mathcal{E}$, if $y^{(\ell-1)} = \xi^{(\ell-1)}$ and $a_{\ell-1} \le 10 \log n$ for $\ell \in [L-1]$, then $y^{(\ell)} = \xi^{(\ell)}$ and $a_\ell \le 10 \log n$.

(**Proving** $a_\ell \le 10 \log n$) Conditioned on event $\mathcal{E}$ (if $L = 1$ then from Part 2 of $\mathcal{E}$, otherwise from Part 3 of $\mathcal{E}$ and by the fact that $a_{\ell-1} \le 10 \log n$), $z^{(\ell)}$ obtained through Line 15 to Line 20 in Algorithm 13.3 satisfies $\|\widehat{x} - \xi^{(\ell-1)} - z^{(\ell)}\|_\infty \le 2^{1-H}\nu_\ell$ and $\mathrm{supp}(z^{(\ell)}) \subseteq S$. Namely, for all $f \in [p]^d$, $\xi_f^{(\ell-1)} + z_f^{(\ell)} \in \mathcal{B}_\infty(\widehat{x}_f, 2^{1-H}\nu_\ell)$. Recall the definition of a'_ℓ in Definition 13.2.7. We can prove that $a_\ell \le a'_\ell$ because if for all $f \in S$,

$$\left|\Pi_{\beta\nu_\ell}\left(\mathcal{B}_\infty\left(\widehat{x}_f + s_\ell^{(a'_\ell)}, 2^{3-H}\nu_\ell\right)\right)\right| = 1,$$

then for all $f \in \mathrm{supp}(y^{(\ell-1)} + z^{(\ell)})$,

$$\left|\Pi_{\beta\nu_\ell}\left(\mathcal{B}_\infty\left(y_f^{(\ell-1)} + z_f^{(\ell)} + s_\ell^{(a'_\ell)}, 2^{1-H}\nu_\ell\right)\right)\right| = 1$$

where

$$\mathcal{B}_\infty\left(y_f^{(\ell-1)} + z_f^{(\ell)} + s_\ell^{(a'_\ell)}, 2^{1-H}\nu_\ell\right) \subseteq \mathcal{B}_\infty\left(\widehat{x}_f + s_\ell^{(a'_\ell)}, 2^{3-H}\nu_\ell\right)$$

which follows by $\xi_f^{(\ell-1)} + z_f^{(\ell)} \in \mathcal{B}_\infty(\widehat{x}_f, 2^{1-H}\nu_\ell)$. Therefore, conditioned on $\mathcal{E}$ (Part 1 of $\mathcal{E}$), $a_\ell \le a'_\ell \le 10 \log n$.

(**Proving** $y_f^{(\ell)} = \xi_f^{(\ell)}$) For $f \in [p]^d$, we will prove that $y_f^{(\ell)} = \xi_f^{(\ell)}$ in two cases.

(**Case 1**) If $f \in \mathrm{supp}(y^{(\ell-1)} + z^{(\ell)}) \subseteq S$. We have

$$\begin{aligned} y_f^{(\ell)} &= \Pi_{\beta\nu_\ell}\left(y_f^{(\ell-1)} + z_f^{(\ell)} + s_\ell^{(a_\ell)}\right) \\ &= \Pi_{\beta\nu_\ell}\left(\xi_f^{(\ell-1)} + z_f^{(\ell)} + s_\ell^{(a_\ell)}\right). \end{aligned}$$

Because $\xi_f^{(\ell-1)} + z_f^{(\ell)} \in \mathcal{B}_\infty(\widehat{x}_f, 2^{1-H}\nu_\ell)$, we have $\xi_f^{(\ell-1)} + z_f^{(\ell)} + s_\ell^{(a_\ell)} \in \mathcal{B}_\infty(\widehat{x}_f + s_\ell^{(a_\ell)}, 2^{1-H}\nu_\ell)$. By the choice of $s_\ell^{(a_\ell)}$, $\Pi_{\beta\nu_\ell}(\xi_f^{(\ell-1)} + z_f^{(\ell)} + s_\ell^{(a_\ell)}) = \Pi_{\beta\nu_\ell}(\widehat{x}_f + s_\ell^{(a_\ell)})$. Thus $y_f^{(\ell)} = \xi_f^{(\ell)}$.

(**Case 2**) If $f \notin \mathrm{supp}(y^{(\ell-1)} + z^{(\ell)})$. We have $y_f^{(\ell)} = 0$. Because $\xi_f^{(\ell-1)} + z_f^{(\ell)} \in \mathcal{B}_\infty(\widehat{x}_f, 2^{1-H}\nu_\ell)$, we have $|\widehat{x}_f| < 2^{2-H}\nu_\ell < 0.1\beta\nu_\ell$ by our choice of H. We can easily prove that $\xi_f^{(\ell)} = 0 = y_f^{(\ell)}$ in the following two cases:

(**Case 2.1**) If $f \in S$, we have $\xi_f^{(\ell)} = \Pi_{\beta\nu_\ell}(\widehat{x}_f + s_\ell^{(a_\ell)}) = 0$ because

$$|\widehat{x}_f| + |s_\ell^{(a_\ell)}| < 0.1\beta\nu_\ell + 2\alpha\nu_\ell < 0.5\beta\nu_\ell.$$

(**Case 2.2**) If $f \in \overline{S}$, $\xi_f^{(\ell)} = 0$ by definition of $\xi^{(\ell)}$.

Therefore, for all $\ell \in [L-1]$, $y^{(\ell)} = \xi^{(\ell)}$ and $a_\ell \le 10 \log n$. Again conditioned on event $\mathcal{E}$ (Part 3 of $\mathcal{E}$), $z^{(L)}$ obtained through Line 15 to Line 20 in Algorithm 13.3 satisfies

$$\|\widehat{x} - y^{(L-1)} - z^{(L)}\|_\infty \le 2^{1-H}\nu_L = 2^{1-H}(2^{-(\log R^* - H + 1)}\mu R^*) = \mu.$$

Therefore, $y^{(L-1)} + z^{(L)}$ on Line 22 gives a desirable output.

□

Now we present our main theorem, which proves the correctness of Algorithm 13.3, and shows its sample complexity and time complexity.

Theorem 13.2.9 (main result, formal version)**.** *Let $n = p^d$ where both p and d are positive integers. Let $x \in \mathbb{C}^{[p]^d}$. Let $k \in \{1, \ldots, n\}$. Assume we know $\mu = \frac{1}{k}\|\widehat{x}_{-k}\|_2$ and $R^* \geq \|\widehat{x}\|_\infty / \mu$ where $\log R^* = O(\log n)$. There is an algorithm (Algorithm 13.3) that takes $O(k \log k \log n)$ samples from x, runs in $O(n \log^3 n \log k)$ time, and outputs a $O(k)$-sparse vector y such that*

$$\|\widehat{x} - y\|_\infty \leq \frac{1}{\sqrt{k}} \min_{k-\text{sparse } x'} \|\widehat{x} - x'\|_2$$

holds with probability at least $1 - 1/\operatorname{poly}(n)$.

Proof. The correctness of Algorithm 13.3 follows directly from Lemma 13.2.7 and Lemma 13.2.8. The number of samples from x is

$$B \cdot R \cdot H = O(k \cdot \log n \cdot \log k) = O(k \log k \log n).$$

Its running time is dominated by $L \cdot H = O(\log k \log n)$ invocations of LinfinityReduce (in Algorithm 13.4). By Lemma 13.2.5, the running time of LinfinityReduce is $O(n \log^2 n)$. Therefore, the running time of Algorithm 13.3 is

$$O(L \cdot H \cdot n \log^2 n) = O(\log k \cdot \log n \cdot n \log^2 n) = O(n \log^3 n \log k).$$

□

Chapter 14

Set Query

14.1 Introduction

This result presented in this section is based on a un-published manuscript, and is a joint work Vasileios Nakos and Zhengyu Wang [NSW18].

Our first result is on the set-query problem. We show that $O(k/\epsilon)$ measurements, $O(\log k)$ update time and $O(k \log k)$ query time are possible. Our hash functions are only 2-wise independent, and the amount of space to store the matrix Φ is only $O(\log k)$ words. The previous work of [Pri11] needed $\Omega(n)$ time to store the matrix, since the columns had to be fully independent, something that makes the particular sketch not applicable in the streaming model. The problem of whether the matrix can be stored in less space was explicitly stated in that paper as an open problem:

"Our analysis assumes that the columns of A are fully independent. It would be valuable to reduce the independence needed, and hence the space required to store A."

Theorem 14.1.1 (Classical set query)**.** *There exists a randomized construction of a linear sketch $\Phi \in \mathbb{R}^{m \times n}$ with $m = O(k/\epsilon)$, such that given $y = \Phi x$ and a set $S \subset [n]$ of cardinality at most k, we can find in $O(k \log k)$ time a k-sparse vector such that*

$$\|x' - x_S\|_2^2 \leq \epsilon \|x_{[n] \setminus S}\|_2^2$$

holds with probability $9/10$. The time to update the linear sketch is $O(\log k)$ and the space to store the matrix is $O(\log k)$ words.

Our second main result concerns the ubiquitous problem of frequency estimation from Fourier measurements. For any vector $x \in \mathbb{C}^n$, let $\widehat{x} \in \mathbb{C}^n$ denote the discrete Fourier transform of x. The only previous known result by the breakthrough work of [Kap17] achieves

	Space	Measurements	Decoding Time	Update Time
[Pri11]	n	k/ϵ	k	1
Theorem 14.1.1	$\log k$	k/ϵ	$k \log k$	$\log k$

Table 14.1: Results on set query. We ignore the "O" for simplicity. "Space" means the space to store matrix, which doesn't include number of measurements. We note that the decoding time of the set query algorithms do **not** depend on ϵ.

	Measurements	Running Time
[Kap17]	k/ϵ	$k/\epsilon \cdot \log^{3.001} n$
Theorem 14.1.2	$k/\epsilon \cdot \log n$	$k/\epsilon \cdot \log n$

Table 14.2: Results on Fourier set query. We ignore the "O" for simplicity. We assume signal is bounded by poly(n). In Fourier set query, there is no update time concept.

sample complexity $O(k/\epsilon)$ and running time $O(\epsilon^{-1} k \log^{2.001} n \log R^*)$ for ℓ_2/ℓ_2 Fourier set query. Here, R^* is an upper bound on the $\|\cdot\|_\infty$ norm of the vector, in most applications being considered poly(n). We indicate how our approach immediately gives an algorithm with $O(\epsilon^{-1} k \log n)$ running time. The result we get has no dependence on the running time on $\log R^*$, but does not achieve the optimal sample complexity.

Theorem 14.1.2 (Fourier set query)**.** *Given a vector $x \in \mathbb{C}^n$, for every $\epsilon \in (0,1)$ and $k \geq 1$, any $S \subseteq [n]$, $|S| = k$, there exists an algorithm that takes $O(\epsilon^{-1} k \log(n/\delta))$ samples, runs in $O(\epsilon^{-1} k \log(n/\delta))$ time, and outputs a vector $x' \in \mathbb{C}^n$ such that $\|(x' - \widehat{x})_S\|_2^2 \leq \epsilon \|\widehat{x}_{[n]\setminus S}\|_2^2 + \delta \|\widehat{x}\|_1^2$ holds with probability at least $9/10$.*

Note that δ dependence is standard in Fourier transform setting, see e.g. [HIKP12a, PS15, CKPS16].

14.2 Classical set query

In this section, we present our set query data structure. We first give the construction of sketching matrix in Section 14.2.1. Then we show our new set query data structure in Section 14.2.2. We give an analysis of the data structure in Section 14.2.4, whose correctness relies on a technical lemma on iterative loop, which is proved in Section 14.2.3.

14.2.1 Construction of sketching matrix

The sketching matrix used in our set query data structure consists of $\log k$ parts, where the i-th part ($i \in [\log k]$) of the sketching matrix corresponds to a count sketch data structure that hashes n elements into B_i bins. We defer the choice of B_i to Section 14.2.2. We present the sketching matrix Φ below.

Definition 14.2.1 (Sketching matrix Φ)**.** For each $i \in [\log k]$, we choose $h_i : [n] \to [B_i]$ to be a pairwise independent hash function, and choose $\sigma_i : [n] \to \{-1, +1\}$ to be a pairwise independent hash function.

For each $i \in [\log k]$, we define COUNT-SKETCH matrix $\Phi^{(i)} \in \mathbb{R}^{B_i \times n}$ as follows

$$\Phi^{(i)}_{j,l} = \begin{cases} \sigma_i(l) & \text{if } h_i(l) = j \\ 0 & \text{otherwise.} \end{cases}$$

Let $m = \sum_{i=1}^{\log k} B_i$. We define matrix $\Phi \in \mathbb{R}^{m \times n}$ as follows

$$\Phi = \begin{bmatrix} \Phi^{(1)} \\ \Phi^{(2)} \\ \cdots \\ \Phi^{(\log k)} \end{bmatrix}.$$

14.2.2 Algorithm

Let C be a sufficiently large constant, and γ be a sufficiently small constant. For $i \in [\log k]$, let $k_i = k\gamma^i$ and $\epsilon_i = \epsilon(10\gamma)^i$. Let $B_i = Ck_i/\epsilon_i$. The set query algorithm maintains the measurement $y = \Phi x$.

On update operation, the algorithm follows directly through the definition of sketching matrix Φ. Namely, on $\textsc{Update}(i, \Delta)$, the algorithm finds the non-zero elements of the i-th column of Φ, and update the measurement y accordingly.

On query operation $\textsc{Query}(x, S)$, the recovery procedure uses x' to record the current best approximation of x, and initially set $x' \leftarrow 0$. The procedure consists of $\log k$ iterations. In the i-th iteration, let $S_i \subseteq S$ denote the set of coordinates in x that are yet to be recovered. Initially $S_1 = S$. Remind that sketching matrix Φ in Definition 14.2.1 consists of $\log k$ parts, and the i-th part corresponds to a count sketch data structure with pair-wise independent hash function h_i and random sign function σ_i. In the i-th iteration of the set query algorithm,

$$T_i \leftarrow \left\{ j \in S_i \;\middle|\; h_i^{-1}(j) \cap S_i = \emptyset \right\}.$$

Intuitively the hash function h_i maps n elements into B_i bins, for any $j \in S_i$, we have $j \in T_i$ if and only if j does not collide with any other elements in S_i (in that case, we say j is isolated).

The procedure also maintains $y^{(i)}$, which is the measurement of the residual vector $x - x'$ (before the start of i-th iteration). After obtaining T_i, the procedure uses $y^{(i)}$ to estimate x_j for every $j \in T_i$. Then the procedure updates S_i and x' accordingly. Finally, the algorithm outputs x'. Our iterative set query algorithm is presented in Algorithm 14.1.

Algorithm 14.1 Iterative Set Query

      $l \leftarrow \sum_{i'=1}^{i-1} B_{i'}$
      For each $j \in T_i$, compute $\widehat{x}_j \leftarrow y^{(i)}_{l+h_i(j)}$
      $S_{i+1} \leftarrow S_i \backslash T_i$
      $y^{(i+1)} \leftarrow y^{(i)} - \Phi \widehat{x}_{T_i}$
      $x' \leftarrow x' + \widehat{x}_{T_i}$
    end for
    return x'
  end procedure
end procedure

14.2.3 Iterative loop analysis

In this subsection, we characterize and prove two properties of the iterative loop in Algorithm 14.1. The first property states that with good probability, as i increases, the size of S_i shrinks by a factor of at least $1 - \gamma$, and otherwise its size does not increase.

This property is guaranteed by identification property of count sketch and our choice of parameters. The second property states that with good probability, the estimation error in each round is small. This is guaranteed by estimation property of count sketch and our choice of parameters. We formalize both properties in Lemma 14.2.1 as follows.

Lemma 14.2.1. *Given parameters $\epsilon \in (0,1), k \geq 1$, for each $i \in [\log k]$, we define*

$$k_i = k\gamma^i, \epsilon_i = \epsilon(10\gamma)^i, B_i = C \cdot k_i/\epsilon_i.$$

For each $i \in [\log k]$, if

$$\forall j \in [i-1], |S_{j+1}| \leq \gamma |S_j|,$$

and

$$\forall j \in [i-1], \sum_{t \in T_j} |x_t - \widehat{x}_t|^2 \leq \epsilon \cdot 2^{-j} \|x_{\overline{S}}\|_2^2.$$

Then we have :

Property (I) : *With probability at least $1 - \frac{1}{C\gamma}(10\gamma)^i$,*

$$|S_{i+1}| \leq \gamma |S_i|,$$

and otherwise $|S_{i+1}| \leq |S_i|$.

Property (II) : *With probability at least $1 - \frac{2}{C}(20\gamma)^i$,*

$$\sum_{t \in T_i} |x_t - \widehat{x}_t|^2 \leq \epsilon \cdot 2^{-i} \|x_{\overline{S}}\|_2^2.$$

Proof. **Proof of Property (I).**

For each $i \in [\log k]$, for each $j \in S_i$, we use $Z_{i,j}$ to denote the boolean random variable where $Z_{i,j} = 1$ if there exists a $j' \in S_i \backslash \{j\}$ such that $h_i(j) = h_i(j')$ and $Z_{i,j} = 0$ otherwise. By the randomness of hash function h_i,

$$\Pr_{h_i}[Z_{i,j} = 1] = \Pr_{h_i}[j \text{ is not isolated from } S_i] \leq |S_i|/B_i.$$

By the statement of the lemma, we know that $|S_i| \leq \gamma^i k$ and $B_i = Ck\gamma^i/\epsilon_i$, thus

$$\Pr_{h_i}[Z_{i,j} = 1] \leq \gamma^i k/B_i \leq \epsilon_i/C.$$

We define $Z_i = \sum_{j \in S_i} Z_{i,j}$. Next, we can show

$$\mathop{\mathbb{E}}_{h_i}[Z_i] = \mathop{\mathbb{E}}_{h_i}[|\{j \in S_i \mid j \text{ is not isolated from } S_i\}|] = \mathop{\mathbb{E}}_{h_i}\left[\sum_{j \in S_i} Z_{i,j}\right] = \sum_{j \in S_i} \mathop{\mathbb{E}}_{h_i}[Z_{i,j}] \leq |S_i|\epsilon_i/C,$$

where the third step follows by linearity of expectation. Therefore,

$$\Pr_{h_i}[Z_i \geq \gamma|S_i|] \leq \mathop{\mathbb{E}}_{h_i}[Z_i]/(\gamma|S_i|) \leq |S_i|\epsilon_i/(C\gamma|S_i|) = \epsilon_i/(C\gamma),$$

where the first step follows by Markov's inequality, and second step follows by $\mathbb{E}_{h_i}[Z_i] \leq |S_i|\epsilon_i/C$. This implies

$$\Pr[|S_{i+1}| \geq \gamma|S_i|] \leq \epsilon(10\gamma)^i/(C\gamma) \leq \frac{1}{C\gamma}(10\gamma)^i.$$

Proof of Property (II).

We first define random variable V_i to be

$$V_i = \sum_{l \in \left(\cup_{j \in S_i} h_i^{-1}(j)\right) \backslash S_i} |x_l^{(i)}|^2.$$

That is, $x^{(i)}$ is the residual signal in the i-th round, and V_i refers to the noise coordinates that are hashed to the same bins as coordinates in S_i.

We can compute the expectation of V_i,

$$\begin{aligned}\mathop{\mathbb{E}}_{h_i}[V_i] &= \mathop{\mathbb{E}}_{h_i}\left[\sum_{l\in\left(\cup_{j\in S_i}h_i^{-1}(j)\right)\setminus S_i}|x_l^{(i)}|^2\right]\\ &\leq k_i\|x^{(i)}_{\overline{S}_i}\|_2^2/B_i\\ &= \frac{\epsilon_i}{C}\|x^{(i)}_{\overline{S}_i}\|_2^2\\ &= \frac{(10\gamma)^i\epsilon}{C}\|x^{(i)}_{\overline{S}_i}\|_2^2,\end{aligned}$$

where the first step follows by the fact that for each $l \in \overline{S_i}$, the probability that $l \in \left(\cup_{j\in S_i}h_i^{-1}(j)\right)\setminus S_i$ under the randomness of h_i is $|S_i|/B_i \leq k_i/B_i$, the second and third step follow by definitions of B_i and ϵ_i, respectively.

By Markov's inequality, we have

$$\Pr_{h_i}\left[V_i \geq \frac{1}{2}\cdot 10^{-i}\epsilon\left\|x^{(i)}_{\overline{S}_i}\right\|_2^2\right] \leq 2\frac{(100\gamma)^i}{C}. \tag{14.1}$$

In the following, we argue conditioned on the event that all elements in T_i are isolated under h_i and $V_i \leq 10^{-i}\epsilon\|x^{(i)}_{\overline{S}_i}\|_2^2/2$.

Recall the definition of $x^{(i)} \in \mathbb{R}^n$,

$$x^{(i)} = x - \sum_{t\in S\setminus S_i}\widehat{x}_t = x - \sum_{j=1}^{i}\sum_{t\in T_j}\widehat{x}_t. \tag{14.2}$$

For any fixed $t \in T_i$, let $b = h_i(t)$. We have

$$\begin{aligned}
\mathop{\mathbb{E}}_{\sigma_i}\left[|x_t - \widehat{x}_t|^2\right] &= \mathop{\mathbb{E}}_{\sigma_i}\left[\left|x_t - \sigma_i(t) \cdot \sum_{l:h_i(l)=b} \sigma_i(l) x_l^{(i)}\right|^2\right] \\
&= \mathop{\mathbb{E}}_{\sigma_i}\left[\left|\sum_{l \in h_i^{-1}(b)\setminus\{t\}} \sigma_i(l) x_l^{(i)}\right|^2\right] \\
&= \sum_{l \in h_i^{-1}(b)\setminus\{t\}} |x_l^{(i)}|_2^2, \qquad (14.3)
\end{aligned}$$

where the first step follows by definition of $\widehat{x}_t$ in Algorithm 14.1 and construction of sketching matrix Φ in Definition 14.2.1, the third step follows by pairwise independence property of random sign function σ_i.

We can upper bound $\mathbb{E}_{\sigma_i}[\sum_{t\in T_i} |x_t - \widehat{x}_t|^2]$ in the following way,

$$\begin{aligned}
\mathop{\mathbb{E}}_{\sigma_i}\left[\sum_{t\in T_i} |x_t - \widehat{x}_t|^2\right] &= \sum_{t\in T_i} \sum_{l \in h_i^{-1}(t)\setminus\{t\}} |x_l^{(i)}|_2^2 && \text{by Eq. (14.3)} \\
&\leq \sum_{l \in \cup_{t\in S_i} h_i^{-1}(t)\setminus\{t\}} |x_l^{(i)}|_2^2 && \text{by definition of } T_i \\
&\leq \epsilon 10^{-i} \|x_{\overline{S}_i}^{(i)}\|_2^2/2 && \text{by Eq. (14.1)} \\
&\leq \epsilon 10^{-i} \|x_{\overline{S}}\|_2^2 && \text{by Eq. (14.5)} \qquad (14.4)
\end{aligned}$$

Second, we show how to upper bound $\|x^{(i)}_{\overline{S}_i}\|_2^2$,

$$\begin{aligned}
\|x^{(i)}_{\overline{S}_i}\|_2^2 &= \|x^{(i)}_{\overline{S}\cup S\backslash S_i}\|_2^2 && \text{by } \overline{S_i} = \overline{S}\cup S\backslash S_i \\
&= \|x^{(i)}_{\overline{S}}\|_2^2 + \|x^{(i)}_{S\backslash S_i}\|_2^2 && \text{by } \overline{S}\cap(S\backslash S_i) = \emptyset \\
&= \|x_{\overline{S}}\|_2^2 + \|x^{(i)}_{S\backslash S_i}\|_2^2 && \text{by } x^{(i)}_{\overline{S}} = x_{\overline{S}} \\
&= \|x_{\overline{S}}\|_2^2 + \sum_{j=1}^{i-1}\|x^{(i)}_{T_j}\|_2^2 && \text{by } S\backslash S_i = T_1\cup T_2\cup\cdots\cup T_{i-1} \\
&= \|x_{\overline{S}}\|_2^2 + \sum_{j=1}^{i-1}\sum_{t\in T_j}|x_t - \widehat{x}_t|^2 && \text{by Eq. (14.2)} \\
&\leq \|x_{\overline{S}}\|_2^2 + \sum_{j=1}^{i-1}\epsilon 2^{-j}\|x_{\overline{S}}\|_2^2 && \text{by statement of Lemma} \\
&\leq 2\|x_{\overline{S}}\|_2^2. && \text{by geometric sum} \qquad (14.5)
\end{aligned}$$

Using Markov's inequality $\Pr[X \geq a] \leq \mathbb{E}[X]/a$, we have

$$\Pr\left[\sum_{t\in T_i}|x_t - \widehat{x}_t|^2 \geq \epsilon 2^{-i}\|x_{\overline{S}}\|_2^2\right] \leq 5^{-i}.$$

Therefore, we complete the proof. □

14.2.4 Main result

In this section, we prove the correctness of our iterative set query algorithm, as well as justify the claimed space complexity, update time and query time. At the core of correctness is an analysis of the iterative loop, which is given as Lemma 14.2.1 in Section 14.2.3.

Theorem 14.2.2. *Let $m = O(k/\epsilon)$. We can give a randomized construction of a matrix $\Phi \in \mathbb{R}^{m\times n}$ (Definition 14.2.1) such that for each set $S \subseteq [n]$, $|S| \leq k$, and for each vector*

$x \in \mathbb{R}^n$, there is an algorithm (Algorithm 14.1) that takes Φx as its input, and finds $x' \in \mathbb{R}^k$ such that

$$\|x' - x_S\|_2^2 \leq \epsilon \|x_{[n]\setminus S}\|_2^2$$

holds with probability 9/10. The space to store matrix Φ is $O(\log k)$ words. The columns of matrix Φ are 2-wise independent. The update time is $O(\log k)$. The decoding time is $O(k \log k)$.

Proof. Our proof is based on properties of the iterative loop in Algorithm 14.1. The properties are formulated as Lemma 14.2.1 in Section 14.2.3. In summary, property (I) in Lemma 14.2.1 shows that with good probability, as i increases, the size of S_i (i.e. the set of coordinates in S that yet to be recovered at the beginning of i-th round) shrinks by a constant factor, and otherwise its size does not increase. Property (II) in Lemma 14.2.1 shows that with good probability, the estimation error in each round is small.

Proof of success probability. It follows by recursively applying Lemma 14.2.1. By union bound, the failure probability is bounded by

$$\sum_{i=1}^{\log k} \left(\frac{1}{C\gamma} (10\gamma)^i + \frac{2}{C} (20\gamma)^i \right) < 1/10,$$

which follows from geometric sum and the choice of parameters.

Proof of estimation error.

$$\|x' - x_S\|_2^2 \leq \sum_{i=1}^{\log k} \sum_{t \in T_i} |x_t - \widehat{x}_t|^2 \leq \sum_{i=1}^{\log k} \epsilon \cdot 2^{-i} \|x_{\overline{S}}\|_2^2 \leq \epsilon \|x_{\overline{S}}\|_2^2.$$

Proof of space to store Φ. Since for each $i \in [\log k]$, $\Phi^{(i)}$ only uses 2 pairwise independent hash functions, the space to store matrix Φ is $O(\log k)$ words.

Proof of update time. Upon update (j, Δ), for each $\Phi^{(i)}$, the algorithm only needs to update one measurement (located at $h_i(j)$). Therefore, the update time is $O(\log k)$. Since every element of the matrix can be computed in $O(1)$ time.

Proof of query time. First of all, we note that the step in Line 18 can be performed in $O(|S_i|)$ time upon query, since we can check every $j \in S_i$, and mark the buckets that have more than one j hashed to them; in the next step we just keep only those coordinates j that are hashed to exactly one bucket. Recursively applying Lemma 14.2.1, we have with constant probability, such that for all $i \in [\log k]$, $|S_{i+1}| \leq \gamma |S_i|$. It implies that for all $i \in [\log k]$, $|S_i| \leq \gamma^{i-1}|S_1| \leq \gamma^{i-1}k$. Note that in iteration $i \in [\log k]$, we need $O(|S_i|)$ update time. Therefore, overall the iterations, the time of this part is

$$\sum_{i=1}^{\log k} O(|S_i|) \leq O\left(\sum_{i=1}^{\log k} \gamma^{i-1} k\right) = O(k),$$

where the last step follows by the choice of γ.

We know that $\|z\|_0 = O(k)$ and $|T_i| = O(k)$. Thus, in each iteration, the time of doing step $y^{(i+1)} \leftarrow y^{(i)} - \Phi Z_{T_i}$ requires $O(k)$ time. Thus the subtraction time over all iterations is $O(k \log k)$, since there are $O(\log k)$ iterations. Putting it together, we get $O(k \log k)$ query time.

□

14.3 Fourier set query

We present some definitions and backgrounds of Fourier transform in Section 14.3.1. Then we introduce spectrum permutations and filter functions in Section 14.3.2. They are used as hashing schemes in Fourier transform literatures. In Section 14.3.3, we introduce collision events. large offset events, and large noise events. We give a new algorithm and provide iterative loop analysis in Section 14.3.4. Finally, we present main result in Section 14.3.5.

14.3.1 Definitions and some backgrounds of Fourier transform

We use $\mathbf{i}$ to denote $\sqrt{-1}$. Note that $e^{\mathbf{i}\theta} = \cos(\theta) + \mathbf{i}\sin(\theta)$. For any complex number $z \in \mathbb{C}$, we have $z = a + \mathbf{i}b$, where $a, b \in \mathbb{R}$. We define the complement of z as $\overline{z} = a - \mathbf{i}b$. We define $|z| = \sqrt{z\overline{z}} = \sqrt{a^2 + b^2}$. For any complex vector $x \in \mathbb{C}^n$, we use $\mathrm{supp}(x)$ to denote the support of x, and then $\|x\|_0 = |\mathrm{supp}(x)|$.

The discrete convolution of functions f and g is given by,

$$(f * g)[n] = \sum_{m=-\infty}^{+\infty} f[m]g[n-m]$$

For a complex vector $x \in \mathbb{C}^n$, we use $\widehat{x} \in \mathbb{C}^n$ to denote its Fourier spectrum,

$$\widehat{x}_i = \frac{1}{\sqrt{n}} \sum_{j=1}^{n} e^{-2\pi \mathbf{i} ij/n} x_j, \forall i \in [n].$$

Then the inverse transform is

$$x_j = \frac{1}{\sqrt{n}} \sum_{i=1}^{n} e^{2\pi \mathbf{i} ij/n} \widehat{x}_i, \forall j \in [n].$$

We define

$$\mathrm{Err}(x, k) = \min_{k-\mathrm{sparse}\ y} \|x - y\|_2.$$

14.3.2 Permutation and filter function

We use the same (pseudorandom) spectrum permutation as [HIKP12a],

Definition 14.3.1. Suppose σ^{-1} exists mod n. We define the permutation $P_{\sigma,a,b}$ by

$$(P_{\sigma,a,b}x)_i = x_{\sigma(i-a)}e^{-2\pi \mathbf{i}\sigma bi/n}.$$

We also define $\pi_{\sigma,b} = \sigma(i-b) \pmod n$. Then we have

Claim 14.3.1. $\widehat{P_{\sigma,a,b}x}_{\pi_{\sigma,b}(i)} = \widehat{x}_i e^{-2\pi \mathbf{i}\sigma ai/n}$.

$h_{\sigma,b}(i) = \mathrm{round}(\pi_{\sigma,b}(i)B/n)$ and $o_{\sigma,b}(i) = \pi_{\sigma,b}(i) - h_{\sigma,b}(i)n/B$. We say $h_{\sigma,b}(i)$ is the "bin" that frequency i is mapped into, and $o_{\sigma,b}(i)$ is the "offset".

We use the same filter function as [HIKP12a, PS15, CKPS16],

Definition 14.3.2. Given parameters $B \geq 1$, $\delta > 0$, $\alpha > 0$. We say that $(G, \widehat{G}') = (G_{B,\delta,\alpha}, \widehat{G}'_{B,\delta,\alpha}) \in \mathbb{R}^n$ is a filter function(Figure 14.1) if it satisfies the following properties

(I) $|\operatorname{supp}(G)| = O(\alpha^{-1}B\log(n/\delta))$,

(I) $\widehat{G}'_i = 1$, if $|i| \leq (1-\alpha)n/(2B)$,

(II) $\widehat{G}'_i = 0$, if $|i| \geq n/(2B)$,

(III) $\widehat{G}'_i \in [0,1]$, for all i,

(IV) $\left\|\widehat{G}' - \widehat{G}\right\|_\infty < \infty$.

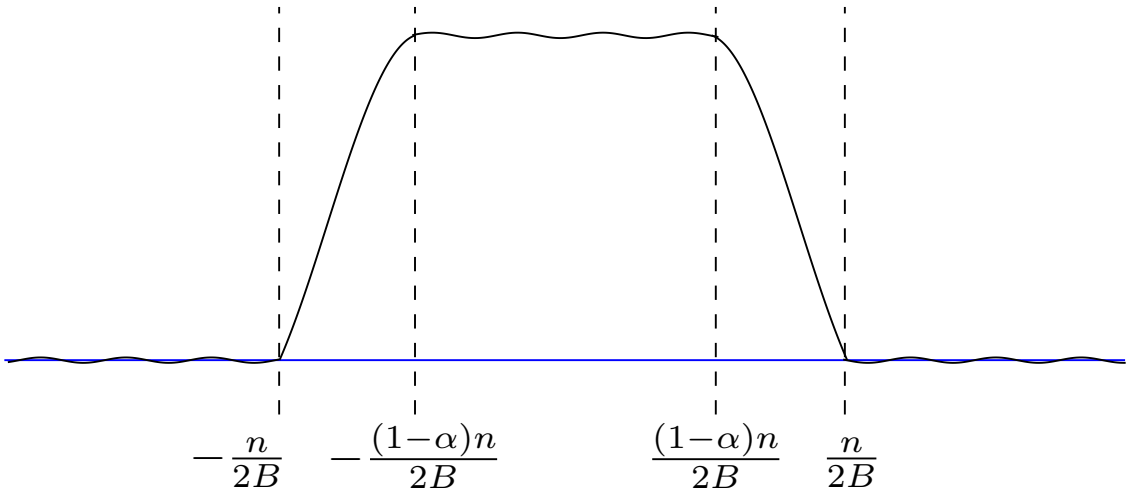

Figure 14.1: Filter $\widehat{G}'$

14.3.3 Collision event, large offset event, and large noise event

We use three types of events defined in [HIKP12a] as basic building blocks for analyzing Fourier set query algorithms. For any $i \in S$, we define three types of events associated with i and S and defined over the probability space induced by σ and b:

Definition 14.3.3 (Collision, large offset, large noise)**.** "Collision" event $E_{\text{coll}}(i)$: holds iff $h_{\sigma,b}(i) \in h_{\sigma,b}(S \backslash \{i\})$.

"Large offset" event $E_{\text{off}}(i)$: holds iff $|o_{\sigma,b}(i)| \geq (1-\alpha)n/(2B)$.

"Large noise" event $E_{\text{noise}}(i)$: holds iff

$$\mathbb{E}\left[\left\|\widehat{x}'_{h^{-1}_{\sigma,b}(h_{\sigma,b}(i)) \backslash S}\right\|_2^2\right] \geq \text{Err}^2(\widehat{x}', k)/(\alpha B).$$

Claim 14.3.2 (Claim 3.1 in [HIKP12a])**.** *For any $i \in S$, the event $E_{\text{coll}}(i)$ holds with probability at most $4|S|/B$.*

Claim 14.3.3 (Claim 3.2 in [HIKP12a]). *For any $i \in S$, the event $E_{\text{off}}(i)$ holds with probability at most α.*

Claim 14.3.4 (Claim 4.1 in [HIKP12a]). *For any $i \in S$, $\Pr[E_{\text{noise}(i)}] \leq 4\alpha$.*

Lemma 14.3.5 (Lemma 4.2 in [HIKP12a]). *Let $a \in [n]$ uniformly at random, B divide n, and the other parameters be arbitrary in*

$$\widehat{u} = \textsc{HashToBins}(x, \widehat{z}, P_{\sigma,a,b}, B, \delta, \alpha).$$

Then for any $i \in [n]$ with $j = h_{\sigma,b}(i)$ and none of $E_{\text{coll}}(i)$, $E_{\text{off}}(i)$ or $E_{\text{noise}}(i)$ holding,

$$\mathbb{E}\left[\left|\widehat{u}_j - \widehat{x}'_i e^{-\frac{2\pi \mathbf{i}}{n} a\sigma i}\right|^2\right] \leq 2\frac{\rho^2}{\alpha B}.$$

Lemma 14.3.6. *Suppose B divides n. The output $\widehat{u}$ of* HashToBins *satisfies*

$$\widehat{u}_j = \sum_{h_{\sigma,b}(i)=j} \widehat{(x-z)}_i (\widehat{G'_{B,\delta,\alpha}})_{-o_{\sigma,b}(i)} \omega^{a\sigma i} \pm \delta \|\widehat{x}\|_1.$$

Let $\zeta = |\{i \in \text{supp}(\widehat{z}) \mid E_{\text{off}}(i)\}|$. The running time of HashToBins *is $O(\frac{B}{\alpha}\log(n/\delta) + \|\widehat{z}\|_0 + \zeta \log(n/\delta))$.*

14.3.4 Iterative loop analysis

Iterative loop analysis for Fourier set query is more tricky than the classic set query, because in the Fourier case, hashing is not perfect, in the sense that by using spectrum permutation and filter function (as the counterpart of hashing techniques), one coordinate can non-trivially contribute to multiple bins. We give iterative loop induction in Lemma 14.3.7.

Lemma 14.3.7. *Given parameters $C \geq 1000$, $\gamma \leq 1/1000$. For any $k \geq 1, \epsilon \in (0,1)$, $R \geq 1$. For each $i \in [R]$, we define*

$$k_i = k\gamma^i, \epsilon_i = \epsilon(10\gamma)^i, \alpha_i = 1/(200i^3), B_i = C \cdot k_i/(\alpha_i^2 \epsilon_i).$$

For each $i \in [R]$:

If for all $j \leq [i-1]$ we have

$$\mathrm{supp}(\widehat{w}^{(j)}) \subseteq S_j, \quad |S_{j+1}| \leq k_{j+1}, \quad \widehat{z}^{(j+1)} = \widehat{z}^{(j)} + \widehat{w}^{(j)}, \quad \widehat{x}^{(j+1)} = \widehat{x} - \widehat{z}^{(j+1)},$$

and

$$\|\widehat{x}^{(j+1)}_{\overline{S}_{j+1}}\|_2^2 \leq (1+\epsilon_j)\|\widehat{x}^{(j)}_{\overline{S}_j}\|_2^2 + \epsilon_j \delta^2 n \|\widehat{x}\|_1^2.$$

Then, with probability $1 - 10\alpha_i/\gamma$, we have

$$\mathrm{supp}(\widehat{w}^{(i)}) \subseteq S_i, \quad |S_{i+1}| \leq k_{i+1}, \quad \widehat{z}^{(i+1)} = \widehat{z}^{(i)} + \widehat{w}^{(i)}, \quad \widehat{x}^{(i+1)} = \widehat{x} - \widehat{z}^{(i+1)},$$

and

$$\|\widehat{x}^{(i+1)}_{\overline{S}_{i+1}}\|_2^2 \leq (1+\epsilon_i)\|\widehat{x}^{(i)}_{\overline{S}_i}\|_2^2 + \epsilon_i \delta^2 n \|\widehat{x}\|_1^2.$$

Proof. We consider a particular step i. We can condition on $|S_i| \leq k_i$.

Collision. Using Claim 14.3.2, for any $t \in S_i$, the event $E_{\mathrm{coll}}(t)$ holds with probability at most

$$4|S_i|/B_i \leq \frac{4k_i}{Ck_i/(\alpha_i^2\epsilon_i)} = 4\alpha_i^2\epsilon_i/C \leq \alpha_i.$$

It means

$$\Pr_{\sigma,b}[E_{\mathrm{coll}}(t)] \leq \alpha_i.$$

Large offset. Using Claim 14.3.3, for any $t \in S_i$, the event $E_{\text{off}}(t)$ holds with probability at most α_i, i.e.

$$\Pr_{\sigma,b}[E_{\text{off}}(t)] \leq \alpha_i.$$

Large noise. Using Claim 14.3.4, for any $t \in S_i$,

$$\Pr_{\sigma,b}[E_{\text{noise}}(t)] \leq 4\alpha_i.$$

We say a coordinate t is "well isolated" if none of the above three events holding. By a union bound over the above three events, we have t is "well isolated" with probability at least $1 - 6\alpha_i$.

Therefore, each $t \in S_i$ lies in T_i with probability at least $1 - 6\alpha_i$. Then by Markov's inequality, we have $|S_i \backslash T_i| \leq \gamma k_i$ with probability $1 - 6\alpha_i/\gamma$. By definition $S_{i+1} = S_i \backslash T_i$, then we know that

$$|S_{i+1}| = |S_i \backslash T_i| \leq \gamma k_i \leq k_{i+1}.$$

Upper bound $\|\widehat{x}^{(i)}_{\overline{S}_i}\|_2^2$. By Lemma statement we have

$$\begin{aligned}
\|\widehat{x}^{(i)}_{\overline{S}_i}\|_2^2 &\leq (1+\epsilon_i)\|\widehat{x}^{(i)}_{\overline{S}_i}\|_2^2 + \epsilon_i \delta^2 n \|\widehat{x}\|_1^2 \\
&\leq (1+\epsilon_i)(1+\epsilon_{i-1})\|\widehat{x}^{(i-1)}_{\overline{S}_{i-1}}\|_2^2 + ((1+\epsilon_i)\epsilon_{i-1} + \epsilon_i)\delta^2 n \|\widehat{x}\|_1^2 \\
&\leq \cdots \\
&\leq \prod_{j=1}^{i}(1+\epsilon_j)\|\widehat{x}_{\overline{S}}\|_2^2 + \sum_{j=1}^{i} \epsilon_j \delta^2 n \|\widehat{x}\|_1^2 \prod_{l=j+1}^{i}(1+\epsilon_l) \\
&\leq 8(\|\widehat{x}_{\overline{S}}\|_2^2 + \delta^2 n \|\widehat{x}\|_1^2), \qquad (14.6)
\end{aligned}$$

where the third step refers to recursively apply the second step, the last step follows by a geometric sum.

For a fixed $t \in S_i$, let $j = h_{\sigma,b}(t)$. By Lemma 3.3, we have

$$\widehat{u}_j - \widehat{x}_t^{(i)}\omega^{a\sigma t} = \sum_{t' \in T_i} \widehat{G}'_{-o_\sigma(i')}\widehat{x}_{t'}^{(i)}\omega^{a\sigma t'} \pm \delta\|\widehat{x}\|_1$$

For each $t \in S_i$, we define set $Q_{i,t} = h_{\sigma,b}^{-1}(j)\backslash\{t\}$. Let T_i be the set of coordinates $t \in S_i$ such that $Q_{i,t} \cap S_i = \emptyset$. Then it is easy to observe that

$$\begin{aligned}\sum_{t\in T_i}\left|\sum_{t'\in Q_{i,t}} \widehat{G}'_{-o_\sigma(t)}\widehat{x}_{t'}^{(i)}\omega^{a\sigma t'}\right|^2 &= \sum_{t\in T}\left|\sum_{t'\in Q_{i,t}\backslash S} \widehat{G}'_{-o_\sigma(t')}\widehat{x}_{t'}^{(i)}\omega^{a\sigma t'}\right|^2 \\ &\le \sum_{t\in S}\left|\sum_{t'\in Q_{i,t}\backslash S} \widehat{G}'_{-o_\sigma(t')}\widehat{x}_{t'}^{(i)}\omega^{a\sigma t'}\right|^2\end{aligned}$$

We can calculate the expectation of $\|\widehat{x}_{T_i}^{(i)} - \widehat{w}^{(i)}\|_2^2$,

$$\begin{aligned}\mathop{\mathbb{E}}_{\sigma,a,b}\left[\left\|\widehat{x}_{T_i}^{(i)} - \widehat{w}^{(i)}\right\|_2^2\right] &= \mathop{\mathbb{E}}_{\sigma,a,b}\left[\sum_{t\in T_i}\left\|\widehat{x}_t^{(i)} - \widehat{w}_t^{(i)}\right\|_2^2\right] \\ &\le \sum_{i\in S} 2\mathop{\mathbb{E}}_{\sigma,a,b}\left[\left|\sum_{i'\in Q_i\backslash S}\widehat{G}'_{-o_\sigma(i)}\omega^{a\sigma i}\right|^2\right] + \delta^2\|\widehat{x}\|_1^2 \\ &\le \sum_{t\in S_i}(\frac{1}{B_i}\|\widehat{x}_{\overline{S}_i}^{(i)}\|_2^2 + \delta^2\|\widehat{x}\|_1^2) \\ &\le \frac{|S_i|}{B_i}\|\widehat{x}_{\overline{S}_i}^{(i)}\|_2^2 + \delta^2|S_i|\cdot\|\widehat{x}\|_1^2 \\ &\le \frac{\epsilon_i\alpha_i^2}{C}\|\widehat{x}_{\overline{S}_i}^{(i)}\|_2^2 + \delta^2|S_i|\cdot\|\widehat{x}\|_1^2,\end{aligned}$$

where the last step follows from $|S_i| \le k_i$ and $B_i = C \cdot k_i/(\alpha_i^2\epsilon_i)$.

Then, using Markov's inequality, we have,

$$\Pr\left[\left\|\widehat{x}^{(i)}_{T_i} - \widehat{w}^{(i)}\right\|_2^2 \geq \frac{\epsilon_i\alpha_i}{C}\|\widehat{x}^{(i)}_{\overline{S}_i}\|_2^2 + \delta^2\frac{|S_i|}{\alpha_i}\|\widehat{x}\|_1^2\right] \leq \alpha_i.$$

Note that

$$\begin{aligned}\frac{\epsilon_i\alpha_i}{C}\|\widehat{x}^{(i)}_{\overline{S}_i}\|_2^2 + \delta^2\frac{|S_i|}{\alpha_i}\|\widehat{x}\|_1^2 \leq& \frac{\epsilon_i}{C}\|\widehat{x}^{(i)}_{\overline{S}_i}\|_2^2 + \delta^2\frac{|S_i|}{\alpha_i}\|\widehat{x}\|_1^2\\ \leq& \frac{\epsilon_i}{C}\|\widehat{x}^{(i)}_{\overline{S}_i}\|_2^2 + \frac{\epsilon_i}{C}\delta^2 B_i\|\widehat{x}\|_1^2\\ \leq& \frac{\epsilon_i}{C}\|\widehat{x}^{(i)}_{\overline{S}_i}\|_2^2 + \frac{\epsilon_i}{C}\delta^2 n\|\widehat{x}\|_1^2\\ \leq& \frac{\epsilon_i}{20}(\|\widehat{x}^{(i)}_{\overline{S}_i}\|_2^2 + \delta^2 n\|\widehat{x}\|_1^2),\end{aligned}$$

where the first step follows by $\alpha_i \leq 1$, the second step follows by $|S_i| \leq k_i = \epsilon_i B_i\alpha_i^2/C$, the third step follows by $B_i \leq n$, the last step follows by $C \geq 1000$.

Thus, we have

$$\Pr\left[\left\|\widehat{x}^{(i)}_{T_i} - \widehat{w}^{(i)}\right\|_2^2 \leq \frac{\epsilon_i}{20}(\|\widehat{x}^{(i)}_{\overline{S}_i}\|_2^2 + \delta^2 n\|\widehat{x}\|_1^2)\right] \geq 1 - \alpha_i. \tag{14.7}$$

Recall that $\widehat{w}^{(i)} = \widehat{z}^{(i+1)} - \widehat{z}^{(i)} = \widehat{x}^{(i)} - \widehat{x}^{(i+1)}$. It is obvious that $\mathrm{supp}(\widehat{w}^{(i)}) \subseteq T_i$.

Conditioning on all coordinates in T_i are well isolated and Eq. (14.7) holds, we have

$$\begin{aligned}
\|\widehat{x}^{(i+1)}_{\overline{S}_{i+1}}\|_2^2 &= \|(\widehat{x}^{(i)} - \widehat{w}^{(i)})_{\overline{S}_{i+1}}\|_2^2 \\
&= \|\widehat{x}^{(i)}_{\overline{S}_{i+1}} - \widehat{w}^{(i)}_{\overline{S}_{i+1}}\|_2^2 \\
&= \|\widehat{x}^{(i)}_{\overline{S}_{i+1}} - \widehat{w}^{(i)}\|_2^2 \\
&= \|\widehat{x}^{(i)}_{\overline{S}_i \cup T_i} - \widehat{w}^{(i)}\|_2^2 && \text{by } S_i = T_i \cup S_{i+1} \\
&= \|\widehat{x}^{(i)}_{\overline{S}_i}\|_2^2 + \|\widehat{x}^{(i)}_{T_i} - \widehat{w}^{(i)}\|_2^2 && \text{by } \overline{S}_i \cap T_i = \emptyset \\
&\leq \|\widehat{x}^{(i)}_{\overline{S}_i}\|_2^2 + \epsilon_i(\|\widehat{x}^{(i)}_{\overline{S}_i}\|_2^2 + \delta^2 n \|\widehat{x}\|_1^2) && \text{by Eq. (14.7)} \\
&= (1+\epsilon_i)\|\widehat{x}^{(i)}_{\overline{S}_i}\|_2^2 + \epsilon_i \delta^2 n \|\widehat{x}\|_1^2. && \text{by definition } \mu_{(i)}
\end{aligned}$$

□

14.3.5 Main result

In this subsection, we give the main result as the following theorem.

Theorem 14.3.8 (Main result)**.** *Given a vector $x \in \mathbb{C}^n$, for every $\epsilon \in (0,1)$ and $k \geq 1$, any $S \subseteq [n]$, $|S| = k$, there exists an algorithm (Algorithm 14.2) that takes*

$$O(\epsilon^{-1} k \log(n/\delta))$$

samples, runs in

$$O(\epsilon^{-1} k \log(n/\delta))$$

time, and outputs a vector $x' \in \mathbb{C}^n$ such that

$$\|(x' - \widehat{x})_S\|_2^2 \leq \epsilon \|\widehat{x}_{[n]\setminus S}\|_2^2 + \delta \|\widehat{x}\|_1^2,$$

holds with probability at least $9/10$.

Proof. **Proof of Sample Complexity.** The sample complexity of ESTIMATION is

$$\sum_{i=1}^{R}(B_i/\alpha_i)\log(n/\delta) = \epsilon^{-1}k\log(n/\delta).$$

Proof of Success Probability.

The failure probability is

$$\sum_{i=1}^{R} 10\alpha_i/\gamma < 1/10.$$

Proof of Final Error

$$\begin{aligned}
\|\widehat{x}_S - \widehat{z}^{(R+1)}\|_2^2 &= \sum_{i=1}^{R}\|\widehat{x}_{T_i}^{(i)} - \widehat{w}^{(i)}\|_2^2 \\
&\le \sum_{i=1}^{R} k_i\mu^{(i)}/20 && \text{by Eq. (14.7)} \\
&\le \sum_{i=1}^{R}\epsilon_i(\|\widehat{x}_{\overline{S}_i}^{(i)}\|_2^2 + \delta^2 n\|\widehat{x}\|_1^2)/20 && \text{by Definition of } \mu^{(i)} \\
&\le \sum_{i=1}^{R}\epsilon_i\cdot 10(\|\widehat{x}_{\overline{S}}\|_2^2 + \delta^2 n\|\widehat{x}\|_1^2)/20 && \text{by Eq. (14.6)} \\
&\le \epsilon(\|\widehat{x}_{\overline{S}}\|_2^2 + \delta^2 n\|\widehat{x}\|_1^2). && \text{by geometric sum}
\end{aligned}$$

Chapter 15

Robust Sparse Recovery via M-estimators

We consider the extensively studied problem of sparse recovery, where the error is measured with respect to M-estimators, such as the Huber or the Tukey loss functions. All previous works have studied the problem under the ℓ_p norms. Thus, our work is the first to explore the more robust error measures of M-estimators, which are very popular in statistics. In specific, given linear measurements $y = Ax$, we want to output a k-sparse vector $x' \in \mathbb{R}^n$ such that

$$\|x' - x\|_M \leq (1+\epsilon) \min_{k-\text{sparse } y} \|y - x\|_M,$$

where $\|x\|_M$ is corresponds to some M-estimator of x. We show that the measurement complexity of different versions of the sparse recovery problem under these more sophisticated error measures does not change, igniting thus an interesting new line of research.

15.1 Introduction

The mathematical framework of compressed sensing, or sparse recovery, aims to reconstruct an approximately k-sparse vector $x \in \mathbb{R}^n$ from linear measurements $y = Ax$. This model can capture many significant problems, which appear in a variety of fields, such as Discrete Signal Processing[LDP07b], Machine Learning [LDW+18], Statistics [Rip04] etc. Depending on the application, the measurement matrix A is drawn from some random matrix ensemble, or can be designed without constraints.

What is important and interesting about this framework, is that it enables us to bypass the Shannon/Nyquist sampling theorem in the case of x being k-sparse or approximately k-sparse. The Shannon/Nyquist theorem tells us that in order to preserve information when uniformly sampling a signal, we must sample at least two times faster than its bandwidth, thus putting a lower bound on the number of measurements we need to obtain.

The applications of sparse recovery to Machine Learning are numerous, see [CDHB09, VGT12, DPFJ16, CMM11, SH11]. Moreover, deep learning approaches combined with sparse recovery techniques in [MPB15, ABEZ16, KLT+16, LDW+18, ZLSD18, BJPD17, BPD18] are proposed, in order to more finely reconstruct signals that are approximately k-sparse, with focus on images. In [VGT12], the authors employ compressed sensing techniques to develop routines for brain mapping situations in neuroscience, where the goal is to solve a support-recovery type of problem for functional MRI (fMRI) data. In [DPFJ16], the authors extend compressed sensing to signals that are represented via a graphical model.

On a high-level, the reason why machine learning applications benefit from sparse recovery is because in such applications we aim to find a mapping between sensory data and

data semantics (the label). In order to do that, a standard approach is to exploit a set of features which captures important data characteristics, and is a closely associated to data labels. We thus transform the raw data into a feature space, where the similarity between data points corresponds to the similarity between features.

The work on compressed sensing is vast, initiated with the seminal paper of Candes and Tao [CRT06b]. The authors show that ℓ_1 minimization satisfies the so-called ℓ_2/ℓ_1 guarantee, when the matrix A is chosen from a Gaussian ensemble. Other important guarantees, such as ℓ_1/ℓ_1 and ℓ_2/ℓ_2 have been extensively studied. The authors in [BIR08b, IR08b] showed that $O(\epsilon^{-1}k\log(n/k))$ measurements suffice for a uniform $(1+\epsilon)$ ℓ_1/ℓ_1 guarantee. It is known that uniform reconstruction (i.e. deterministic algorithms) is not possible under ℓ_2/ℓ_2, so one has to resort to randomized algorithm. In [PW11] Price and Woodruff give a variety of interesting results for the randomized cases of ℓ_2/ℓ_2 and ℓ_1/ℓ_1 sparse recovery, where they also show a difference between the exactly k-sparse and the $O(k)$-sparse case. More precisely, they show that if one is allowed to output a $2k$-sparse vector, the dependence on ϵ is strictly better than if one is allowed to output an exactly k-sparse vector. This fact, apart from being an interesting phenomenon, is useful in applications such as imaging, where we are not constrained to output an exactly k-spare vector. The state of the art for ℓ_2/ℓ_2 is [GLPS10], where the authors show that $O((k/\epsilon)\log(n/k))$ measurements are sufficient, and also give a sub-linear time recovery procedure.

All previous work was focused on ℓ_p/ℓ_p, where the error is measured with respect to some ℓ_p norm. In applications, sometimes these error measurements might be insufficient. For example, in the presence of outliers the strongest of the above ℓ_2/ℓ_2 guarantees, behaves poorly. For that, the Huber norm is introduced [Hub64], which combines an ℓ_2 norm for

small x with an ℓ_1 norm for large x. As mentioned in [CKY97, GS+99] the Huber norm is of particular interest, because it is "recommended for almost all situations", and because it is "most robust" with respect to the presence of outliers and to the number of iterations than the ℓ_2 norm. The aforementioned facts, along with its smoothness properties, have made the Huber norm useful in Machine learning applications. Moreover, while some measures, such as ℓ_1 , treat small residuals with the same importance as large residuals, it is often more appropriate to use Huber norm, since relatively small noise insensitive misfit measures can yield far more stable estimates in several cases, such as in geophysics applications [GS+99].

Recently, [SK18] studies a formulation of robust sparse recovery, where the noise is sparse but adversarial.

Roadmap. Section 15.1.1 provides a summary of our techniques. We present our main result in Section 15.1.2. We provide a complete proof for Huber set query and a short proof sketch for Huber sparse recovery in Section 15.2. We made a conclusion in Section 15.3. We deferred the complete proof for Huber, Tukey and other results into later sections.

Notations. We use $[n]$ to denote $\{1, 2, \cdots, n\}$. For a vector $x \in \mathbb{R}^n$, we use $\|x\|_1$ to denote its entry-wise ℓ_1 norm. We use $\|x\|_2$ to denote its entry-wise ℓ_2 norm. We use $\mathrm{supp}(x) \subseteq [n]$ to denote a set of non-zero indices. We use $\|x\|_0$ to denote the number of non-zero entries in x. ($\|x\|_0 = |\mathrm{supp}(x)|$) Let x_{-k} denote the vector obtained by zeroing out largest k coordinates (in absolute) of x. We will sometimes refer to x_{-k} as the tail of x, whereas we will refer to $x - x_{-k}$ as the head of x.

15.1.1 Our techniques

All of our results are based on the ubiquitous CountSketch data structure, which hashes every coordinate $i \in [n]$ to one of $O(k)$ buckets, and repeats $O(\log n)$ times. This data structure can be used to solve the ℓ_p heavy hitters problems, as well as the sparse recovery under the ℓ_2/ℓ_2 guarantee [PW11]. It is not hard to see that ℓ_1/ℓ_1 can also be achieved via the same data structure. Interestingly, our theorems indicate that the Huber and Tukey guarantees can also be obtained via CountSketch.

In specific, we use the CountSketch to obtain estimates for all $i \in [n]$, and then form the set S of the k coordinates with the largest estimates, as in previous work. Now, it might be the case that some elements in the head are not included in S, which means that they have been displaced by some other elements in the tail. In the case that the threshold τ for the Huber function is "small" enough, i.e. less than every $|x_j|$, for every $j \in S$ and $j \in \text{head}(k)$, we can bound the error similarly to the ℓ_1/ℓ_1 case. An analogous thing happens in the case that τ, is large enough, i.e. $\tau \geq \|x\|_\infty$, where can bound the error similarly to the ℓ_2/ℓ_2 case. Things are more complicated in the case that τ falls somewhere in between S and $\text{head}(k)$, where our guarantee needs to bound the ℓ_1 norm on the left-hand side, by the ℓ_2 norm on the right-hand side. This at first glance seems to be something impossible to do, but a careful glance reveals an interesting property: in the case of $\tau = 1$, if we estimate every $|x_i|$ up to Δ and if Δ is, then every displaced element in the head should should be $1 + \Delta = (1 + \Theta(\Delta))^2$, so we can hope to employ a similar argument to the ℓ_2/ℓ_2, as this property implicitly allows us to reduce the problem to the case where the right-hand side and the left-hand side are measured with respect to the ℓ_2 norm. If Δ is large enough then intuitively the mass of coordinates displaced "does not matter". because they were small

compared to the noise, and we can charge them to the tail. Of course, a careful combination of arguments and techniques needs to be addressed for the analysis to work out.

We note that the algorithm we suggest is not novel per se, but we rather indicate that the classic CountSketch data structure gives also the stronger Huber guarantee.

15.1.2 Our results

In the field of sparse recovery / compressive sensing, researchers usually consider ℓ_p norms as error estimates. Two well-known problems, arise when setting $p = 2$, giving birth to ℓ_2/ℓ_2 and ℓ_1/ℓ_1 problems.

$$\ell_2/\ell_2 : \|x - x'\|_2 \leq (1+\epsilon)\|x_{-k}\|_2,$$
$$\ell_1/\ell_1 : \|x - x'\|_1 \leq (1+\epsilon)\|x_{-k}\|_1,$$

where x is the ground-truth vector, x_{-k} is the vector that is obtained after zeroing out the largest k coordinates (in absolute) of x, x' is the k-sparse we output and $\epsilon \in (0,1)$ is the accuracy parameter.

We consider the problem of sparse recovery, when the error is measured with respect to an M-estimators. M-estimators are specified by a function $H : \mathbb{R} \to \mathbb{R}_{\geq 0}$ where $H(x) = H(-x)$, $H(0) = 0$, and $H()$ is non-decreasing $|x|$. We use $\|\cdot\|_H$ to denote a new "norm" (However, it might not be true norms in fact, because it doesn't satisfies triangle inequality). For a vector $x \in \mathbb{R}^n$, we use $\|x\|_H$ to denote $\sum_{i=1}^n H(x_i)$.

Huber function [Hub64] and Tukey function [Tuk60] have been two well-known M-estimators, which have been proven useful to researchers for more than 50 years. In this

work, we will mainly focus on these two estimators, which are also the most common ones. We first provide the definition of Huber function and Tukey function.

Definition 15.1.1 (Huber function)**.** Given parameter $\tau > 0$,

$$H(x) = \begin{cases} |x|^2/\tau & \text{if } |x| \leq \tau; \\ |x| & \text{if } |x| > \tau. \end{cases}$$

Note that an alternative definition of Huber is $|x|^2/2\tau$ if $|x| \leq \tau$ and $|x| - \tau/2$ if $|x| > \tau$. Our techniques work for both of those definitions. This is also being observed in some other problems, e.g. regression [CW15b] and low-rank approximation [CW15a].

We define Tukey function [Tuk60] as follows

Definition 15.1.2 (Tukey function)**.** Given parameter $\tau > 0$,

$$H(x) = \begin{cases} 1 - (1 - (x/\tau)^2)^3, & \text{if } |x| \leq \tau; \\ 1, & \text{if } |x| > \tau. \end{cases}$$

It is not hard to observe that both the Huber and Tukey function satisfy three basic properties: they vanish at zero, i.e., $H(0) = 0$, are symmetric and non-decreasing.

15.1.2.1 Set-query

We start by presenting a problem called "set query" which plays a crucial role in solving sparse recovery problem. Set query problem is first formally defined by Price [Pri11] and recently got studied in the context of Sparse Fourier transform[Kap17].

Definition 15.1.3 (Set-query)**.** Let $A \in \mathbb{R}^{m \times n}$ be some implicit matrix we want to design. For any accuracy parameter ϵ and set S with $|S| = k$, our goal is to read Ax and output

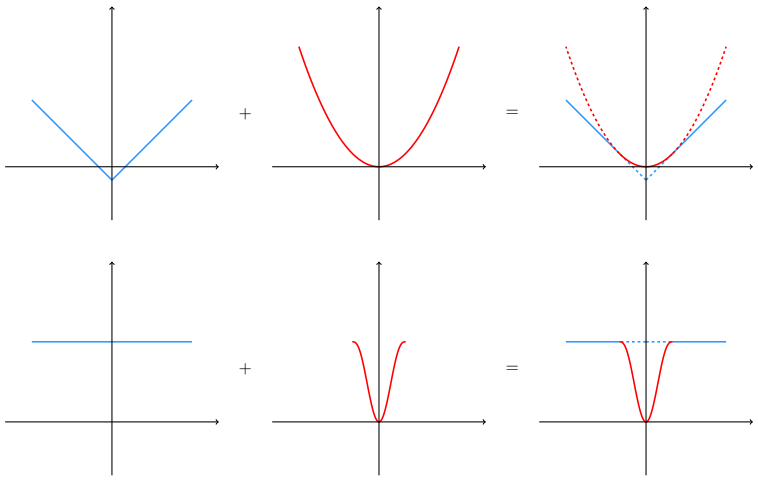

Figure 15.1: (a) Huber function (top) (b) Tukey function (bottom)

vector $x' \in \mathbb{R}^k$ such that

$$\|x' - x_S\|_H \leq \epsilon \cdot \|x_{[n]\setminus S}\|_H,$$

where $\|x\|_H = \sum_i H(x_i)$ and H is some function.

We give some formal definitions of what we are able to achieve in terms of measurements, column sparsity and decoding time.

Definition 15.1.4 (Measurements, column sparsity, decoding time)**.** There are several things we want to optimize,

1. The number of measurements, is the number of rows of A.
2. Column sparsity is, for any $u \cdot e_i$, the time we need to compute $A \cdot u \cdot e_i$, where $u \in \mathbb{R}$ and $e_i \in \mathbb{R}^n$ has 1 in the i-th coordinate and 0 everywhere else.
3. Decoding time means once Ax is given, the time we need to output x'.

Note that the decoding time is not necessarily larger than the number of measurements.

Our set-query results on M-estimators are given in the following theorem.

Theorem 15.1.1 (Set-query)**.** *Let function $H : \mathbb{R} \to \mathbb{R}_{\geq 0}$ be either Huber function or Tukey function. There is an implicit matrix $A \in \mathbb{R}^{m \times n}$ with $m = O(\epsilon^{-1} k \log k)$ and $O(\log k)$ column sparsity. For any $S \subseteq [n]$ such that $|S| = k$, there is an algorithm which given Ax, runs in $O(k \log k)$ decoding time, and outputs a vector $x' \in \mathbb{R}^k$ such that*

$$\|x' - x_S\|_H \leq \epsilon \cdot \|x_{[n] \setminus S}\|_H$$

holds with probability $9/10$.

Remark 15.1.1. Although the matrix has $m = O(\epsilon^{-1} k \log k)$, but our algorithm doesn't need to use all the measurements for the set-query algorithm. The way our algorithm is designed implies that the decoding time is independent of accuracy parameter ϵ.

For a vector $x \in \mathbb{C}^n$, we define its Fourier transform $\widehat{x} \in \mathbb{C}^n$ where $\forall i \in [n]$, $\widehat{x}_i = \sum_{j=1}^n \frac{1}{\sqrt{n}} x_j e^{-2\pi \mathbf{i} ij/n}$. Similarly, we define the inverse Fourier transform of $\widehat{x} \in \mathbb{C}^n$ to be x where $\forall j \in [n]$, $x_j = \sum_{i=1}^n \frac{1}{\sqrt{n}} \widehat{x}_i e^{2\pi \mathbf{i} ij/n}$. Now, we're ready to present our Fourier set query result,

Theorem 15.1.2 (Fourier set query)**.** *Given a vector $x \in \mathbb{C}^n$, for every $\epsilon \in (0, 1)$ and $k \geq 1$, any $S \subseteq [n]$, $|S| \leq k$, there exists an algorithm (Algorithm 15.3) that takes $O(\epsilon^{-1} k \log k \cdot \log(n/\delta))$ samples, runs in $O(\epsilon^{-1} k \log k \cdot \log(n/\delta))$ time, and outputs a vector $x' \in \mathbb{C}^n$ such that*

$$\|(x' - \widehat{x})_S\|_H \leq \epsilon \|\widehat{x}_{[n] \setminus S}\|_H + \delta \|\widehat{x}\|_H$$

holds with probability at least $1 - 1/\operatorname{poly}(k)$.

We can think of $\|\widehat{x}\|_H$ being bounded by $\mathrm{poly}(n)$. Then we can set $\delta = 1/\mathrm{poly}(n)$. This assumption, along with the additional δ factor is common in Fourier literature, e.g. [HIKP12a, PS15, CKPS16].

15.1.2.2 Sparse Recovery

We first present k-sparse recovery results under Huber/Tukey function. Our algorithm achieves $O(\epsilon^{-2}k\log n)$ measurements which matches the state-of-the-art ℓ_2/ℓ_2 algorithm (see [PW11]).

Theorem 15.1.3 (Main result, Sparse recovery, Optimal measurements)**.** *Let H denote either Huber function (see Def. 15.1.1) or Tukey function (see Def. 15.1.2). There exists a distribution of $\Phi \in \mathbb{R}^{m\times n}$ with $m = O(\epsilon^{-2}k\log n)$ and $O(\log n)$ column sparsity, and a recovery algorithm, such that for each $x \in \mathbb{R}^n$, $k \in [n]$ and $\epsilon \in (0,1)$, the recovery algorithm takes Φx as its input, runs in $O(n\log n)$ time, and outputs k-*sparse *vector $x' \in \mathbb{R}^n$ so that with probability $1 - 1/\mathrm{poly}(n)$,*

$$\|x' - x\|_H \leq (1+\epsilon) \min_{k-\text{sparse } y} \|y - x\|_H.$$

15.2 Algorithm and Analysis

We start by defining a well-known tool called Count-Sketch [CCF02].

Definition 15.2.1 (Count-Sketch [CCF02])**.** A count sketch data structure with bucket size B and replicates R corresponds to a measurement matrix $\Phi \in R^{BR\times n}$. Matrix Φ is a concatenation of $\Phi^{(1)}, \ldots, \Phi^{(R)}$, where each $\Phi^{(r)} \in \mathbb{R}^{B\times n}$ ($r \in [R]$) is defined by a pariwise hash function $h_i : [n] \to [B]$ and a pairwise sign function $\sigma_i : [n] \to \{-1, 1\}$, such that for

each $j \in [B]$ and $i \in [n]$,

$$\Phi_{j,i}^{(r)} = \begin{cases} \sigma_r(i) & \text{if } h_r(i) = j, \\ 0 & \text{otherwise.} \end{cases}$$

The data structure maintains the value of Φx and for each $i \in [n]$, it gives

$$x_i' = \text{median}\left(\sigma_1(i) \cdot (\Phi^{(1)}x)_{h_1(i)}, \ldots, \sigma_R(i) \cdot (\Phi^{(R)}x)_{h_R(i)}\right)$$

as estimation to x_i.

15.2.1 Set query algorithm for Huber

Our set query algorithm for Huber loss function is presented in Algorithm 15.1. The algorithm uses count-sketch data structure with bucket number $B = O(\epsilon^{-1}k)$ and replicate number $R = O(\log k)$.

Algorithm 15.1 Set Query Algorithm

procedure SETQUERY(n, k, ϵ, S, x) ▷ Theorem 15.2.1
  $B \leftarrow O(\epsilon^{-1}k)$
  $R \leftarrow O(\log k)$
  Construct count sketch with bucket size B and replicates R according to Definition 15.2.1
  $y \leftarrow \Phi x$ ▷ In streaming setting we maintain y when receiving updates to x
  for $i \in S$ **do**
    $x_i' \leftarrow \text{median}_{r \in [R]} \sigma_r(i) y_{h_r(i)}^{(r)}$ ▷ $y = (y^{(1)}, \ldots, y^{(R)})$
  end for
  return x_S'
end procedure

Now we provide a correctness proof for the set-query algorithm under Huber function. For simplicity we let $\tau = 1$, but our proof extends to arbitrary τ. In order to express $\|x_{[n]\setminus S}\|_H$

in a handy form, we first partition the coordinates in $[n]\backslash S$ into P and Q, where P contains small coordinates whose absolute values are less than τ and Q contains those who are larger than τ. By guarantee of the count-sketch, we can bound the error of each estimate for coordinates in S. We then bound the error in Huber loss function by discussing the absolute error is either less than or greater than τ.

Theorem 15.2.1 (Set-query, Huber case of Theorem 15.1.1)**.** *Let function H be defined as Definition 15.1.1. There is an algorithm (Algorithm 15.1) that takes $O(\epsilon^{-1}k\log k)$ samples/times and outputs a vector $x' \in \mathbb{R}^n$ such that*

$$\|x'_S - x_S\|_H \leq \epsilon \cdot \|x_{[n]\backslash S}\|_H$$

holds with probability $1 - 1/\operatorname{poly}(k)$.

Proof. We choose $B = \epsilon^{-1}k$. We define set $P, Q \subset [n]\backslash S$ as follows

$$P = \{i \mid |x_i| \leq 1, i \in [n]\backslash S\}, Q = \{i \mid |x_i| \geq 1, i \in [n]\backslash S\}.$$

We define $P_{B/6}$ to be top $B/6$ coordinates in P, and define $P' = P\backslash P_{B/6}$. Similarly we define $Q_{B/6}$ to be top $B/6$ coordinates in Q, and define $Q' = Q\backslash Q_{B/6}$.

Let $R = O(\log k)$. For each $i \in S$, we estimate x_i as $x'_i = \operatorname{median}_{j\in[R]}\{y^{(j)}_{h_j(i)}\}$. We can prove that with probability $1 - 1/\operatorname{poly}(k)$,

$$|x'_i - x_i| \leq \sqrt{(\|x_{P'}\|_2^2 + \|x_{Q'}\|_2^2)/B}.$$

Note that $\|x_{\overline{S}}\|_H = \|x_P\|_2^2 + \|x_Q\|_1$.

We prove the final result by considering two cases:

Case (1)

$$\sqrt{(\|x_{P'}\|_2^2 + \|x_{Q'}\|_2^2)/B} \leq 1;$$

Case (2)

$$\sqrt{(\|x_{P'}\|_2^2 + \|x_{Q'}\|_2^2)/B} > 1.$$

Case (1) $\sqrt{(\|x_{P'}\|_2^2 + \|x_{Q'}\|_2^2)/B} \leq 1$.

In the following, we prove that $\|x_{Q'}\|_2^2 \leq \|x_{Q'}\|_1$. First, note that

$$\|x_{Q'}\|_2 \leq \sqrt{\|x_{P'}\|_2^2 + \|x_{Q'}\|_2^2} \leq \sqrt{B}.$$

By Lemma 15.5.2, we can also bound $\|x_{Q'}\|_2$ to be

$$\|x_{Q'}\|_2 \leq \frac{1}{\sqrt{B}}\|x_Q\|_1.$$

Combining these two inequality on $\|x_{Q'}\|_2$, we get

$$\|x_{Q'}\|_2^2 \leq \sqrt{B} \cdot \frac{1}{\sqrt{B}}\|x_Q\|_1 \leq \|x_Q\|_1.$$

By definition of Huber norm,

$$\begin{aligned}\|x'_S - x_S\|_H &\leq \frac{k}{B}(\|x_{P'}\|_2^2 + \|x_{Q'}\|_2^2) \\ &\leq \frac{k}{B}(\|x_P\|_2^2 + \|x_Q\|_1) \\ &= \epsilon\|x_{\overline{S}}\|_H.\end{aligned}$$

Case (2) $\sqrt{\frac{\|x_{P'}\|_2^2 + \|x_{Q'}\|_2^2}{B}} > 1$.

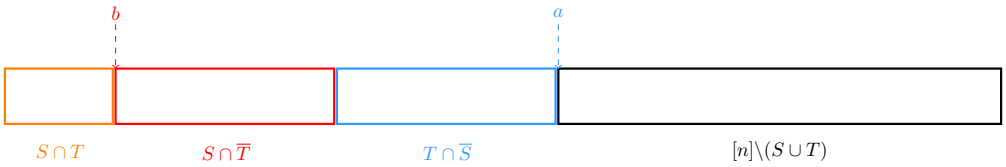

Figure 15.2: $\|x_{S\cap\overline{T}}\|_H - \|x_{T\cap\overline{S}}\|_H$ is the displacement error

The error is $\|x'_S - x_S\|_H \leq \frac{k}{\sqrt{B}}(\|x_{P'}\|_2 + \|x_{Q'}\|_2)$. We can bound $\|x_{Q'}\|_2 \leq \frac{1}{\sqrt{B}}\|x_Q\|_1$ by Lemma 15.5.2. Now trying to bound $\|x_{P'}\|_2$. If $\|x_{P'}\|_2 \leq \|x_{Q'}\|_2$ we are done. Otherwise we have $\|x_{P'}\|_2 \geq \sqrt{B/2}$ and so $\|x_{P'}\|_2 \leq \frac{\|x_{P'}\|_2}{\sqrt{B/2}}\|x_{P'}\|_2 \leq \sqrt{2/B}\|x_P\|_2^2$. Either case we can finally bound $\|x'_S - x_S\|_H$ by $2\epsilon\|x_{\overline{S}}\|_H$. □

15.2.2 Proof of Theorem 15.1.3

Algorithm 15.2 Sparse Recovery Algorithm

procedure SPARSERECOVERY(n, k, ϵ, x)
  $B \leftarrow O(\epsilon^{-2}k)$
  $R \leftarrow O(\log n)$
  Construct count sketch with bucket size B and replicates R according to Definition 15.2.1
  $y \leftarrow \Phi x$ ▷ In streaming setting we maintain y when receiving updates to x
  for $i = 1 \to n$ **do**
    $x'_i \leftarrow \text{median}_{r\in[R]}\, \sigma_r(i) y^{(r)}_{h_r(i)}$ ▷ $y = (y^{(1)}, \ldots, y^{(R)})$
  end for
  Let T denote the set of coordinates that are k largest (in absolute) of x'
  return x'_T
end procedure

The high-level idea. Let S denote the top-k largest coordinates in absolute. Let

T denote the set coordinates the algorithm outputs. Then we can rewrite $\|x - x'_T\|_H$ as

$$\begin{aligned}
&\|x - x'_T\|_H \\
&= \|(x - x')_T\|_H + \|x_{\overline{T}}\|_H \\
&= \|(x - x')_T\|_H + (\|x_{\overline{T}}\|_H - \|x_{\overline{S}}\|_H) + \|x_{\overline{S}}\|_H \\
&= \underbrace{\|(x - x')_T\|_H}_{\text{set-query}} + \underbrace{(\|x_{S\cap\overline{T}}\|_H - \|x_{T\cap\overline{S}}\|_H)}_{\text{displacement}} + \|x_{\overline{S}}\|_H.
\end{aligned}$$

Using Set-query, we know that $\|(x - x')_T\|_H \leq (\epsilon/2)\|x_{\overline{S}}\|_H$. Now the question is how to bound "displacement" by $(\epsilon/2)\|x_{\overline{S}}\|_H$ and we explain the formal proof in next a few pages.

Proof. of Theorem 15.1.3. Our algorithm is presented in Algorithm 15.2. Let x_{-k} denotes the vector x with absolute largest k coordinates removed. We use count sketch to give each x_i (where $i \in [n]$) an estimate. In particular, we choose the number of buckets $B = O(\epsilon^{-2}k)$ and the number of duplicates $R = O(\log n)$ for the count sketch data structure. Let x'_i denote the estimate obtained by the count sketch for x_i. Let T denote the largest k coordinates in absolute value in x'. The recovery algorithm outputs x'_T as a k-sparse approximation to x.

Note that the count sketch data structure takes $B \cdot R = O(\epsilon^{-2}k \log n)$ measurements. Its update time is $O(R) = O(\log n)$ time, and the time to obtain x' is $O(n \cdot R) = O(n \log n)$. Taking largest k coordinates from x' requires $O(n \log n)$ time. Thus the total query time is $O(n \log n)$. In the following, we show that $\|x - x'_T\|_H \leq (1 + \epsilon)\|x_{-k}\|_H$.

By Lemma 15.5.1, for each $i \in [n]$, with probability $1 - 1/\operatorname{poly}(n)$,

$$(x_i - x'_i)^2 \leq \frac{\epsilon^2}{4k}\|x_{-4k/\epsilon^2}\|_2^2 \leq \frac{\epsilon^2}{4k}\|x_{-4k}\|_2^2. \tag{15.1}$$

Let S denote the largest k coordinates in absolute value in x. Recall that $\overline{S} = [n]\backslash S$, $\overline{T} = [n]\backslash T$, and $x_{-k} = x_{\overline{S}}$. The recovery error is

$$\|x - x'_T\|_H = \|(x - x')_T\|_H + \|x_{\overline{T}}\|_H. \tag{15.2}$$

By point estimation guarantee given in Eq. (15.5) and results from Huber set query.

$$\begin{aligned}\|(x - x')_T\|_H &= \sum_{i \in T} H(x_i - x'_i) \\ &\leq |T| \cdot H(\frac{\epsilon}{2\sqrt{k}}\|x_{-4k}\|_2) \\ &\leq \frac{\epsilon}{2}\|x_{-k}\|_H.\end{aligned}$$

Note that

$$\begin{aligned}\|x_{\overline{T}}\|_H &= (\|x_{\overline{T}}\|_H - \|x_{\overline{S}}\|_H) + \|x_{\overline{S}}\|_H \\ &= (\|x_{S \cap \overline{T}}\|_H - \|x_{\overline{S} \cap T}\|_H) + \|x_{-k}\|_H\end{aligned}$$

where the second step follows by canceling out the coordinates in $\overline{S} \cap \overline{T}$. In the following, our goal is to show that $\sum_{i \in S \cap \overline{T}} H(x_i) - \sum_{i \in \overline{S} \cap T} H(x_i) \leq \frac{\epsilon}{2}\|x_{-k}\|_H$.

If $S \cap \overline{T} = \emptyset$, then $S = T$ and $\sum_{i \in S \cap \overline{T}} H(x_i) - \sum_{i \in \overline{S} \cap T} H(x_i) = 0$. In the following, we assume that $S \cap \overline{T} \neq \emptyset$. Let $b = \max_{i \in S \cap \overline{T}} |x_i|$, and $a = \min_{i \in \overline{S} \cap T} |x_i|$. Because Huber function $H(t)$ is monotonically increasing as $|t|$ increases,

$$\|x_{S \cap \overline{T}}\|_H - \|x_{\overline{S} \cap T}\|_H \leq |\overline{S} \cap T| \cdot (H(b) - H(a)).$$

By Lemma 15.2.5, we have

$$b - a \leq \frac{\epsilon}{\sqrt{k}}\|x_{-4k}\|_2. \tag{15.3}$$

Moreover, by definition that $a = \min_{i \in \overline{S} \cap T} |x_i|$ and let $r = |\overline{S} \cap T|$,

$$a \leq \frac{\|x_{\overline{S} \cap T}\|_2}{\sqrt{r}} \leq \frac{\|x_{-k}\|_2}{\sqrt{r}}. \tag{15.4}$$

We are going to prove that $H(b) - H(a) \leq \frac{\epsilon}{2} \frac{\|x_{-k}\|_H}{|\overline{S} \cap T|}$. We discuss in three cases: case (1) $\tau \leq a$, case (2) $a < \tau < b$, case (3) $b \leq \tau$. We analyze these three cases in Claim 15.2.2, Claim 15.2.3 and Claim 15.2.4. □

Claim 15.2.2. *Let $r = |\overline{S} \cap T|$. If $\tau \leq a$, then $H(b) - H(a) \leq \frac{\epsilon}{2} \frac{\|x_{-k}\|_H}{r}$.*

Proof. For simplicity, we use r to denote $|\overline{S} \cap T|$. By definition of T, we know that $1 \leq r \leq k$. Let P, Q be a partition of $\overline{S}$ where

$$P = \{i \mid |x_i| \leq \tau, i \in \overline{S}\}, Q = \{i \mid |x_i| > \tau, i \in \overline{S}\}.$$

By triangle inequality $\|x_{-5k}\|_2 \leq \|x_P\|_2 + \|(x_Q)_{-4k}\|_2$. By definition of Huber function $\|x_{-k}\|_H = \frac{1}{\tau}\|x_P\|_2^2 + \|x_Q\|_1$. Because $\tau \leq a$, $\overline{S} \cap T \subseteq Q$. Thus $\|x_Q\|_1 \geq \|x_{\overline{S} \cap T}\|_1 \geq \tau |\overline{S} \cap T| = \tau \cdot r$. Therefore,

$$\|x_{-k}\|_H \geq \frac{1}{\tau}\|x_P\|_2^2 + \tau r \geq 2\sqrt{\frac{1}{\tau}\|x_P\|_2^2 \cdot \tau r} = 2\sqrt{r} \cdot \|x_P\|_2.$$

So we have $\|x_P\|_2 \leq \frac{1}{2\sqrt{r}}\|x_{-k}\|_H$. By Lemma 15.5.2,

$$\|(x_Q)_{-4k}\|_2 \leq \frac{1}{2\sqrt{k}}\|x_Q\|_1 \leq \frac{1}{2\sqrt{r}}\|x_Q\|_1 \leq \frac{1}{2\sqrt{r}}\|x_{-k}\|_H.$$

Therefore,

$$\begin{aligned} H(b) - H(a) = b - a &\leq \frac{\epsilon}{\sqrt{r}} \|x_{-5k}\|_2 \\ &\leq \frac{\epsilon}{\sqrt{r}} (\|x_P\|_2 + \|(x_Q)_{-4k}\|_2) \\ &\leq \frac{\epsilon}{\sqrt{r}} \left(\frac{1}{2\sqrt{r}} \|x_{-k}\|_H + \frac{1}{2\sqrt{r}} \|x_{-k}\|_H \right) \\ &\leq \frac{\epsilon \|x_{-k}\|_H}{r}. \end{aligned}$$

□

Claim 15.2.3. *If $a < \tau < b$, then $H(b) - H(a) \leq \frac{\epsilon}{2} \frac{\|x_{-k}\|_H}{|\overline{S} \cap T|}$.*

Claim 15.2.4. *If $b \leq \tau$, then $H(b) - H(a) \leq \frac{\epsilon}{2} \frac{\|x_{-k}\|_H}{|\overline{S} \cap T|}$.*

We provide the proofs of the above two Claims in Section 15.7.

Lemma 15.2.5. *Let vector $u, v \in \mathbb{R}^n$ such that $\|u - v\|_\infty \leq \Delta$. Let S be the largest k coordinates in u, and let T be the largest k coordinates in v. Let $b = \max_{i \in S \cap \overline{T}} u_i$ and $a = \min_{i \in \overline{S} \cap T} u_i$. Then $b - a \leq 2\Delta$.*

Proof. Let $\lambda = \max_{i \in \overline{T}} v_i$. We have

$$b = \max_{i \in S \cap \overline{T}} u_i \leq \max_{i \in \overline{T}} u_i \leq \Delta + \max_{i \in \overline{T}} v_i = \Delta + \lambda.$$

On the other hand,

$$a = \min_{i \in \overline{S} \cap T} u_i \geq \min_{i \in T} u_i \geq -\Delta + \min_{i \in T} v_i \geq -\Delta + \lambda.$$

Therefore,

$$b - a \leq (\Delta + \lambda) - (-\Delta + \lambda) \leq 2\Delta.$$

□

15.3 Conclusion

In this work, we gave the first set of sparse recovery algorithms when the error is measured with respect to Huber and Tukey functions. Because of the usefulness of these M-estimators, we believe that this will be proved to be an important line of research, demanding new ideas and techniques, and offering fruitful results both in theory and in practice.

15.4 Preliminaries

In this section, we give definitions of Huber function, reverse Huber function and Tukey function. All these functions have a parameter $\tau > 0$ such that the function is defined as one "simple" function on domain $\{x : |x| \leq \tau\}$ and another "simple" function on domain $\{x : |x| > \tau\}$. In particular, Huber function is defined to be a quadratic function for $|x| \leq \tau$ and a linear function for $|x| > \tau$. Inverse Huber function is opposite. Tukey function is defined approximately to be a quadratic function for $|x| \leq \tau$, and a constant function for $|x| > \tau$.

When measuring errors in terms of these functions, we are more robust to outliers. Because these functions in domain $\{x : |x| > \tau\}$ grow slower than domain $\{x : |x| \leq \tau\}$.

15.4.1 Huber estimator

Given parameter $\tau > 0$, Huber function [Hub64] is defined as follows.

Definition 15.4.1 (Huber function)**.**

$$H(x) = \begin{cases} |x|^2/\tau & \text{if } |x| \leq \tau; \\ |x| & \text{if } |x| > \tau. \end{cases}$$

In addition, as appeared in [SWZ18], one can also define reverse Huber function with parameter τ as

$$H(x) = \begin{cases} |x| & \text{if } |x| \leq \tau; \\ |x|^2/\tau & \text{if } |x| > \tau. \end{cases}$$

15.4.2 Tukey estimator

Tukey function [Tuk60] is defined as follows.

Definition 15.4.2 (Tukey function)**.**

$$H(x) = \begin{cases} 1 - (1 - (x/\tau)^2)^3, & \text{if } |x| \leq \tau; \\ 1, & \text{if } |x| > \tau. \end{cases}$$

It is easy to observe that for $|x| \leq \tau$,

$$\begin{aligned} H(x) &= 1 - (1 - 3(x/\tau)^2 + 3(x/\tau)^4 - (x/\tau)^6) \\ &= 3(x/\tau)^2 - 3(x/\tau)^4 + (x/\tau)^6 \\ &= \frac{3}{4}(x/\tau)^2 + \frac{9}{4}(x/\tau)^2 - 3(x/\tau)^4 + (x/\tau)^6 \\ &= \frac{3}{4}(x/\tau)^2 + (x/\tau)^2(\frac{3}{2} - (x/\tau)^2)^2 \\ &\geq \frac{3}{4}(x/\tau)^2. \end{aligned}$$

Similarly, we can also give an upper bound of $H(x)$,

$$\begin{aligned} H(x) &= 3(x/\tau)^2 - 3(x/\tau)^4 + (x/\tau)^6 \\ &\leq 3(x/\tau)^2 + (x/\tau)^6 \\ &\leq 4(x/\tau)^2. \end{aligned}$$

Therefore, we have the following fact, i.e. Tukey function is within a constant factor of the quadratic function for $|x| \leq \tau$. Therefore, in our analysis in later sections, we approximate Tukey function as a quadratic function for $|x| \leq \tau$.

Fact 15.4.1. *If* $|x| \leq \tau$*,* $H(x) \in [\frac{3}{4}(x/\tau)^2, 4(x/\tau)^2]$*; Otherwise* $H(x) = 1$*.*

15.5 Set Query

In this section, we present our set query results on reverse Huber function and Tukey function. The results on Huber function is presented in the main text. We summarize our results on set query in Table 15.1. Since we extensively apply the count-sketch data structure, we present as follows.

Definition 15.5.1 (Count Sketch)**.** A count sketch data structure with bucket size B and replicates R corresponds to a measurement matrix $\Phi \in R^{BR\times n}$. Matrix Φ is a concatenation of $\Phi^{(1)}, \ldots, \Phi^{(R)}$, where each $\Phi^{(r)} \in \mathbb{R}^{B\times n}$ $(r \in [R])$ is defined by a pariwise hash function $h_i : [n] \to [B]$ and a pairwise sign function $\sigma_i : [n] \to \{-1, 1\}$, such that for each $j \in [B]$ and $i \in [n]$,

$$\Phi^{(r)}_{j,i} = \begin{cases} \sigma_r(i) & \text{if } h_r(i) = j, \\ 0 & \text{otherwise.} \end{cases}$$

The data structure maintains the value of Φx and for each $i \in [n]$, it gives

$$x'_i = \text{median}\left(\sigma_1(i) \cdot (\Phi^{(1)}x)_{h_1(i)}, \ldots, \sigma_R(i) \cdot (\Phi^{(R)}x)_{h_R(i)}\right)$$

as esimation to x_i.

Let $x' \in \mathbb{R}^n$ denote the approximation given by the count sketch data structure. We have the following guarantee for count sketch with bucket size B and replicates R.

Lemma 15.5.1 ([CCF02])**.** *Let $x \in \mathbb{R}^n$, and let $x' \in \mathbb{R}^n$ be the output of a count sketch data structure (Definition 15.5.1) with bucket size B and replicate R. For each $i \in [n]$, with probability at least $1 - 2^{-\Omega(R)}$,*

$$(x_i - x'_i)^2 \leq \frac{2}{B}\|x_{-B/2}\|_2^2.$$

Table 15.1: Set Query

	Measurements	Running time	Column sparsity
Theorem 15.2.1, Huber	$\epsilon^{-1}k\log k$	$k\log k$	$\log k$
Theorem 15.5.3, Reverse Huber	$\epsilon^{-1}k\log k$	$k\log k$	$\log k$
Theorem 15.5.4, Tukey	$\epsilon^{-1}k\log k$	$k\log k$	$\log k$

The following is a standard lemma in compressive sensing literatures that bounds the ℓ_2 norm of a vector with largest (in absolute value) k coordinates removed in terms of ℓ_1 norm of its original vector. We also include its proof for completeness.

Lemma 15.5.2. *For any $x \in \mathbb{R}^n$ and any $k \in [n]$, $\|x_{-k}\|_2 \leq \frac{1}{\sqrt{k}}\|x\|_1$, where x_{-k} denotes the vector obtained by zeroing out largest k coordinates (in absolute) of x.*

Proof. We partition the coordinates of x to be $B_1, B_2, \ldots$ where B_1 contains largest k coordinates, and B_2 contains the next largest k coordinates, and so on. We have

$$\begin{aligned}
\|x_{-k}\|_2 &\leq \sum_{i=2}^{n/k} \|x_{B_i}\|_2 \\
&\leq \sum_{i=2}^{n/k} \sqrt{k \cdot (\|x_{B_{i-1}}\|_1/k)^2} \\
&= \frac{1}{\sqrt{k}} \sum_{i=1}^{n/k-1} \|x_{B_i}\|_1 \\
&\leq \frac{1}{k}\|x\|_1.
\end{aligned}$$

where the second step follows by Cauchy-Schwarz inequality. □

15.5.1 ϵ-approximation for reverse Huber function

We present our set query result for reverse Huber functions. The result is quite symmetric to our result for Huber function.

Theorem 15.5.3 (Reverse Huber set-query)**.** *Let function H be defined as Definition 15.4.1. There is an algorithm that takes $O(\epsilon^{-1} k \log k)$ samples/times and outputs a vector $x' \in \mathbb{R}^n$ such that*

$$\|x'_S - x_S\|_H \leq \epsilon \cdot \|x_{[n]\backslash S}\|_H$$

holds with probability $1 - 1/\operatorname{poly}(k)$.

Proof. We choose $B = O(\epsilon^{-1}k)$ and $R = O(\log k)$, and use the count-sketch data structure with bucket size $O(B)$ and replicate number $O(R)$. Let $x' \in \mathbb{R}^n$ denote the estimate given by the count-sketch data structure. By Lemma 15.5.1, we have the guarantee that with probability $1 - 1/\operatorname{poly}(k)$,

$$|x'_i - x_i| \leq \sqrt{\frac{\|x_{-B}\|_2^2}{B}}.$$

We define set $P, Q \subset [n]\backslash S$ as follows

$$P = \{i \mid |x_i| \leq 1, i \in [n]\backslash S\}, Q = \{i \mid |x_i| \geq 1, i \in [n]\backslash S\}.$$

We define $P_{B/6}$ to be top $B/6$ coordinates in P, and define $P' = P\backslash P_{B/6}$. Similarly we define $Q_{B/6}$ to be top $B/6$ coordinates in Q, and define $Q' = Q\backslash Q_{B/6}$. We have $\sqrt{\frac{\|x_{-B}\|_2^2}{B}} \leq \sqrt{\frac{\|x_{P'}\|_2^2 + \|x_{Q'}\|_2^2}{B}}$.

Note that

$$\|x_{\overline{S}}\|_H = \|x_P\|_1 + \|x_Q\|_2^2.$$

We prove the final result by considering two cases: case (1) $\sqrt{\frac{\|x_{P'}\|_2^2+\|x_{Q'}\|_2^2}{B}} \leq 1$; Case (2) $\sqrt{\frac{\|x_{P'}\|_2^2+\|x_{Q'}\|_2^2}{B}} > 1$.

Case (1) $\sqrt{\frac{\|x_{P'}\|_2^2+\|x_{Q'}\|_2^2}{B}} \leq 1$.

The error is

$$\begin{aligned}\|x'_S - x_S\|_H &\leq k\sqrt{\frac{\|x_{P'}\|_2^2 + \|x_{Q'}\|_2^2}{B}} \\ &\leq \frac{k}{\sqrt{B}}(\|x_{P'}\|_2 + \|x_{Q'}\|_2).\end{aligned}$$

By Lemma 15.5.2, we have $\|x_{P'}\|_2 \leq \frac{1}{\sqrt{B}}\|x_P\|_1$. Now we are trying to upper bound $\|x_{Q'}\|_2$. If $\|x_{Q'}\|_2 \leq \|x_{P'}\|_2$ we are done. Otherwise we have $\|x_{Q'}\|_2 \geq \sqrt{B/2}$ and so $\|x_{Q'}\|_2 \leq \frac{\|x_{Q'}\|_2}{\sqrt{B/2}}\|x_{Q'}\|_2 \leq \sqrt{2/B}\|x_Q\|_2^2$. Either case we can finally bound $\|x'_S - x_S\|_H$ by $2\epsilon\|x_{\overline{S}}\|_H$.

Case (2) $\sqrt{\frac{\|x_{P'}\|_2^2+\|x_{Q'}\|_2^2}{B}} > 1$.

We have

$$\begin{aligned}\|x'_S - x_S\|_H &\leq \frac{k}{B}(\|x_{P'}\|_2^2 + \|x_{Q'}\|_2^2) \\ &\leq \frac{k}{B}(\|x_{P'}\|_1 + \|x_{Q'}\|_2^2) \\ &\leq \frac{k}{B}(\|x_P\|_1 + \|x_Q\|_2^2) \\ &= \epsilon\|x_{\overline{S}}\|_H,\end{aligned}$$

where the second step follows by the fact that each coordinate in P' is less than 1. □

15.5.2 ϵ-approximation for Tukey function

Theorem 15.5.4 (Tukey set-query)**.** *Let function H be defined as Definition 15.4.2. There is an algorithm that takes $O(\epsilon^{-1} k \log k)$ samples, $O(k \log k)$ decoding times, $O(\log k)$ update time, and outputs a vector $x' \in \mathbb{R}^n$ such that*

$$\|x'_S - x_S\|_H \leq \epsilon \cdot \|x_{[n]\backslash S}\|_H$$

holds with probability $9/10$.

Proof. Without loss of generality, we assume that $\tau = 1$. We approximate Tukey function to be $H(x) = 1$ for $|x| > 1$ and $H(x) = x^2$ for $|x| \leq 1$.

Let $B = O(\epsilon^{-1} k)$ and $R = O(\log k)$, and use the count-sketch data structure with bucket size $O(B)$ and replicate number $O(R)$. Let $x' \in \mathbb{R}^n$ denote the estimate given by the count-sketch data structure.

We define $P, Q \subseteq [n]\backslash S$ as follows

$$P = \{i \mid |x_i| \leq 1, i \in [n]\backslash S\}, Q = \{i \mid |x_i| > 1, i \in [n]\backslash S\}.$$

We consider the following two cases.

Case 1. $|Q| > B/4$.

We have

$$\|x'_S - x_S\|_H \leq k = \frac{k}{|Q|} \cdot |Q| \leq \frac{k}{B/4}|Q| \leq \frac{4k}{B}\|x_{-k}\|_H \leq \epsilon \|x_{-k}\|_H.$$

Case 2. $|Q| \leq B/4$.

By Lemma 15.5.1, for each $i \in S$, with probability at least $1 - 1/\operatorname{poly}(k)$, we have

$$|x'_i - x_i| \leq \sqrt{\frac{\|x_{-2B}\|_2^2}{2B}} \leq \sqrt{\frac{\|x_P\|_2^2}{2B}}.$$

Applying a union bound to coordinates in S, we have with probability at least $1 - \operatorname{poly}(k)$,

$$\|x'_S - x_S\|_H \leq kH(\sqrt{\frac{\|x_P\|_2^2}{2B}}).$$

Then Case 2(a) $\sqrt{\|x_P\|_2^2/2B} \geq 1$. We have

$$\|x'_S - x_S\|_H \leq k \leq \frac{k}{2B}\|x_P\|_2^2 \leq \frac{k}{2B}\|x_{-k}\|_H \leq \epsilon\|x_{-k}\|_H.$$

Case 2(b) $\sqrt{\|x_P\|_2^2/2B} < 1$. We have

$$\|x'_S - x_S\|_H \leq \frac{k}{2B}\|x_P\|_2^2 \leq \frac{k}{2B}\|x_{-k}\|_H \leq \epsilon\|x_{-k}\|_H.$$

□

15.6 Fourier set query

In this section, we give set query algorithms from Fourier measurements, when the error is measured with respect to Huber norm and Tukey norm. All of the results in this section follow from the fact that we can simulate the count sketch data structure in Fourier case, by losing a factor of $\log n$ on the number of measurements (we also lose a $\log n$ factor in update time and query time).

This simulation is standard (as in for example [HIKP12a]) by using (pseudo)random spectral permutation and filtering functions. Let B denote bucket size. Let $P = \{i \in [n] \mid |\widehat{x}_i| < \tau\}$ and $Q = \{i \in [n] \mid |\widehat{x}_i| \geq \tau\}$. Let P' denote the set after removing top $O(k)$ coordinates from P, and similarly let Q' denote the set after removing top $O(k)$ coordinates from Q. We can guarantee that with high probability for each coordinate $i \in S$, the error for our estimation to $\widehat{x}_i$ is bounded by $\sqrt{\frac{\|\widehat{x}_{P'}\|_2^2 + \|\widehat{x}_{Q'}\|_2^2}{B}}$. Following the proof on set query results in Section 15.5, this yields to $\ell_H/\ell_H \leq \epsilon$ guarantee for function H being Huber function or Tukey function.

Theorem 15.6.1 (Fourier point estimation guarantee)**.** *Given a vector $x \in \mathbb{C}^n$, for every $\epsilon \in (0,1)$ and $k \geq 1$, any $S \subseteq [n]$, $|S| \leq k$, there exists an algorithm (Algorithm 15.3) that takes*

$$O(\epsilon^{-1} k \log k \cdot \log n)$$

samples, runs in

$$O(\epsilon^{-1} k \log k \cdot \log n)$$

time, and outputs a vector $x' \in \mathbb{C}^n$ *such that for each* $i \in S$,

$$|x'_i - \widehat{x}_i| \leq \sqrt{\frac{\|\widehat{x}_{P'}\|_2^2 + \|\widehat{x}_{Q'}\|_2^2}{B}},$$

holds with probability at least $1 - 1/\operatorname{poly}(k)$.

Before showing the proof to Theorem 15.6.1, we first present some basic definitions and basic building blocks for Fourier sparse recovery. Readers can refer to [HIKP12a] for more details.

For a complex vector $x \in \mathbb{C}^n$, we use $\widehat{x} \in \mathbb{C}^n$ to denote its Fourier spectrum,

$$\widehat{x}_i = \frac{1}{\sqrt{n}} \sum_{j=1}^{n} e^{-2\pi \mathbf{i} ij/n} x_j, \forall i \in [n].$$

Then the inverse transform is

$$x_j = \frac{1}{\sqrt{n}} \sum_{i=1}^{n} e^{2\pi \mathbf{i} ij/n} \widehat{x}_i, \forall j \in [n].$$

The discrete convolution of functions f and g is given by,

$$(f * g)[n] = \sum_{m=-\infty}^{+\infty} f[m] g[n-m]$$

We use the same (pseudorandom) spectrum permutation as [HIKP12a],

Definition 15.6.1. Suppose σ^{-1} exists mod n. We define the permutation $P_{\sigma,a,b}$ by

$$(P_{\sigma,a,b} x)_i = x_{\sigma(i-a)} e^{-2\pi \mathbf{i} \sigma b i/n}.$$

We also define $\pi_{\sigma,b} = \sigma(i-b) \pmod{n}$. Let $h_{\sigma,b}(i) = \operatorname{round}(\pi_{\sigma,b}(i) B/n)$ and $o_{\sigma,b}(i) = \pi_{\sigma,b}(i) - h_{\sigma,b}(i) n/B$. We say $h_{\sigma,b}(i)$ is the "bin" that frequency i is mapped into, and $o_{\sigma,b}(i)$ is the "offset".

We use the same filter function as [HIKP12a, PS15, CKPS16],

Definition 15.6.2. Given parameters $B \geq 1$, $\delta > 0$, $\alpha > 0$. We say that $(G, \widehat{G}') = (G_{B,\delta,\alpha}, \widehat{G}'_{B,\delta,\alpha}) \in \mathbb{R}^n$ is a filter function if it satisfies the following properties

$$
\begin{aligned}
&\text{(I)} \ |\operatorname{supp}(G)| = O(\alpha^{-1} B \log(n/\delta)), \\
&\text{(I)} \ \widehat{G}'_i = 1, && \text{if } |i| \leq (1-\alpha)n/(2B), \\
&\text{(II)} \ \widehat{G}'_i = 0, && \text{if } |i| \geq n/(2B), \\
&\text{(III)} \ \widehat{G}'_i \in [0,1], && \text{for all } i, \\
&\text{(IV)} \ \left\| \widehat{G}' - \widehat{G} \right\|_\infty < \infty.
\end{aligned}
$$

We present our Fourier set query algorithm in Algorithm 15.3. We choose bucket size $B = O(k/\epsilon)$ and number of repetitions $R = O(\log k)$. For the filter function, we choose $\delta = 1/\operatorname{poly}(n)$ so that the noise introduced by the filter is negligible. Let α be a very small constant. We use procedure EstimateValues in r-th repetition where $r \in [R]$ to obtain an unbiased estimator for $\widehat{x}_S$ (up to error $\delta \|\widehat{x}\|_1$), denoted by $w^{(r)}$. Finally, for each $i \in S$, we estimate $\widehat{x}_i$ by $x'_i \leftarrow \text{median}_{r \in [R]} w_i^{(r)}$. By taking the median of a set of complex numbers, we mean that we take the median of real part and imaginary part separately, and then add these two parts together.

We use three types of events defined in [HIKP12a] as basic building blocks for analyzing Fourier set query algorithms. For any $i \in S$, we define three types of events associated with i and S and defined over the probability space induced by σ and b:

Definition 15.6.3 (Collision, large offset, large noise)**.** "Collision" event $E_{\text{coll}}(i)$: holds iff $h_{\sigma,b}(i) \in h_{\sigma,b}(S \backslash \{i\})$.

"Large offset" event $E_{\text{off}}(i)$: holds iff $|o_{\sigma,b}(i)| \geq (1-\alpha)n/(2B)$.

"Large noise" event $E_{\text{noise}}(i)$: holds iff

$$\mathbb{E}\left[\left\|\widehat{x}'_{h^{-1}_{\sigma,b}(h_{\sigma,b}(i))\setminus S}\right\|_2^2\right] \geq \text{Err}^2(\widehat{x}', k)/(\alpha B).$$

Claim 15.6.2 (Claim 3.1 in [HIKP12a]). *For any $i \in S$, the event $E_{\text{coll}}(i)$ holds with probability at most $4|S|/B$.*

Claim 15.6.3 (Claim 3.2 in [HIKP12a]). *For any $i \in S$, the event $E_{\text{off}}(i)$ holds with probability at most α.*

Claim 15.6.4 (Claim 4.1 in [HIKP12a]). *For any $i \in S$, $\Pr[E_{\text{noise}(i)}] \leq 4\alpha$.*

Lemma 15.6.5 (Lemma 4.2 in [HIKP12a]). *Let $a \in [n]$ uniformly at random, B divide n, and the other parameters be arbitrary in*

$$\widehat{u} = \text{HashToBins}(x, P_{\sigma,a,b}, B, \delta, \alpha).$$

Then for any $i \in [n]$ with $j = h_{\sigma,b}(i)$ and none of $E_{\text{coll}}(i)$, $E_{\text{off}}(i)$ or $E_{\text{noise}}(i)$ holding,

$$\mathbb{E}\left[\left|\widehat{u}_j - \widehat{x}'_i e^{-\frac{2\pi \mathbf{i}}{n} a\sigma i}\right|^2\right] > 2\frac{\rho^2}{\alpha B}.$$

Lemma 15.6.6. *Suppose B divides n. The output $\widehat{u}$ of* HashToBins *satisfies*

$$\widehat{u}_j = \sum_{h_{\sigma,b}(i)=j} \widehat{x}_i \widehat{(G'_{B,\delta,\alpha})}_{-o_{\sigma,b}(i)} \omega^{a\sigma i} \pm \delta\|\widehat{x}\|_1.$$

The running time of HashToBins *is $O(\frac{B}{\alpha}\log(n/\delta))$.*

Proof of Theorem 15.6.1. We give Fourier set query algorithm in Algorithm 15.3. The total number of measurements and decoding time is $O(R) \cdot O(B \log \frac{n}{\alpha}) = O(\epsilon^{-1} k \log k \log n)$.

For each repetition r, for each $i \in S$, we can union bound the probability that none of three bad events (collision, large offset, large noise) happens by $\frac{1}{10}$. Conditioned on no bad events happened, by Lemma 15.6.5, $w_i^{(r)}$ is a good estimation for $\widehat{x}_i$ in the sense that $\mathbb{E}[|\widehat{x}_i - w_i^{(r)}|^2] = O(\frac{\|x_P\|_2^2 + \|x_Q\|_2^2}{B})$. By Markov inequality with only very small constant probability that $|\widehat{x}_i - w_i^{(r)}| \geq \frac{1}{2}\sqrt{\frac{\|x_P\|_2^2 + \|x_Q\|_2^2}{B}}$. By applying Chernoff bound, we can prove that with probability $2^{-\Omega(R)}$, $|\widehat{x}_i - \mathrm{median}_{r \in [R]} w_i^{(r)}| \geq \frac{1}{2}\sqrt{\frac{\|x_P\|_2^2 + \|x_Q\|_2^2}{B}}$. □

Corollary 15.6.7 (Fourier set query)**.** *Given a vector $x \in \mathbb{C}^n$, for every $\epsilon \in (0,1)$ and $k \geq 1$, any $S \subseteq [n]$, $|S| \leq k$, there exists an algorithm (Algorithm 15.3) that takes*

$$O(\epsilon^{-1} k \log k \cdot \log n)$$

samples, runs in

$$O(\epsilon^{-1} k \log k \cdot \log n)$$

time, and outputs a vector $x' \in \mathbb{C}^n$ such that

$$\|(x' - \widehat{x})_S\|_H \leq \epsilon \|\widehat{x}_{\overline{S}}\|_H,$$

holds with probability at least $1 - 1/\operatorname{poly}(k)$. The corollary holds when function H is Huber function or Tukey function.

15.7 Sparse recovery

15.7.1 k-sparse recovery for Huber function

In this subsection, we present our k-sparse recovery results for Huber function.

Theorem 15.7.1. *Let H denote Huber function defined in Definition 15.4.1. There exists a distribution of $\Phi \in \mathbb{R}^{m \times n}$ with $m = O(\epsilon^{-2} k \log n)$ and a recovery algorithm, such that for each $x \in \mathbb{R}^n$, $k \in [n]$ and $\epsilon \in (0, 1)$, the recovery algorithm takes Φx as its input and outputs*

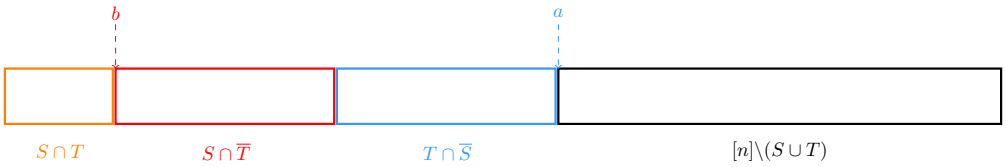

Figure 15.3: $\|x_{S\cap\overline{T}}\|_H - \|x_{T\cap\overline{S}}\|_H$ is the displacement error

k-sparse *vector* $x' \in \mathbb{R}^n$ *so that with probability* $1 - 1/\operatorname{poly}(n)$,

$$\|x' - x\|_H \leq (1+\epsilon) \min_{k-\text{sparse } y} \|y - x\|_H.$$

The update time is $O(\log n)$ *and the recovery time is* $O(n \log n)$.

Proof. Let x_{-k} denotes the vector x with the largest k coordinates in magnitude zeroed out.

We use count sketch to give each x_i (where $i \in [n]$) an estimate. In particular, we choose the number of buckets to be $B = O(\epsilon^{-2}k)$ and the number of repetitions to be $R = O(\log n)$. Let x'_i denote the estimate obtained by the count sketch for x_i. Let T denote the largest k coordinates in absolute value in x'. The recovery algorithm outputs x'_T as a k-sparse approximation to x.

Note that the count sketch data structure takes $B \cdot R = O(\epsilon^{-2}k \log n)$ measurements. Its update time is $O(R) = O(\log n)$ time, and the time to obtain x' is $O(n \cdot R) = O(n \log n)$. Taking largest k coordinates from x' requires $O(n \log n)$ time. Thus the total query time is $O(n \log n)$. In the following, we show that $\|x - x'\|_H \leq (1+\epsilon)\|x_{-k}\|_H$.

By Lemma 15.5.1, for each $i \in [n]$, with probability $1 - 1/\operatorname{poly}(n)$,

$$(x_i - x'_i)^2 \leq \frac{\epsilon^2}{64k}\|x_{-64k/\epsilon^2}\|_2^2 \leq \frac{\epsilon^2}{64k}\|x_{-64k}\|_2^2. \tag{15.5}$$

Let S denote the largest k coordinates of x in magnitude. The error is

$$\|x - x'\|_H = \sum_{i \in T} H(x_i - x'_i) + \sum_{i \in \overline{T}} H(x_i). \tag{15.6}$$

By point estimation guarantee given in Eq. (15.5) and results from Huber set query,

$$\begin{aligned}\sum_{i \in T} H(x_i - x'_i) &\leq |T| \cdot H(\frac{\epsilon}{8\sqrt{k}} \|x_{-64k}\|_2) \\ &\leq \frac{\epsilon}{8} \|x_{-k}\|_H.\end{aligned}$$

Note that

$$\begin{aligned}\sum_{i \in \overline{T}} H(x_i) &= \left(\sum_{i \in \overline{T}} H(x_i) - \sum_{i \in \overline{S}} H(x_i) \right) + \sum_{i \in \overline{S}} H(x_i) \\ &= \left(\sum_{i \in S \cap \overline{T}} H(x_i) - \sum_{i \in \overline{S} \cap T} H(x_i) \right) + \|x_{-k}\|_H,\end{aligned}$$

where the second step follows by canceling out the coordinates in $\overline{S} \cap \overline{T}$. In the following, our goal is to show that $\sum_{i \in S \cap \overline{T}} H(x_i) - \sum_{i \in \overline{S} \cap T} H(x_i) \leq \frac{7}{8} \epsilon \|x_{-k}\|_H$.

If $S \cap \overline{T} = \emptyset$, then $S = T$ and $\sum_{i \in S \cap \overline{T}} H(x_i) - \sum_{i \in \overline{S} \cap T} H(x_i) = 0$. In the following, we assume that $S \cap \overline{T} \neq \emptyset$. Let $b = \max_{i \in S \cap \overline{T}} |x_i|$, and $a = \min_{i \in \overline{S} \cap T} |x_i|$. Because Huber function $H(t)$ is monotonically increasing as $|t|$ increases,

$$\sum_{i \in S \cap \overline{T}} H(x_i) - \sum_{i \in \overline{S} \cap T} H(x_i) \leq |\overline{S} \cap T| \cdot (H(b) - H(a)).$$

Our final goal is to prove that $H(b) - H(a) \leq \frac{7\epsilon \|x_{-k}\|_H}{8|\overline{S} \cap T|}$. We discuss in three cases: case (1) $\tau \leq a$, case (2) $a < \tau < b$, case (3) $b \leq \tau$. We analyze these three cases in Claim 15.7.2, Claim 15.7.3 and Claim 15.7.4.

Before diving into case analysis, we first prove two inequalities: one is an upper bound of $b - a$, and the other is an upper b ound of a. They will be used repeatedly in the case analysis.

By Eq. (15.5), any $i \in [n]$, $|x_i - x'_i| \leq \frac{\epsilon}{8\sqrt{k}}\|x_{-64k}\|_2$. That is, $\|x - x'\|_\infty \leq \Delta$ where $\Delta = \frac{\epsilon}{8\sqrt{k}}\|x_{-64k}\|_2$. By Lemma 15.7.5,

$$b - a \leq \frac{\epsilon}{4\sqrt{k}}\|x_{-64k}\|_2. \tag{15.7}$$

Moreover, by definition that $a = \min_{i \in \overline{S} \cap T} |x_i|$,

$$a \leq \frac{\|x_{\overline{S}\cap T}\|_2}{\sqrt{|\overline{S} \cap T|}} \leq \frac{\|x_{-k}\|_2}{\sqrt{|\overline{S} \cap T|}}. \tag{15.8}$$

□

Claim 15.7.2. *If $\tau \leq a$, then $H(b) - H(a) \leq \frac{7\epsilon}{8}\frac{\|x_{-k}\|_H}{|\overline{S}\cap T|}$.*

Proof. Let P, Q be a partition of $\overline{S}$ where

$$P = \{i \mid |x_i| \leq \tau, i \in \overline{S}\}, Q = \{i \mid |x_i| > \tau, i \in \overline{S}\}.$$

Note that the coordinates in x_{-64k}, which equals to $\overline{S} = P \cup Q$ with largest (in absolute value) $63k$ coordinates removed, are fully contained in P union Q with largest (in absolute value) $63k$ coordinates removed. By triangle inequality,

$$\|x_{-64k}\|_2 \leq \|x_P\|_2 + \|(x_Q)_{-63k}\|_2. \tag{15.9}$$

In the following, we are going to bound both $\|x_P\|_2$ and $\|(x_Q)_{-63k}\|_2$ in terms of $\|x_{-k}\|_H$.

By definition of Huber function $\|x_{-k}\|_H = \frac{1}{\tau}\|x_P\|_2^2 + \|x_Q\|_1$. Because $\tau \le a$, $\overline{S} \cap T \subseteq Q$. Thus $\|x_Q\|_1 \ge \|x_{\overline{S}\cap T}\|_1 \ge \tau|\overline{S} \cap T|$. Therefore,

$$\begin{aligned}\|x_{-k}\|_H &\ge \frac{1}{\tau}\|x_P\|_2^2 + \tau|\overline{S} \cap T| \\ &\ge 2\sqrt{\frac{1}{\tau}\|x_P\|_2^2 \cdot \tau|\overline{S} \cap T|} = 2\sqrt{|\overline{S} \cap T|} \cdot \|x_P\|_2.\end{aligned}$$

So we have

$$\|x_P\|_2 \le \frac{1}{2\sqrt{|\overline{S} \cap T|}}\|x_{-k}\|_H.$$

In order to bound $\|(x_Q)_{-63k}\|_2$, by Lemma 15.5.2,

$$\begin{aligned}\|(x_Q)_{-63k}\|_2 &\le \frac{1}{\sqrt{63k}}\|x_Q\|_1 \le \frac{1}{7\sqrt{|\overline{S} \cap T|}}\|x_Q\|_1 \\ &\le \frac{1}{7\sqrt{|\overline{S} \cap T|}}\|x_{-k}\|_H.\end{aligned}$$

Therefore,

$$\begin{aligned}& H(b) - H(a) \\ =\ & b - a \\ \le\ & \frac{\epsilon}{4\sqrt{|\overline{S} \cap T|}}\|x_{-64k}\|_2 \\ \le\ & \frac{\epsilon}{4\sqrt{|\overline{S} \cap T|}}(\|x_P\|_2 + \|(x_Q)_{-63k}\|_2) \\ \le\ & \frac{\epsilon}{4\sqrt{|\overline{S} \cap T|}}\left(\frac{1}{2\sqrt{|\overline{S} \cap T|}}\|x_{-k}\|_H + \frac{1}{7\sqrt{|\overline{S} \cap T|}}\|x_{-k}\|_H\right) \\ \le\ & \frac{\epsilon\|x_{-k}\|_H}{4|\overline{S} \cap T|},\end{aligned}$$

where the first line follows from definition of Huber function and $a \geq \tau$, the second line follows by Eq. (15.7), the third follows by Eq. (15.9), the forth line follows by the bounds of $\|x_P\|_2$ and $\|(x_Q)_{-63k}\|_2$ we just obtained. □

Claim 15.7.3. *If $a < \tau < b$, then $H(b) - H(a) \leq \frac{7\epsilon}{8} \frac{\|x_{-k}\|_H}{|\overline{S} \cap T|}$.*

Proof. Let $P = \{i \mid |x_i| \leq \tau, i \in \overline{S}\}, Q = \{i \mid |x_i| > \tau, i \in \overline{S}\}$. We discuss in two cases depending on whether the size of Q is greater than $9k$ or not.

(1) If $|Q| \leq 9k$. We first bound $H(b) - H(a)$ as follows

$$\begin{aligned}
& H(b) - H(a) \\
= & \, b - a^2/\tau \\
\leq & \, b^2/\tau - a^2/\tau \\
= & \, \frac{1}{\tau}(b-a)(b+a) \\
\leq & \, \frac{\epsilon \|x_{-10k}\|_2}{4\tau\sqrt{k}} (\frac{\epsilon \|x_{-10k}\|_2}{4\sqrt{k}} + 2a) \\
\leq & \, \frac{\epsilon \|x_{-10k}\|_2}{4\tau\sqrt{k}} (\frac{\epsilon \|x_{-10k}\|_2}{4\sqrt{k}} + 2\frac{\|x_P\|_2}{\sqrt{|\overline{S} \cap T|}}) \\
= & \, \frac{\epsilon^2 \|x_{-10k}\|_2^2}{16\tau k} + \frac{\epsilon \|x_{-10k}\|_2 \|x_P\|_2}{2\sqrt{k}\sqrt{|\overline{S} \cap T|}} \\
\leq & \, \frac{\epsilon}{\tau |\overline{S} \cap T|} (\frac{1}{16}\|x_{-10k}\|_2^2 + \frac{1}{2}\|x_{-10k}\|_2 \cdot \|x_P\|_2),
\end{aligned}$$

where the forth step follows by Eq.(15.7), and the fifth step follows by Eq.(15.8).

Because $|Q| \leq 9k$, $\|x_{-10k}\|_2 \leq \|x_P\|_2$, and thus

$$H(b) - H(a) \leq \frac{\epsilon}{\tau |\overline{S} \cap T|} \cdot \frac{9}{16}\|x_P\|_2^2 \leq \frac{9\epsilon \|x_{-k}\|_H}{16 |\overline{S} \cap T|}.$$

(2) If $|Q| > 9k$. First note that

$$b - a^2/\tau \leq 2(b-a),$$

because

$$b + a^2/\tau \geq 2\sqrt{b \cdot a^2/\tau} \geq 2a.$$

Furthermore, $b - a \leq \frac{\epsilon\|x_{-64}\|_2}{4\sqrt{k}} \leq \frac{\epsilon\|x_{-10}\|_2}{4\sqrt{k}}$, where

$$\|x_{-10k}\|_2 \leq \|(x_Q)_{-9k}\|_2 + \|x_P\|_2 \leq \frac{1}{\sqrt{9k}}\|x_Q\|_1 + \|x_P\|_2.$$

Also note that $\|x_{-k}\|_H = \|x_Q\|_1 + \frac{1}{\tau}\|x_P\|_2^2 \geq 2\sqrt{\|x_Q\|_1 \cdot \|x_P\|_2^2/\tau} \geq 6\sqrt{k}\|x_P\|_2$. Therefore,

$$\begin{aligned} H(b) - H(a) &= b - a^2/\tau \\ &\leq \frac{2\epsilon}{4\sqrt{k}}\|x_{-10}\|_2 \\ &\leq \frac{2\epsilon}{4\sqrt{k}}\left(\frac{1}{\sqrt{9k}}\|x_{-k}\|_H + \frac{1}{6\sqrt{k}}\|x_{-k}\|_H\right) \\ &= \frac{\epsilon\|x_{-k}\|_H}{4k} \leq \frac{\epsilon\|x_{-k}\|_H}{4|\overline{S} \cap T|}. \end{aligned}$$

□

Claim 15.7.4. *If $b \leq \tau$, then $H(b) - H(a) \leq \frac{7\epsilon}{8}\frac{\|x_{-k}\|_H}{|\overline{S}\cap T|}$.*

Proof. The analysis is similar to classical ℓ_2/ℓ_2 sparse recovery case. We have

$$\begin{aligned}
& H(b) - H(a) \\
= & \frac{b^2}{\tau} - \frac{a^2}{\tau} \\
= & \frac{1}{\tau}(b-a)(b+a) \\
= & \frac{1}{\tau}(b-a)(b-a+2a) \\
\leq & \frac{1}{\tau} \cdot \frac{\epsilon}{4\sqrt{k}}\|x_{-k}\|_2 \cdot (\frac{\epsilon}{4\sqrt{k}}\|x_{-k}\|_2 + 2\frac{\|x_{-k}\|_2}{\sqrt{|\overline{S} \cap T|}}) \\
\leq & \frac{1}{\tau} \cdot \frac{\epsilon\|x_{-k}\|_2}{4\sqrt{|\overline{S} \cap T|}} \cdot (\frac{\|x_{-k}\|_2}{4\sqrt{|\overline{S} \cap T|}} + 2\frac{\|x_{-k}\|_2}{\sqrt{|\overline{S} \cap T|}}) \\
= & \frac{1}{\tau} \cdot \frac{9\epsilon\|x_{-k}\|_2^2}{16|\overline{S} \cap T|} \\
= & \frac{9\epsilon\|x_{-k}\|_H}{16|\overline{S} \cap T|},
\end{aligned}$$

where the first step follows by definition of Huber function, the forth step follows by Eq. (15.7) and Eq.(15.8), the fifth step follows by $|\overline{S} \cap T| \leq |T| = k$ and $\epsilon \leq 1$, the last step follows because by definition of $b = \max_{i \in S \cap \overline{T}} |x_i|$, for any $j \in [n] \backslash S$, $|x_j| \leq \min_{i \in S} |x_i| \leq b \leq \tau$ and then by definition of Huber function $\|x_{-k}\|_H = \frac{1}{\tau}\|x_{-k}\|_2^2$. □

Lemma 15.7.5. *Let vector $u, v \in \mathbb{R}^n$ such that $\|u - v\|_\infty \leq \Delta$. Let S be the largest k coordinates in u, and let T be the largest k coordinates in v. Let $b = \max_{i \in S \cap \overline{T}} u_i$ and $a = \min_{i \in \overline{S} \cap T} u_i$. Then $b - a \leq 2\Delta$.*

Proof. Let $\lambda = \max_{i \in \overline{T}} v_i$. We have

$$b = \max_{i \in S \cap \overline{T}} u_i \leq \max_{i \in \overline{T}} u_i \leq \Delta + \max_{i \in \overline{T}} v_i = \Delta + \lambda.$$

On the other hand,

$$a = \min_{i \in \overline{S} \cap T} u_i \geq \min_{i \in T} u_i \geq -\Delta + \min_{i \in T} v_i \geq -\Delta + \lambda.$$

Therefore

$$b - a \leq (\Delta + \lambda) - (-\Delta + \lambda) \leq 2\Delta.$$

□

15.7.2 k-sparse recovery for Tukey function

In this subsection, we present our k-sparse recovery results for Tukey function. Similar to results for Huber function, we use count-sketch to estimate each coordinate and then find the top k ones. Moreover, our proof for Tukey function has a similar structure, where we first decompose estimation error into set query error and displacement error, and then discuss the displacement error in several cases.

Theorem 15.7.6. *Let H denote Tukey function defined in Definition 15.4.2. There exists a distribution of $\Phi \in \mathbb{R}^{m \times n}$ with $m = O(\epsilon^{-2} k \log n)$ and a recovery algorithm, such that for each $x \in \mathbb{R}^n$, $k \in [n]$ and $\epsilon \in (0, 1)$, the recovery algorithm takes Φx as its input and outputs k-sparse vector $x' \in \mathbb{R}^n$ so that with probability $1 - 1/\operatorname{poly}(n)$,*

$$\|x' - x\|_H \leq (1 + \epsilon) \min_{k-\text{sparse } y} \|y - x\|_H,$$

The update time is $O(\log n)$ and the recovery time is $O(n \log n)$.

Proof. Let x_{-k} denotes the vector x with absolute largest k coordinates removed.

We use count sketch to give each x_i (where $i \in [n]$) an estimate. In particular, we choose the number of buckets $B = O(\epsilon^{-2}k)$ and the number of duplicates $R = O(\log n)$ for the count sketch data structure. Let x'_i denote the estimate obtained by the count sketch for x_i. Let T denote the largest k coordinates in absolute value in x'. The recovery algorithm outputs x'_T as a k-sparse approximation to x.

Note that the count sketch data structure takes $B \cdot R = O(\epsilon^{-2}k \log n)$ measurements. Its update time is $O(R) = O(\log n)$ time, and the time to obtain x' is $O(n \cdot R) = O(n \log n)$. Taking largest k coordinates from x' requires $O(n \log n)$ time. Thus the total query time is $O(n \log n)$. In the following, we show that $\|x - x'_T\|_H \leq (1+\epsilon)\|x_{-k}\|_H$.

By Lemma 15.5.1, for each $i \in [n]$, with probability $1 - 1/\operatorname{poly}(n)$,

$$(x_i - x'_i)^2 \leq \frac{\epsilon^2}{10k}\|x_{-10k/\epsilon^2}\|_2^2.$$

Let S denote the largest k coordinates in absolute value in x. The recovery error is

$$\|x - x'_T\|_H = \sum_{i \in T} H(x_i - x'_i) + \sum_{i \in \overline{T}} H(x_i).$$

By point estimation guarantee and results from Tukey set query in Theorem 15.2.1,

$$\sum_{i \in T} H(x_i - x'_i) \leq |T| \cdot H(\frac{\epsilon}{\sqrt{10k}}\|x_{-4k}\|_2) \leq \frac{\epsilon}{3}\|x_{-k}\|_H.$$

Note that

$$\begin{aligned}\sum_{i \in \overline{T}} H(x_i) &= \left(\sum_{i \in \overline{T}} H(x_i) - \sum_{i \in \overline{S}} H(x_i)\right) + \sum_{i \in \overline{S}} H(x_i) \\ &= \left(\sum_{i \in S \cap \overline{T}} H(x_i) - \sum_{i \in \overline{S} \cap T} H(x_i)\right) + \|x_{-k}\|_H,\end{aligned}$$

where the second step follows by canceling out the coordinates in $\overline{S} \cap \overline{T}$. In the following, our goal is to show that $\sum_{i \in S \cap \overline{T}} H(x_i) - \sum_{i \in \overline{S} \cap T} H(x_i) \leq \frac{2}{3}\epsilon \|x_{-k}\|_H$.

If $S \cap \overline{T} = \emptyset$, then $S = T$ and $\sum_{i \in S \cap \overline{T}} H(x_i) - \sum_{i \in \overline{S} \cap T} H(x_i) = 0$. In the following, we assume that $S \cap \overline{T} \neq \emptyset$. Let $b = \max_{i \in S \cap \overline{T}} |x_i|$, and $a = \min_{i \in \overline{S} \cap T} |x_i|$. Because Huber function $H(t)$ is monotonically increasing as $|t|$ increases,

$$\sum_{i \in S \cap \overline{T}} H(x_i) - \sum_{i \in \overline{S} \cap T} H(x_i) \leq |\overline{S} \cap T| \cdot (H(b) - H(a)).$$

By Lemma 15.7.5

$$b - a \leq \frac{\epsilon}{\sqrt{10k}} \|x_{-10k/\epsilon^2}\|_2.$$

In the following, we are going to prove that $H(b) - H(a) \leq \frac{\epsilon}{2} \frac{\|x_{-k}\|_H}{|\overline{S} \cap T|}$. We discuss in three cases: case (1) $\tau \leq a$, case (2) $a < \tau < b$, case (3) $b \leq \tau$.

Case (1) $\tau \leq a$.

In this case $H(a) = H(b) = 1$ and $H(b) - H(a) = 0$.

Case (2) $a < \tau < b$.

Let $P = \{i \in \overline{S} \mid |x_i| < \tau\}$, and $Q = \{i \in \overline{S} \mid |x_i| \geq \tau\}$. We have

$$\|x_{-k}\|_H = |Q| + \|x_P\|_2^2$$

and

$$\begin{aligned} H(b) - H(a) &= 1 - a^2 = (1 - a)(1 + a) \\ &\leq \frac{\epsilon \|x_{-10k/\epsilon^2}\|_2}{\sqrt{k}} \cdot (1 + a) \leq \frac{2\epsilon \|x_{-10k/\epsilon^2}\|_2}{\sqrt{k}}. \end{aligned}$$

If $|Q| > \epsilon^{-2}k$, then we have $H(b) - H(a) \leq 1$ while $\|x_{-k}\|_H \geq |Q| > \epsilon^{-2}k$. Thus $H(b) - H(a) \leq \frac{\epsilon}{k}\|x_{-k}\|_H \leq \frac{\epsilon}{|S\cap\overline{T}|}\|x_{-k}\|_H$.

If $|Q| \leq \epsilon^{-2}k$ and $\|x_{-10k/\epsilon^2}\|_2 > \sqrt{k}$, then $\|x_P\|_2 \geq \|x_{-10k/\epsilon^2}\|_2 > \sqrt{k}$, and so $\|x_{-10k/\epsilon^2}\|_2 \leq \frac{\|x_P\|_2}{\sqrt{k}} \cdot \|x_P\|_2 = \frac{\|x_P\|_2^2}{\sqrt{k}} \leq \frac{1}{\sqrt{k}}\|x_{-k}\|_H$. Thus $H(b) - H(a) \leq \frac{2\epsilon}{k}\|x_{-k}\|_H \leq \frac{2\epsilon}{|S\cap\overline{T}|}\|x_{-k}\|_H$.

If $|Q| \leq \epsilon^{-2}k$ and $\|x_{-10k/\epsilon^2}\|_2 \leq \sqrt{k}$. We have $\|x_P\|_2 \geq \|x_{-10k/\epsilon^2}\|_2$. By definition that $a = \min_{i\in\overline{S}\cap T}|x_i|$, $a \leq \frac{\|x_{\overline{S}\cap T}\|_2}{\sqrt{|\overline{S}\cap T|}} \leq \frac{\|x_P\|_2}{\sqrt{|\overline{S}\cap T|}}$. Therefore,

$$\begin{aligned} H(b) - H(a) &\leq \frac{\epsilon\|x_{-10k/\epsilon^2}\|_2}{\sqrt{k}} \cdot \left(\frac{\epsilon\|x_{-10k/\epsilon^2}\|_2}{\sqrt{k}} + 2\frac{\|x_P\|_2}{\sqrt{|\overline{S}\cap T|}}\right) \\ &\leq \frac{\epsilon\|x_P\|_2}{\sqrt{|\overline{S}\cap T|}} \cdot 3\frac{\|x_P\|_2}{\sqrt{|\overline{S}\cap T|}} \\ &\leq \frac{3\epsilon}{|\overline{S}\cap T|}\|x_P\|_2^2 \\ &\leq \frac{3\epsilon}{|\overline{S}\cap T|}\|x_{-k}\|_H. \end{aligned}$$

Case (3) $b \leq \tau$.

The analysis is similar to classical ℓ_2/ℓ_2 sparse recovery case. We have

$$\begin{aligned}
H(b) - H(a) &= \frac{b^2}{\tau} - \frac{a^2}{\tau} \\
&= \frac{1}{\tau}(b-a)(b+a) \\
&= \frac{1}{\tau}(b-a)(b-a+2a) \\
&\leq \frac{1}{\tau} \cdot \frac{\epsilon}{\sqrt{k}}\|x_{-k}\|_2 \cdot (\frac{\epsilon}{\sqrt{k}}\|x_{-k}\|_2 + 2\frac{\|x_{-k}\|_2}{\sqrt{|\overline{S} \cap T|}}) \\
&\leq \frac{1}{\tau} \cdot \frac{\epsilon\|x_{-k}\|_2}{\sqrt{|\overline{S} \cap T|}} \cdot (\frac{\|x_{-k}\|_2}{\sqrt{|\overline{S} \cap T|}} + 2\frac{\|x_{-k}\|_2}{\sqrt{|\overline{S} \cap T|}}) \\
&= \frac{1}{\tau} \cdot \frac{3\epsilon\|x_{-k}\|_2^2}{|\overline{S} \cap T|} \\
&= \frac{3\epsilon\|x_{-k}\|_H}{|\overline{S} \cap T|},
\end{aligned}$$

where the first step follows by definition of Huber function, the forth step follows by Eq. (15.7) and Eq.(15.8), the fifth step follows by $|\overline{S} \cap T| \leq |T| = k$ and $\epsilon \leq 1$, the last step follows because by definition of $b = \max_{i \in S \cap \overline{T}} |x_i|$, for any $j \in [n] \backslash S$, $|x_j| \leq \min_{i \in S} |x_i| \leq b \leq \tau$ and then by definition of Huber function $\|x_{-k}\|_H = \frac{1}{\tau}\|x_{-k}\|_2^2$. □

Part IV

Matrix Factorizations

Chapter 16

Weighted Low Rank Approximation

The classical low rank approximation problem is: given a matrix A, find a rank-k matrix B such that the Frobenius norm of $A - B$ is minimized. It can be solved efficiently using, for instance, the Singular Value Decomposition (SVD). If one allows randomization and approximation, it can be solved in time proportional to the number of non-zero entries of A with high probability.

Inspired by practical applications, we consider a *weighted* version of low rank approximation: for a non-negative weight matrix W we seek to minimize $\sum_{i,j}(W_{i,j} \cdot (A_{i,j} - B_{i,j}))^2$. The classical problem is a special case of this problem when all weights are 1. Weighted low rank approximation is known to be NP-hard, so we are interested in a meaningful parametrization that would allow efficient algorithms.

In this paper we present several efficient algorithms for the case of small k and under the assumption that the weight matrix W is of low rank, or has a small number of distinct columns. An important feature of our algorithms is that they do not assume anything about the matrix A. We also obtain lower bounds that show that our algorithms are nearly optimal in these parameters. We give several applications in which these parameters are small. To the best of our knowledge, the present paper is the first to provide algorithms for the weighted low rank approximation problem with provable guarantees.

Perhaps even more importantly, our algorithms proceed via a new technique, which we call "guess the sketch". The technique turns out to be general enough to give solutions to several other fundamental problems: adversarial matrix completion, weighted non-negative matrix factorization and tensor completion.

16.1 Introduction

Low rank approximation is arguably one of the most well-studied problems in randomized numerical linear algebra, with diverse applications to clustering [DFK+04, FSS13, LBKW14, CEM+15], data mining [AFK+01], distance matrix completion [Cha12], information retrieval [PRTV00], learning mixtures of distributions [AM05, KSV08], recommendation systems [DKR02], and web search [AFKM01, Kle99]. In practice one often has a low rank matrix which has been corrupted with noise of bounded norm, and low rank approximation allows one to approximately recover the original matrix. Low rank approximation may also help explain a dataset, revealing low dimensional structure in high dimensional data. Given a low rank approximation, one can store a matrix and compute a matrix-vector product much more efficiently by storing the corresponding factorization. It can also be used as a preprocessing step in applications, that is, by first projecting data onto a lower-dimensional subspace one preserves important properties of the input, but can now run subsequent algorithms in the lower-dimensional space. For example, it has been proposed to reduce the data dimension in Non-Negative Matrix Factorization [LS00] (more on this below), and Latent Dirichlet Allocation (LDA) [BNJ01].

The basic low rank approximation problem is: given an $n \times n$ matrix A, find a matrix $\widehat{A}$ of rank at most k for which $\|A - \widehat{A}\|_F$ is minimized, where for a matrix B, $\|B\|_F = \left(\sum_{i,j} B_{i,j}^2\right)^{1/2}$ is its Frobenius norm. This formulation intuitively corresponds to the matrix $\widehat{A}$ capturing as much of the variance of A as possible. It is well-known that the optimal solution is given by A_k, which if $U\Sigma V^\top$ is the singular value decomposition (SVD) of A, where U and V are orthogonal matrices and Σ is a non-negative diagonal matrix with $\Sigma_{1,1} \geq \Sigma_{2,2} \geq \cdots \geq \Sigma_{n,n}$, then $A_k = U\Sigma_k V^\top$, where Σ_k agrees with Σ on its first k

diagonal entries and is 0 otherwise. Although the SVD is computable in polynomial time, it is often acceptable to output a matrix $\widehat{A}$ for which $\|A - \widehat{A}\|_F \leq (1+\epsilon)\|A - A_k\|_F$ with high probability. In the latter case, much more efficient algorithms are known, and it is possible to compute such an $\widehat{A}$ in $\mathrm{nnz}(A) + n \cdot \mathrm{poly}(k/\epsilon)$ time, where $\mathrm{nnz}(A)$ denotes the number of non-zero entries of A [CW13, MM13, NN13a]. We note that for typical applications k and $1/\epsilon$ are assumed to be much smaller than n, e.g., in [Har14] they are treated as absolute constants.

Despite the large body of work on low rank approximation, the *weighted* case is not well understood. In this case one is given an $n \times n$ matrix A and an $n \times n$ matrix W with $W_{i,j} \geq 0$, and one seeks to solve:

$$\min_{\text{rank-}k \text{ matrices } \widehat{A}} \|W \circ (A - \widehat{A})\|_F^2 = \min_{\text{rank-}k \text{ matrices } \widehat{A}} \sum_{i,j} W_{i,j}^2 (A_{i,j} - \widehat{A}_{i,j})^2.$$

The classical low rank approximation is a special case in which $W_{i,j} = 1$ for all i and j. However, in general there may not be a good reason to weight all elements of the approximation error $A - \widehat{A}$ equally, especially if one is given prior knowledge about the distribution of the errors. For example, suppose the columns of A each come from a low-dimensional subspace but one of the columns is then shifted by a fixed large vector so that its mean is different. One may first want to recenter the data by subtracting off the mean from each of the columns. While this is possible without weighted low rank approximation, suppose instead that each of the columns of A comes from a perturbation of columns in a low dimensional subspace but one of the columns has a much larger variance. Then if all weights were equal, it would be enough for $\widehat{A}$ to fit this one single large variance column, which fails to capture the entire low-dimensional subspace. One way of fixing this is to reweight each entry of A

by the inverse of its variance. This is a common technique used in gene expression analysis, where the error model for microarray measurements provides entry-specific noise estimates, or when entries of A represent aggregates of many samples such as in word co-occurrence matrices and non-uniform weights are needed to appropriately capture any differences in the sample sizes; see [SJ03] for a discussion, and also the Wikipedia entry on weighted low rank approximation for a brief introduction.

While the extension of low rank approximation to the weighted case goes back to work of Young in 1940 [You40], its complexity is not well-understood, partly because the weighted case does not admit a solution via the SVD and may have many local minima [SJ03]. Early work by Shpak [Shp90] looked at gradient-based approaches while Lu et al. [LPW97, LA03] looked at alternating minimization methods. These were significantly sped up in practice by the work of Srebro and Jaakkola [SJ03], with success in various applications such as color image restoration [MES08], though there are no provable time bounds and in the worst case the running times could be exponential or worse. In fact, weighted low rank approximation is known to be NP-hard to approximate up to a $(1 \pm 1/\operatorname{poly}(n))$ factor [GG11]. We note that this also follows from the fact that matrix completion, arguably one of the most important special cases of weighted low rank approximation in which case all weights are 0 or 1, which we discuss more below, is also known to be NP-hard [Pee96, HMRW14]. Typically, though, assumptions such as incoherence and randomly sampled entries allow one to circumvent this hardness [CR09, LLR16]. There is some debate as to whether these assumptions are valid, for instance in [SW15] an argument is made why randomly missing entries may not hold for real-world datasets.

Many natural questions are left open from previous work. In particular the main

question as we see it is the following:

- *For which weight matrices W is the problem tractable? More generally, is it possible to identify a natural parameter of W and to obtain parameterized complexity bounds in terms of that parameter?*

16.1.1 Our Results

In this work we provide an answer to the above questions by parameterizing the complexity of the problem in terms of the *rank of the weight matrix* W and the *number of distinct columns of the weight matrix.* Note that we make *no assumptions* about the input matrix A. Let OPT denote the quantity $\min_{\text{rank-}k \text{ matrices } \widehat{A}} \|W \circ (\widehat{A} - A)\|_F^2$. Our main theorems are the following. For a function f, define $\widetilde{f} = f \cdot \text{poly}(\log(f))$.

Theorem 16.1.1 (Algorithm for Weighted Low Rank Approximation)**.** *Let r be the rank of W. There is an algorithm running in time $n^{O(k^2 r/\epsilon)}$ which outputs a factorization (into an $n \times k$ and a $k \times n$ matrix) of a rank-k matrix $\widehat{A}$ for which*

$$\|W \circ (A - \widehat{A})\|_F^2 \leq (1 + \epsilon)\,\text{OPT},$$

with probability at least $9/10$.

We also have the following theorem.

Theorem 16.1.2 (Algorithm for Weighted Distinct Columns)**.** *Let r be the number of distinct columns of W. For every $\epsilon > 0$ and for an arbitrarily small constant $\gamma > 0$, there is an algorithm running in time $O((\text{nnz}(A) + \text{nnz}(W)) \cdot n^{\gamma}) + n \cdot 2^{\widetilde{O}(k^2 r^2/\epsilon)}$ which outputs a factorization (into an $n \times k$ and a $k \times n$ matrix) of a rank-k matrix $\widehat{A}$ for which*

$$\|W \circ (A - \widehat{A})\|_F^2 \leq (1 + \epsilon)\,\text{OPT},$$

with probability at least $9/10$.

Note that Theorem 16.1.2 does not make any assumptions on the number of distinct rows, which is important for the applications described below.

Let us point out two things here:

- Before only the case of W having rank 1 was known to be provably solvable in polynomial time by a direct reduction to the SVD[1];
- The result for at most r distinct columns implies that, with respect to this parametrization, the weighted low rank approximation problem is fixed-parameter tractable.

We complement the above positive results by proving a lower bound, which assumes the Exponential Time Hypothesis for the average case hardness of random 4-SAT. We state the assumption as follows.

Assumption 16.1.3 ("Random Exponential Time Hypothesis")**.** *Let $c > \ln 2$ be a constant. Consider a random 4-SAT formula on n variables in which each clause has 4 literals, and in which each of the $16n^4$ clauses is picked independently with probability c/n^3. Then any algorithm which always outputs 1 when the random formula is satisfiable, and outputs 0 with probability at least $1/2$ when the random formula is unsatisfiable, must run in $2^{c'n}$ time on some input, where $c' > 0$ is an absolute constant.*

We are not aware of prior work using this form of the Exponential Time Hypothesis, though both the Exponential Time Hypothesis and Feige's original assumption [Fei02] that there is no polynomial time algorithm for the problem in Assumption 16.1.3 are commonly

[1]Namely, in that case, we can rewrite the problem as $\min_{\text{rank-}k \text{ matrices } \widehat{A}} \|D(\widehat{A} - A)E\|_F^2$ for diagonal matrices D and E, from which we can replace A with DAE and solve the unweighted low rank approximation, obtaining an $\widehat{A}$ for which we can then output $D^{-1}\widehat{A}E^{-1}$ if the diagonal entries of D and E are non-zero. If they are zero we can first remove rows and columns from A

used. We do not know of any better algorithm for the problem in Assumption 16.1.3 and have consulted several experts[2] about the assumption who do not know a counterexample to it. Instead of calling it "Random-ETH", some experts[3] suggest other names, e.g. average case ETH or Feige-ETH.

Theorem 16.1.4 (Weighted Low Rank Approximation Hardness)**.** *Let r be an upper bound on the number of distinct columns of W. Under Assumption 16.1.3, there is an absolute constant $\epsilon_0 \in (0,1)$ for which any algorithm for solving the weighted low rank approximation algorithm with $\epsilon \leq \epsilon_0$ and for any $k \geq 1$, with constant probability, requires $2^{\Omega(r)}$ time. Further, this holds even if W also only has r distinct rows.*

Note that for constant k and ϵ, and $r \geq C \log n$ for a constant $C > 0$, our upper bound assuming at most r distinct columns is $2^{\widetilde{O}(r^2)}$, which nearly matches our lower bound in Theorem 16.1.4 of $2^{\Omega(r)}$.

There are naturally arising applications in which the rank of the weight matrix or the number of distinct columns is small. Consider a matrix in which the rows correspond to users and the columns correspond to ratings of a movie, such as in the Netflix matrix. Further, suppose for each movie, there are r columns, indicating different aspects of the movie to be rated, such as acting, plot, sound effects, visual effects, etc. For a given user, one can look at the distribution of scores across movies along one of these aspects. These distributions may have different variances for that user and one can renormalize the scores by the reciprocal of their variance. In this case, the weight matrix consists of r distinct columns, one for each

[2]Personal communication with Russell Impagliazzo and Ryan Williams.
[3]Personal communication with Lijie Chen and Aviad Rubinstein.

aspect, each copied n/r times, where n/r is the total number of movies. Each entry of a column is a variance for a certain user for that aspect. This naturally generalizes to other applications for which the columns can be clustered into r groups, such as in stochastic block models or more general latent space models [Cha12]. Also, in some of these applications, one would want a low rank nonnegative factorization, and we remark that we can achieve this below.

Suppose now that A has constant rank k. A consequence of Theorem 16.1.1, which we elaborate on more below, is that even if an adversary deletes up to $O(1)$ entries in each column of A in an arbitrary way, one can still recover a matrix $\widehat{A}$ of rank at most k which agrees with A on all of the remaining entries in $\text{poly}(n)$ time. This is a form of *adversarial* matrix completion, which was studied in [HKZ11, SW15]. In these works the authors had to make an incoherence assumption on the entries of A, which may not always hold, e.g., in the presence of outliers. Without this assumption the prior results would not be able to recover such an $\widehat{A}$ even if a single adversarially chosen entry was deleted in each column.

16.1.2 Other Results

Our techniques can be applied to weighted non-negative factorization, a problem that has been extensively studied both in the unweighted (see, e.g., [AGKM12, Moi13]) and weighted cases (see, e.g., [GVS03, GZD10, KG12, ZZGM15, YC09]). In this problem, one seeks *non-negative* matrices $U \in \mathbb{R}^{n\times k}$ and $V \in \mathbb{R}^{k\times n}$ for which

$$\forall i, j \text{ such that } W_{i,j} > 0,\ A_{i,j} = (U \cdot V)_{i,j},$$

where the unweighted case corresponds to $W_{i,j} = 1$ for all i and j. This problem naturally arises in applications such as topic modeling in which negative entries do not make sense. In a beautiful line of work [AGKM12, Moi13], an upper bound of $n^{O(k^2)}$ was established for the unweighted case. By combining their techniques with ours, we obtain the first results for the weighted case when the weight matrix W has rank at most r. We defer the details to the full version of the paper.

Finally, there is a simple bi-criteria approximation algorithm for weighted low rank approximation when the weight matrix has entries that are all either 0 or 1. In this case it is possible to obtain a rank-rk approximation to A in $\text{nnz}(A) + \text{nnz}(W) + n \cdot \text{poly}(rk/\epsilon)$ time with cost at most $(1+\epsilon)$ times the cost of the best rank-k approximation. Here r denotes the rank of the weight matrix. This has a better dependence on r and could be useful when one does not need to output a matrix of rank exactly k. This is given in the full version of the paper.

16.1.3 Our Techniques

To prove Theorem 16.1.1, we first prove a structural theorem about regression. Then our main new theme is what we call "guessing a sketched matrix".

Structural Regression Theorem Given any number t of multiple response regression instances, i.e., instances of the form $\min_{X^1,X^2,\cdots,X^t} \|A^iX^i - B^i\|_F^2$, where $A^1,\ldots,A^t$ and $B^1,\ldots,B^t$ are matrices and each A^i has rank at most k, if one is interested in simultaneously minimizing the sum of their costs, i.e., the objective function is $\min_{X^1,X^2,\cdots,X^t} \sum_{i=1}^t \|A^iX^i - B^i\|_F^2$, then one can choose a Gaussian matrix S with $O(k/\epsilon)$ rows and if one solves the problem $\min_{Y^1,Y^2,\cdots,Y^t} \sum_{i=1}^t \|SA^iY^i - SB^i\|_F^2$, then the minimizers $Y^1, Y^2, \cdots, Y^t$ for this latter problem satisfy $\sum_{i=1}^t \|A^iY^i - B^i\|_F^2 \leq (1+\epsilon) \min_{X^1,X^2,\cdots,X^t} \sum_{i=1}^t \|A^iX^i - B^i\|_F^2$ with high constant probability. Interestingly, the number of rows of S does not depend on the number t of regression instances, and is optimal already for $t = 1$ and when B^1 only has a single column [CW09]. This also generalizes affine embeddings in [CW13] in which $t = 1$ and B^1 may have multiple columns; we stress that the design matrices A^i may be different. The proof uses a novel observation that a Gaussian S is a *subspace embedding on average over i*. This part uses a tail bound from [CD05] for the condition number for a Gaussian matrix. Having this, we bootstrap the approximation to $(1 \pm \epsilon)$ using the approximate matrix product property of a Gaussian matrix.

Guessing a Sketched Matrix Given our structural result, the main new theme of this paper is to "guess a sketched matrix". Suppose one is given an optimization problem of the

form

$$p_1(x_1, \ldots, x_v) \geq 0, p_2(x_1, \ldots, x_v) \geq 0, \ldots, p_m(x_1, \ldots, x_v) \geq 0,$$

where each p_i is a polynomial of degree at most d, the $x_1, \ldots, x_v$ are indeterminates over the reals, and we are are interested in an assignment to $x_1, \ldots, x_v$ which simultaneously satisfies these c polynomial inequalities. Then this can be solved in time $(md)^{O(v)}$ using generic solvers [Ren92d, Ren92b, Ren92a, BPR96], and such techniques have been used in the context of database theory [EFW10], non-negative matrix factorization [AGKM12, Moi13], learning mixtures of Gaussians [LS15], computing approximate PSD factorizations [BDL16], and solving small-scale mixed-norm low rank approximation instances [CW15a]. There are two kinds of algorithms for semi-algebraic sets: the ones from [Ren92a, Ren92b, BPR96] are able to determine if a given sem-algebraic set is empty or not. The one from [Ren92d] is able to return a δ-approximate solution to a given semi-algebraic formulae by paying an extra factor of $\log(\frac{1}{\delta})$ in the running time. For weighted low-rank approximation, there are two ways to output the matrices. One is using the algorithm from [Ren92d] directly. Another option is to perform binary search using the algorithm from [Ren92a, Ren92b, BPR96] for the entries of $\widehat{A}_{ij}$ one by one.

Our main idea here is to use polynomial optimization for large-scale non-convex optimization by combining it directly with sketching. For example, suppose one is given the multiple response regression problem $\min_V \|UV - A\|_F^2$ in which the number of columns of U is small. The twist though, is that *both U and V are unknown*! Then UV is just a low rank approximation to A, and if we knew U we could solve the sketched optimization problem $\min_X \|SUV - SA\|_F^2$, for a random oblivious sketching matrix S, and our solution V would

be a good solution to the original problem. Since we do not know U, we instead choose a random S and create variables for $S \cdot U$, which is small, and also compute $S \cdot A$, which we know. We then solve a regression problem for V in terms of the variables that we created for $S \cdot U$. Given V, we can then plug it into the original regression problem and solve for U in terms of V which is in turn in terms of our variables for $S \cdot U$. Finally we can verify the solution by requiring that $\|UV - A\|_F^2$ is small, which is now a system in a small number of variables. This verification step is essential because our S only has a probabilistic guarantee that it works for a fixed U with good probability, but crucially, we know there *exists* a U for which it works, and so by doing the verification step we will find such a U. We note there are several issues with this approach which we discuss below.

While this may seem like an unnecessarily complicated way of doing standard low rank approximation, this idea proves crucial for weighted low rank approximation. In this case, using say, the rank constraint on the weight matrix W, and using our structural result on multiple instances of regression, we are able to choose a single sketching matrix S and create variables for only r regression problems, $SD_{W_1}U, \ldots, SD_{W_r}U$, where $D_{W_1}, \ldots, D_{W_r}$ are diagonal matrices with independent columns of W on each diagonal, and U is a fixed optimal solution. We can then try to express all regression solutions $\min_{X^i} \|D_{W_i}UX^i - D_{W_i}A^i\|_2^2$, for $i = 1, \ldots, n$ and where X^i and A^i are the i-th columns of X and A respectively, in terms of these variables, and hope to carry out the procedure above.

Dealing with Linear Dependencies At this point another obstacle arises which is that when the columns of a given $D_{W_i}U$ are not linearly independent, there is no way to write down the pseudoinverse of $D_{W_i}U$ in terms of the variables we have created. We also cannot afford

to create more than $r \cdot \text{poly}(k/\epsilon)$ variables, since our optimization procedure is exponential in this quantity, and so we cannot create new variables for each $i = 1, \ldots, n$. To get around this, we observe that there is a solution $U \cdot V$ for which for all i, the first $\min(|\text{supp}(D_{W_i})|, k)$ columns of U are linearly independent, where $\text{supp}(D_{W_i})$ denotes the set of non-zero entries of W_i, and further the solution cost of $U \cdot V$ is an arbitrarily small amount larger than that of the optimal cost. This follows by a simple perturbation argument applied to the optimal solution. This immediately gives an algorithm with additive error when we parameterize W by its rank.

In order to turn it into a relative error algorithm, we need a lower bound on the cost assuming that the cost is non-zero. The main idea here is that if we correctly guess which subsets of columns are linearly independent for the different matrices D_{W_i}, then we can set up a non-negative polynomial system and provided this system has non-zero cost, we can apply known lower bounds on the cost of polynomial optimazation problems as a function of the degrees, number of variables, number of constraints, and coefficient sizes [Bas14]. While this is not an algorithmic procedure, since we cannot afford to make guess for each D_{W_i} without spending exponential in n time, it suffices for lower bounding the cost. Given such a lower bound, the above perturbation argument can then be used to argue that we achieve relative error.

While this leads to our time bound in the case in which we parameterize the weight matrix by its rank, in the case in which we parameterize by the number of distinct columns of W, this is too slow. The issue is that we have at least n constraints to enforce, namely, that the first $\min(\text{supp}(W_i), k)$ columns of $SD_{W_i}U$ are linearly independent. This would lead to a running time of $n^{\text{poly}(rk/\epsilon)}$ as opposed to the $\text{poly}(n) \cdot 2^{\text{poly}(kr/\epsilon)}$ that we desire. We

notice though that when we have r distinct columns, there are only r constraints to enforce, one for each distinct column. These are "not equal" constraints but can be transformed to a single equality constraint of degree $\text{poly}(rk/\epsilon)$ by introducing a single auxiliary variable. While this ultimately enables us to write down all the entries of V using only a $\text{poly}(rk/\epsilon)$ number of variables, we are then faced with the task of writing down U in terms of such a V. Here a priori we could have many distinct *rows* in W, and may have n constraints to enforce. We observe though that since the entries of W are integers in $\{1, 2, \ldots, \text{poly}(n)\}$, if we round them to the nearest power of $1+\epsilon$, the solution cost changes only by a $(1+\epsilon)$-factor. Moreover, given that we have r distinct columns, for any row it is entirely specified on these r columns and after rounding, there are only $O((\log n)/\epsilon)^r$ choices for entries on these r columns, which upper bounds the number of distinct rows. This ultimately allows us to write down U in terms of V with only $O((\log n)/\epsilon)^r$ not equal constraints. This ultimately yields our improved running time when parameterizing W by its number of distinct columns.

Dealing with Rational Functions There is a subtle problem with the above arguments. When one solves for the i-th column V^i of V in terms of $SD_{W_i}U$, the entries of V^i are *rational functions* rather than polynomials, and we cannot afford to clear the denominators of V^i for every i without blowing up the degree of the polynomials to $\Omega(n)$, which would give a running time of $n^{\text{poly}(kr/\epsilon)}$. While this is not a problem when we parameterize the problem by the rank of W, since we anyway spend this amount of time, this is a problem when we parameterize by the number of distinct columns of W, in which we seek polynomial time even for super-constant r (and constant k/ϵ). Instead, we write V as $V' \cdot D$, where V' has entries which are polynomials, and D is a diagonal matrix whose entries are $\frac{1}{\det(U^\top D_{W_i} S^\top S D_{W_i} U)}$,

given by Cramer's rule. The entries of D are rational functions, and we would like to make them polynomials. Since W has at most r distinct columns, D has at most r distinct entries and we can create r new variables for the entries of D. However, when we try to solve for U in terms of V we face the same problem again: we can write U as $E \cdot U'$, where U' only has polynomial entries, but since we do not assume a small number of distinct rows of W, it follows that E could have n distinct entries $\frac{1}{\det(U^\top D_{W^i} S^\top S D_{W^i} U)}$ for $i = 1, \ldots, n$, where D_{W^i} is the diagonal matrix with the i-th row of W on the diagonal. As mentioned above, we fix this problem by rounding the entries of W to powers of $1 + \epsilon$, and then observing that the number of distinct rows of W can only be $O((\log n)/\epsilon)^r$ after rounding.

Other Methods Our techniques for weighted non-negative matrix factorization and tensor completion largely follow these ideas as well, where we combine our "guessing a sketched matrix" approach with techniques of Arora, Ge, Kannan and Moitra [AGKM12] and Moitra [Moi13]. Our bi-criteria solution directly follows from known sketching results.

16.2 Preliminaries

Notation Let $\mathbb{R}$ denote the real numbers, and $\mathbb{R}_{\geq 0}$ denote the nonnegative real numbers. Let $\|A\|$ (and sometimes $\|A\|_2$) denote the spectral norm of matrix A. Let $\|A\|_F^2 = \sum_{i,j} A_{i,j}^2$ denote the Frobenius norm of A. Let $W \circ A$ denote the entry-wise product of matrices W and A. Let $\|A\|_W^2 = \sum_{i,j} W_{i,j}^2 A_{i,j}^2$ denote the weighted Frobenius norm of A. Let $\text{nnz}(A)$ denote the number of nonzero entries of A. Let $\det(A)$ denote the determinant of a square matrix A. Let $A^\top$ denote the transpose of A. Let $A^\dagger$ denote the Moore-Penrose pseudoinverse of A. Let A^{-1} denote the inverse of a full rank square matrix A.

For the weight matrix W, we always use W_j to denote the j-th column vector of W, and W^i to denote the i-th row of W. Let D_{W_j} denote the diagonal matrix with entries from the column vector W_j and D_{W^i} denote the diagonal matrix with entries from the row vector W^i.

The following real algebraic geometry definitions are needed when proving a lower bound for the minimum nonzero cost of our problem. For a full discussion, we refer the reader to Bochnak *et al.* [BCR87]. Here we use the brief summary by Basu *et al.*[BPR05].

Definition 16.2.1 ([BPR05])**.** Let R be a real closed field.

Given $x = (x_1, \cdots, x_v) \in R^v, r \in R, r > 0$, we denote

$$B_v(x, r) = \{y \in R^v \mid \|y - x\|^2 < r^2\} \qquad \text{(open ball)},$$
$$\bar{B}_v(x, r) = \{y \in R^v \mid \|y - x\|^2 \leq r^2\} \qquad \text{(closed ball)}.$$

A set $S \subset R^v$ is open if it is the union of open balls, i.e., if every point of U is contained in an open ball contained in U.

A set $S \subset R^v$ is closed if its complement is open. Clearly, the arbitrary union of open sets is open and the arbitrary intersection of closed sets is closed.

Semi-algebraic sets are defined by a finite number of polynomial inequalities and equalities.

A semi-algebraic set has a finite number of connected components, each of which is semi-algebraic. Here, we use the topological definition of a connected component, which is a maximal connected subset (ordered by inclusion), where connected means it cannot be divided into two disjoint nonempty closed sets.

A closed and bounded semi-algebraic set is compact.

A semi-algebraic set $S \subset R^v$ is semi-algebraically connected if S is not the disjoint union of two non-empty semi-algebraic sets that are both closed in S. Or, equivalently, S does not contain a non-empty semi-algebraic strict subset which is both open and closed in S.

A semi-algebraically connected component of a semi-algebraic set S is a maximal semi-algebraically connected subset of S.

Renegar [Ren92a, Ren92b] and Basu *et al.* [BPR96] independently provided an algorithm for the decision problem for the existential theory of the reals is to decide the truth or falsity of a sentence $(x_1, \cdots, x_v)F(f_1, \cdots, f_m)$ where F is a quantifier-free Boolean formula with atoms of the form $\text{sign}(f_i) = \sigma$ with $\sigma \in \{0, 1, -1\}$. Note that this problem is equivalent to deciding if a given semi-algebraic set is empty or not. Here we formally state that theorem. For a full discussion of algorithms in real algebraic geometry, we refer reader to [BPR05] and [Bas14].

Theorem 16.2.1 (Decision Problem [Ren92a, Ren92b, BPR96]). *Given a real polynomial system $P(x_1, x_2, \cdots, x_v)$ having v variables and m polynomial constraints*

$$f_i(x_1, x_2, \cdots, x_v)\Delta_i 0, \forall i \in [m],$$

where Δ_i is any of the "standard relations": $\{>, \geq, =, \neq, \leq, <\}$, let d denote the maximum degree of all the polynomial constraints and let H denote the maximum bitsize of the coefficients of all the polynomial constraints. Then in

$$(md)^{O(v)} \operatorname{poly}(H)$$

time one can determine if there exists a solution to the polynomial system P.

The key result we used for proving lower bound is the following bound on the minimum value attained by an integer polynomial restricted to a compact connected component of a basic closed semi-algebraic subset of $\mathbb{R}^v$ defined by polynomials with integer coefficients in terms of the degrees and the bitsizes of the coefficients of the polynomials involved.

Theorem 16.2.2 (Jeronimo, Perrucci and Tsigaridas [JPT13]). *Let $T = \{x \in \mathbb{R}^v \mid f_1(x) \geq 0, \cdots, f_\ell(x) \geq 0, f_{\ell+1}(x) = 0, \cdots, f_m(x) = 0\}$ be defined by polynomials $f_1, \cdots, f_m \in \mathbb{Z}[x_1, \cdots, x_v]$ with $n \geq 2$, degrees bounded by an even integer d and coefficients of absolute value at most H, and let C be a compact connected component of T. Let $g \in \mathbb{Z}[x_1, \cdots, x_v]$ be a polynomial of degree at most d and coefficients of absolute value bounded by H. Then, the minimum value that g takes over C is satisfies that if it is not zero, then its absolute value is greater than or equal to*

$$(2^{4-v/2}\widetilde{H}d^v)^{-v2^v d^v},$$

where $\widetilde{H} = \max\{H, 2v + 2m\}$.

While the above theorem involves notions from topology, we shall apply it in an elementary way. Namely, in our setting T will be bounded and so every connected component, which is by definition closed, will also be bounded and therefore compact. As the connected components partition T the theorem will just be applied to give a global minimum value of g on T provided that it is non-zero.

16.3 Multiple Regression Sketch

Theorem 16.3.1. *Let $A^1, \ldots, A^m \in \mathbb{R}^{n \times k}$ be m matrices of size $n \times k$. Let $b^1, \ldots, b^m \in \mathbb{R}^{n \times 1}$ be m column vectors of dimension n.*

For $1 \leq i \leq m$ denote:

$$x^i = \operatorname*{argmin}_{x \in \mathbb{R}^{k \times 1}} \left\| A^i x - b^i \right\|_2^2$$

the solution of the i-th regression problem.

Let $S \in \mathbb{R}^{t \times n}$ be a random matrix with i.i.d. Gaussian entries with zero mean and standard deviation $1/\sqrt{t}$. For $1 \leq i \leq m$ denote:

$$y^i = \operatorname*{argmin}_{y \in \mathbb{R}^{k \times 1}} \left\| SA^i y - Sb^i \right\|_2^2$$

the solution of the i-th regression problem in the sketch space.

We claim that for every $0 < \epsilon < 1/2$ one can set $t = O(k/\epsilon)$ such that:

$$\sum_{i=1}^{m} \left\| A^i y^i - b^i \right\|_2^2 \leq (1+\epsilon) \cdot \sum_{i=1}^{m} \left\| A^i x^i - b^i \right\|_2^2.$$

The rest of this section is devoted to the proof of this theorem.

For $1 \leq i \leq m$ we let $D^i \geq 1$ denote the smallest number such that for every $x \in \mathbb{R}^{k \times 1}$ and $\lambda \in \mathbb{R}$ one has:

$$\left\| S\left(A^i x + \lambda b^i\right) \right\|_2^2 \in \left[\frac{1}{D^i}; D^i \right] \cdot \left\| A^i x + \lambda b^i \right\|_2^2.$$

Claim 16.3.2. *For every i*

$$\left\| A^i y^i - b^i \right\|_2^2 \leq \left(D^i\right)^2 \cdot \left\| A^i x^i - b^i \right\|_2^2.$$

Proof. This follows from the definition of D^i. □

Claim 16.3.3. *One can set $t = O(k/\epsilon)$ such that for every i*

$$\Pr_S\left[D^i \geq 1.01\right] \leq 2^{-\Omega(1/\epsilon)}.$$

Proof. This follows from Theorem 2.1 from [Woo14b]. □

Claim 16.3.4. *One can set $t = O(k/\epsilon)$ such that for every i*

$$\mathop{\mathbb{E}}_S\left[\left\|A^i y^i - b^i\right\|_2^2 - \left\|A^i x^i - b^i\right\|_2^2 \;\middle|\; D^i \leq 1.01\right] \leq \epsilon \cdot \left\|A^i x^i - b^i\right\|_2^2.$$

Proof. This follows from the proofs of Theorem 2.8 and Theorem 2.16 from [Woo14b] (adapted to Gaussian matrices). □

Claim 16.3.5. *One can set $t = O(k/\epsilon)$ such that for every i*

$$\mathop{\mathbb{E}}_S\left[\left(D^i\right)^2 \;\middle|\; D^i \geq 1.01\right] = O(1).$$

Proof. One can see that D^i is polynomially related to the condition number of a random $O(k/\epsilon) \times (k+1)$ matrix with i.i.d. Gaussian entries; indeed it corresponds to the maximum distortion of S applied to the vectors in the column span of an $n \times (k+1)$ orthonormal matrix U whose columns span the space spanned by the columns of A^i together with b^i. By rotational invariance, $S \cdot U$ also has i.i.d. Gaussian entries. To understand the condition number one can invoke the main result from [CD05] which gives for all sufficiently large t: $\Pr_S\left[D^i \geq t\right] = \frac{1}{t^{\Theta(k/\epsilon)}}$. Thus,

$$\mathop{\mathbb{E}}_S\left[\left(D^i\right)^2 \;\middle|\; D_i \geq 1.01\right] \leq O(1) + \int_{1.01}^{\infty} \frac{t^2}{t^{\Theta(k/\epsilon)}}\, dt = O(1).$$

□

Having these Claims, let us complete the proof. We have for every $1 \leq i \leq m$:

$$\begin{aligned}
& \mathop{\mathbb{E}}_{S}\left[\left\|A^i y^i - b^i\right\|_2^2 - \left\|A^i x^i - b^i\right\|_2^2\right] \\
= & \Pr_S\left[D^i \geq 1.01\right] \cdot \mathop{\mathbb{E}}_{S}\left[\left\|A^i y^i - b^i\right\|_2^2 - \left\|A^i x^i - b^i\right\|_2^2 \;\middle|\; D^i \geq 1.01\right] \\
+ & \Pr_S\left[D^i \leq 1.01\right] \cdot \mathop{\mathbb{E}}_{S}\left[\left\|A^i y^i - b^i\right\|_2^2 - \left\|A^i x^i - b^i\right\|_2^2 \;\middle|\; D^i \leq 1.01\right] \\
\leq & 2^{-\Omega(1/\epsilon)} \cdot \mathop{\mathbb{E}}_{S}\left[\left(D^i\right)^2 - 1 \;\middle|\; D^i \geq 1.01\right] \cdot \left\|A^i x^i - b^i\right\|_2^2 \\
+ & \Pr_S\left[D^i \leq 1.01\right] \cdot \mathop{\mathbb{E}}_{S}\left[\left\|A^i y^i - b^i\right\|_2^2 - \left\|A^i x^i - b^i\right\|_2^2 \;\middle|\; D^i \leq 1.01\right] \\
\leq & 2^{-\Omega(1/\epsilon)} \cdot \mathop{\mathbb{E}}_{S}\left[\left(D^i\right)^2 - 1 \;\middle|\; D^i \geq 1.01\right] \cdot \left\|A^i x^i - b^i\right\|_2^2 \\
+ & \epsilon \cdot \left\|A^i x^i - b^i\right\|_2^2 \\
\leq & O(\epsilon) \cdot \left\|A^i x^i - b^i\right\|_2^2,
\end{aligned}$$

where the second step is by Claim 16.3.2 and Claim 16.3.3, the third step is by Claim 16.3.4, and the fourth step is by Claim 16.3.5.

Summing over i and applying the Markov's inequality, we are done.

While the above result is for Gaussian sketching matrices, one can also combine a Gaussian random matrix with a Count-Sketch matrix [CW13]. This way we are still getting $O(k/\epsilon)$ rows, but now one can perform a matrix-vector multiplication in time proportional to the sparsity of the vector plus $\text{poly}(k\widetilde{r}/\epsilon)$, where $\widetilde{r}$ is the dimension of the union of column spaces of A^i (which is at most km in the worst case, but is much smaller for our applications).

16.4 Additive Approximation

In this Section, to demonstrate the new technique, we prove the following theorem.

Theorem 16.4.1. *Given $A, W \in \mathbb{R}^n$, $1 \leq k \leq n$ and $0 < \epsilon, \tau < 0.1$ such that:*

- $\operatorname{rank}(W) = r$*;*
- *all the non-zero entries of A and W are multiples of $\delta > 0$;*
- *all the entries of A and W are at most $\Delta > 0$ in absolute value,*

one can output a number Λ in time $n^{O(k^2 r/\epsilon)} \cdot \log^{O(1)}(\frac{\Delta}{\delta\tau})$ such that $\mathrm{OPT} \leq \Lambda \leq (1+\epsilon)\,\mathrm{OPT} + \tau$, where

$$\mathrm{OPT} = \min_{U \in \mathbb{R}^{n\times k}, V \in \mathbb{R}^{k\times n}} \|(UV - A) \circ W\|_F^2.$$

We first assume that W has no zero entries; later, we will remove this assumption by being slightly more careful.

Lemma 16.4.2.

$$\mathrm{OPT} \leq \mathrm{poly}(n, \Delta)$$

Proof. Set U and V to be the zero matrices. □

Let us expand the objective function in two ways. On the one hand:

$$\left\|(UV - A) \circ W\right\|_F^2 = \sum_{i=1}^{n} \left\|U^i V D_{W^i} - A^i D_{W^i}\right\|_2^2. \tag{16.1}$$

On the other hand:

$$\left\|(UV - A) \circ W\right\|_F^2 = \sum_{j=1}^{n} \left\|D_{W_j} U V_j - D_{W_j} A_j\right\|_2^2. \tag{16.2}$$

We can sketch (16.1) and (16.2) using Gaussian matrices $S' \in \mathbb{R}^{n \times t}$ and $S'' \in \mathbb{R}^{t \times n}$ as follows:

$$\sum_{i=1}^{n} \left\|U^i V D_{W^i} S' - A^i D_{W^i} S'\right\|_2^2.$$

and

$$\sum_{j=1}^{n} \left\|S'' D_{W_j} U V_j - S'' D_{W_j} A_j\right\|_2^2.$$

Denote, for $1 \leq i \leq n$, $P^i := V D_{W^i} S'$ and for $1 \leq j \leq n$ denote $Q_j := S'' D_{W_j} U$.

The crucial observation is that we can encode all P^i's and Q_j's using linear functions of $2krt$ variables, since W has rank r, and we can represent its rows/columns as linear combinations of r fixed rows/columns.

For fixed P^i's we define:

$$\widehat{U} := \operatorname*{argmin}_{U \in \mathbb{R}^{n \times k}} \sum_{i=1}^{n} \left\|U^i P^i - A^i D_{W^i} S'\right\|_2^2.$$

Similarly, for fixed Q_j's we define:

$$\widehat{V} := \operatorname*{argmin}_{V \in \mathbb{R}^{k \times n}} \sum_{j=1}^{n} \left\|Q_j V_j - S'' D_{W_j} A_j\right\|_2^2.$$

Let us use $\left\|\left(\widehat{U}\widehat{V} - A\right) \circ W\right\|_F^2$ as a proxy for the objective function. We need to argue that we can, in fact, minimize the new objective function efficiently, and that it gives a good approximation to the original objective function, if $t = \Theta(k/\epsilon)$, with high probability.

Optimization We assume that all P^i's and Q_j's have the maximum rank k. Later we will show that, since W has no zero entries, this does not affect the quality of the solution found under this non-degeneracy constraint.

Assuming non-degeneracy of P^i's and Q_j's, we can express $\widehat{U}$ and $\widehat{V}$ as follows:

$$\widehat{U}^i = A^i D_{W^i} S'(P^i)^\top \left(P^i(P^i)^\top\right)^{-1}$$

and

$$\widehat{V}_j = \left(Q_j^\top Q_j\right)^{-1} Q_j^\top S'' D_{W_j} A_j. \tag{16.3}$$

Since the entries of P^i's and Q_j's are linear functions of $2krt$ variables, we can represent the entries of $\widehat{U}$ and $\widehat{V}$ as rational functions over $2krt$ variables and of degree $O(k)$ (we use Cramer's formula for that).

Finally, we can represent $\left\| \left(\widehat{U}\widehat{V} - A\right) \circ W \right\|_F^2$ as a rational function over $2krt$ variables of degree $O(kn)$.

We can minimize the objective function using the algorithm for checking the feasibility of a system of polynomial inequalities from Theorem 16.2.1, together with a binary search over the value of the objective function. Each iteration of the binary search takes time

$$(\#\text{degree of the polynomials})^{O(\#\text{variables})} \cdot \text{poly}(\text{input size}).$$

Since the degree is $O(nk)$, the number of variables is $O(rkt) = O(k^2 r/\epsilon)$, and the input size is $\text{poly}(n, \log(\Delta/\delta))$, the running time of a single iteration of the binary search is

$$n^{O(k^2 r/\epsilon)} \cdot \log^{O(1)}(\Delta/\delta).$$

Finally, to perform the binary search, we need $O(\log(n\Delta/\tau)/\epsilon)$ iterations to check for the existence of a solution with cost at most $(1+\epsilon)\,\mathrm{OPT}+\tau$ (assuming that sketching and non-degeneracy constraints on P^i's and Q_j's increase the cost to at most $(1+\epsilon)\,\mathrm{OPT}+\tau$, which we will show later), since, by Lemma 16.4.2, $\mathrm{OPT} \leq \mathrm{poly}(n, \Delta)$. The overall running time is thus: $n^{O(k^2 r/\epsilon)} \cdot \log^{O(1)}(\frac{\Delta}{\delta\tau})$.

Near-optimality Here we show that one can set $t = O(k/\epsilon)$ so that, with high probability,

$$\min_{P^i, Q_j} \left\| \left(\widehat{U}\widehat{V} - A\right) \circ W \right\|_F^2 \leq (1+\epsilon) \cdot \min_{U,V} \left\| (UV - A) \circ W \right\|_F^2 + \tau'. \tag{16.4}$$

for every $\tau' > 0$. This, together with the above discussion about the optimization procedure, concludes the analysis of the algorithm.

As such, (16.4) follows from Theorem 16.3.1. Indeed, if the optimal solution is U^*V^*, then set $Q_j := S'' D_{W_j} U^*$. Q_j may be degenerate, but, since W has no zero entries, we can perturb U^* by an arbitrarily small amount to make Q_j non-degenerate (with probability one over S''). Then, with high probability over S'', we have

$$\left\| \left(U^*\widehat{V} - A\right) \circ W \right\|_F^2 \leq (1+\epsilon) \cdot \left\| (U^*V^* - A) \circ W \right\|_F^2 + \tau' \tag{16.5}$$

for an arbitrarily small $\tau' > 0$. Similarly, we can set $P^i = \widehat{V} D_{W^i} S'$ (again, it can be degenerate, but the same argument as above for Q_j applies), which gives, with high probability over S',

$$\left\| \left(\widehat{U}\widehat{V} - A\right) \circ W \right\|_F^2 \leq (1+\epsilon) \cdot \left\| \left(U^*\widehat{V} - A\right) \circ W \right\|_F^2 + \tau' \tag{16.6}$$

for an arbitrarily small $\tau' > 0$.

Combining (16.5) and (16.6), we are done.

16.4.1 Handling Weight Matrices With Zero Entries

Here we prove the version of Theorem 16.4.1 for the case when W is allowed to have zero entries. Let us first see what breaks in the previous argument.

What does not work anymore is that (after a small perturbation) $Q_j = S'' D_{W_j} U$ and $P^i = V D_{W^i} S'$ can be assumed to have the maximum possible rank k. Nevertheless, we can assume that every Q_j has rank equal to

$$t_j = \min(k, \text{the number of non-zero entries of } W_j).$$

Moreover, we can assume that the first t_j columns of Q_j are linearly-independent. A similar argument applies to P^i's as well.

The above argument allows us to express $\widehat{U}$ and $\widehat{V}$ as before, but instead of Q_j we use the first t_j columns of Q_j (and, similarly for the P^i's).

16.5 Multiplicative Approximation

In order to get a genuine multiplicative $(1+\epsilon)$-approximation, we need to lower bound OPT–provided that it is not equal to zero–which would allow us to set $\tau \leq \epsilon \cdot \mathrm{OPT}$ in the algorithm from the previous section.

We do this for the following optimization problem:

$$\min_{\substack{U,V: \\ \|UV\|_F^2 \leq (\Delta/\delta)^{\mathrm{poly}(n)}}} \|(UV - A) \circ W\|_F^2.$$

Note that we assume $\|UV\|_F$ has an upper bound, as otherwise we cannot write down U and V using $\mathrm{poly}(n)$ bits.

Using the approach outlined above, one can write down a rational function $p(x_1, \ldots, x_l)/q(x_1, \ldots, x_l)$ such that:

- $l = O(k^2 r/\epsilon)$;
- for every x such that $q(x) \neq 0$, one has $p(x)/q(x) \geq \mathrm{OPT}$;
- for every $\tau' > 0$, there exists x^* such that $p(x^*)/q(x^*) \leq (1+\epsilon)\,\mathrm{OPT} + \tau'$;
- both p and q are homogeneous, and their degrees are $O(kn)$;
- the coefficients of p and q are integers with absolute values at most $(\Delta/\delta)^{\mathrm{poly}(n)}$;
- $q(x) = \prod_{i=1}^{2n} g_i^2(x)$, where every $g_i(x)$ is the determinant polynomial.

Only the fifth item needs an explanation. If sketch matrices S' and S'' were integer, then the last item would hold automatically (by scaling up all the coefficients). But, in

reality, S' and S'' are Gaussian matrices. Fortunately, one can show that it is possible to discretize them up to $\pm 1/\operatorname{poly}(n)$ so that the multiple regression theorem (Theorem 16.3.1) still goes through. Indeed, this just follows from the fact that discretization to $\pm 1/\operatorname{poly}(n)$ preserves condition number and subspace embeddings (since one argues about preserving lengths of unit vectors), and approximate matrix product properties used in that theorem.

Lower Bound We use the same way explained in section 16.4 to create variables, write down the system in a small number of variables, and also create some "$\neq 0$" constraints. It will generate $2n$ determinant polynomials, which are defined in the following way,

$$\begin{aligned} g_i(x) &= \det((SD_{W_i}U)^\top_{P_i}(SD_{W_i}U)_{P_i}), \forall i \in [n] \\ g_{i+n}(x) &= \det((VD_{W^i}S)^{Q_i}((VD_{W^i}S)^{Q_i}))^\top), \forall i \in [n] \end{aligned}$$

where P_i and Q_i are maximal linearly indepdent subsets. Then we can write down the following optimization problem,

$$\begin{aligned} \min_{x\in\mathbb{R}^l} \quad & p(x)/q(x) \\ s.t. \quad & g_i^2(x) \neq 0, \forall i \in [2n], \\ & q(x) = \prod_{i=1}^{2n} g_i^2(x) \end{aligned}$$

To lower bound $p(x)/q(x)$, let us introduce a new variable y. Lower bounding $p(x)/q(x)$ is equivalent to lower bounding $p(x)y$ subject to $q(x)y - 1 = 0$. By assumption $\|U\|_F^2, \|V\|_F^2 \leq (\Delta/\delta)^{\operatorname{poly}(n)}$[4], we know the upper bound of all the variables we created

[4]A priori, we know only that $\|UV\|_F^2$ is bounded. But we can get that each of the matrices is bounded by taking an optimal solution and orthonormalizing one of the matrices.

except for y. In order to give an upper bound for y, it suffices to show a lower bound for $q(x)$. By definition, $q(x)$ is the square of the product of all the determinant polynomials. Thus, for every determinant polynomial $g_i(x)$, we need to show that if $g_i^2(x)$ is nonzero, then it is at least something.

Define B to be an ℓ_2-ball with bounded radius, e.g.,

$$B = \left\{ x \in \mathbb{R}^l \;\middle|\; \sum_{i=1}^{l} x_i^2 \leq (\Delta/\delta)^{\mathrm{poly}(n)} \right\}.$$

By [BPR05], we know that B is a closed and bounded semi-algebraic set. Thus B is also compact. Let x^* denote the optimal solution of the original problem $\min_{x\in\mathbb{R}^l} g_i^2(x)$ when all variables are bounded. Because the radius of the ball B is large enough, $x^* \in B$. Define $T_1 = \{x \in \mathbb{R}^l | g_i(x) \geq 0\}$ and let $T = T_1 \cap B$. By definition (see [BPR05]), T_1 is a basic closed semi-algebraic set. Thus, the intersection of T_1 and B is a semi-algebraic set with a finite number of connected components. Because B is compact and T_1 is closed, each of these connected components is compact. There must exist one compact connected component C which contains the optimal soltuion x^*. Applying Theorem 16.2.2 on system $\{T, C, g_i^2(x)\}$, we conclude that if $g_i^2(x)$ is not zero, then it is at least

$$\begin{aligned} \left((\Delta/\delta)^{\mathrm{poly}(n)}\right)^{-k^{O(l)}} &= (\Delta/\delta)^{-\mathrm{poly}(n)2^{\widetilde{O}(l)}} \\ &= (\Delta/\delta)^{-\mathrm{poly}(n)} \end{aligned}$$

which immediately gives us an upper bound for y,

$$y \leq ((\Delta/\delta)^{\mathrm{poly}(n)})^n = (\Delta/\delta)^{\mathrm{poly}(n)}.$$

Now, we are able to show a lower bound for $p(x)y$. Define

$$T_1 = \left\{ x \in \mathbb{R}^l, y \in \mathbb{R} \;\middle|\; \prod_{i=1}^{m} g_i^2(x) y - 1 = 0 \right\}.$$

Define B to be a bounded ball over $l+1$ variables,

$$B = \left\{ (x, y) \in \mathbb{R}^{l+1} \;\middle|\; \sum_{i=1}^{l} x_i^2 + y^2 \leq (\Delta/\delta)^{\mathrm{poly}(n)} \right\}.$$

By [BPR05], B is a closed and bounded semi-algebraic set. Thus B is also compact. Define $T = T_1 \cap B$. Let (x^*, y^*) denote the optimal solution of $\min_{(x,y)\in T_1} p(x)y$, then (x^*, y^*) is also the optimal solution of $\min_{(x,y)\in T} p(x)y$, because all variables are bounded and the radius of the ball is large enough.

By definition (see [BPR05]), T_1 is a basic closed semi-algebraic set. Thus, the intersection of T_1 and B is a semi-algebraic set with a finite number of connected components. Because B is compact and T_1 is closed, each of the connected components is compact.

There must exist a compact connected component that contains the optimal solution (x^*, y^*). Let C denote that component. Applying Theorem 16.2.2 on system $\{T, C, p(x)y\}$, where the number of constraints is bounded by $O(1)$, the maximum coefficient of absolute value is bounded by $(\Delta/\delta)^{\mathrm{poly}(n)}$, the maximum degree is bounded by $O(nk)$, the number of variables is bounded by $l = O(rk^2/\epsilon)$, we conclude that if the minimum cost is not zero, then it is at least

$$((\Delta/\delta)^{\mathrm{poly}(n)})^{-n^{O(rk^2/\epsilon)}} = \exp\left(-n^{O(k^2 r/\epsilon)} \log^{O(1)}(\Delta/\delta)\right). \tag{16.7}$$

Hence, OPT is at least (16.7) as well.

Plugging $\tau \ll \epsilon \cdot$ (16.7) $\leq \epsilon\,\mathrm{OPT}$ into the algorithm from the previous section with an additional constraint $\|\widehat{U}\widehat{V}\|_F^2 \leq (\Delta/\delta)^{\mathrm{poly}(n)}$, we do binary search to narrow down the range of $[\Lambda^-, \Lambda^+]$ until we reach Λ. During the jth step of binary search, we use Theorem 16.2.1

to check if the following semi-algebraic set is empty or not,

$$S = \{x \in \mathbb{R}^l \mid p(x) \leq \Lambda_j^+ q(x), p(x) \geq \Lambda_j^- q(x), q(x) \neq 0\}$$

where Λ_1^- is initialized to be τ and Λ_1^+ is initialized to be $\text{poly}(n, \Delta)$. We obtain the following theorem.

Theorem 16.5.1. *Given $A, W \in \mathbb{R}^n$, $1 \leq k \leq n$ and $0 < \epsilon, \tau < 0.1$ such that:*

- $\text{rank}(W) = r$*;*
- *all the non-zero entries of A and W are multiples of $\delta > 0$;*
- *all the entries of A and W are at most $\Delta > 0$ in absolute value,*

one can output a number Λ in time $n^{O(k^2 r/\epsilon)} \cdot \log^{O(1)} \frac{\Delta}{\delta\tau}$ such that $\text{OPT} \leq \Lambda \leq (1+\epsilon)\,\text{OPT}$, where

$$\text{OPT} = \min_{\substack{U \in \mathbb{R}^{n\times k}, V \in \mathbb{R}^{k\times n} \\ \|UV\|_F^2 \leq \left(\frac{\Delta}{\delta}\right)^{\text{poly}(n)}}} \|(UV - A) \circ W\|_F^2.$$

16.6 Recovering the Solution Itself

Here we show how to recover an approximate solution, not only the value of OPT.

The idea is to recover the entries of U and V one by one and use the algorithm from the previous section for the corresponding decision problem. We initialize the semi-algebraic set to be

$$S = \{x \in \mathbb{R}^l \mid q(x) \neq 0, p(x) \leq \Lambda q(x)\}$$

We start by recovering the first entry of U. We perform the binary search to localize the entry within an interval of length δ', which takes $\mathrm{poly}(n) \cdot \log\left(\frac{\Delta}{\delta\delta'}\right)$ invocations of the decision algorithm. For each step of binary search, we use 16.2.1 to determine if the following semi-algebraic set S is empty or not,

$$S \cap \{U_{1,1}(x) \geq \widehat{U}^{-}_{1,1}, U_{1,1}(x) \leq \widehat{U}^{+}_{1,1}\}$$

After that, we declare the first entry of U to be any point in this interval. This changes the cost of the solution by at most $\delta' \cdot \left(\frac{\Delta}{\delta}\right)^{\mathrm{poly}(n)}$. Then, we add an equality constraint that fixes the entry of $\widehat{U}$ to this value, and add a new constraint into S permanently, e.g. $S \leftarrow S \cap \{U_{1,1}(x) = \widehat{U}_{1,1}\}$. Next, we repeat the same with the second entry of U and so on.

This allows us to recover a *solution* of cost at most $(1+\epsilon)\,\mathrm{OPT} + \tau$ in time

$$n^{O(k^2 r/\epsilon)} \cdot \log^{O(1)}(\Delta/(\delta\tau)).$$

16.7 Adversarial Matrix Completion

Here we prove the following theorem.

Theorem 16.7.1. *Let $B \in \mathbb{R}^{n \times n}$ be a rank-k matrix with entries that are multiples of $\delta > 0$ bounded by $\Delta > 0$.*

Let $1 \leq r \leq n$ be an integer parameter.

Let C be an $n \times n$ matrix, where in every column there are at most r question marks *and other entries are equal to the corresponding entries of B.*

Then, there is an algorithm that:

- *receives C as an input;*
- *outputs a rank-k matrix that is τ-close to C in Frobenius norm (restricted to the entries that are not replaced with a question mark);*
- *has running time $n^{O(k^2 r)} \cdot \log^{O(1)}\left(\frac{\Delta}{\delta\tau}\right)$.*

A naive attempt is to use the algorithm from the previous section with W equal to 0 for the missing entries and to 1 for the "surviving" entries. Unfortunately, setting W like this does not work, since W may not have small rank.

We fix it by proving the following lemma.

Lemma 16.7.2. *For every set system $z_1, z_2, \ldots, z_n \subseteq [n]$ with $|z_j| \leq r$ there exists a rank-$(2r+1)$ integer matrix W such that, for every $1 \leq i \leq n$, the entry in the i-th column and j-th row,*

$$W_i^j \begin{cases} = 0 & \text{if } j \in z_i \\ > 0 & \text{if } j \in [n] \backslash z_i \end{cases}$$

Moreover, all the entries of W are bounded by $n^{O(r)}$ in absolute value.

Recall that for the i-th column of W, z_i denotes the set of row indices that have zero entry. For the i-th column of W, define a polynomial $p_i(x)$ such that

$$p_i(x) = \prod_{\ell \in z_i} (x-j)^2 = \sum_{\ell=1}^{2|z_i|+1} a_{i\ell} x^{\ell-1}$$

where all $a_{i\ell}$ are integers. Since $2|z_i|+1$ is at most $2r+1$, we can also think of $p_i(x)$ as a degree $2r$ polynomial,

$$p_i(x) = \sum_{\ell=1}^{2r+1} a_{i\ell} x^{\ell-1}$$

Then, we can use $a_{i\ell}$ to create a basis $T \in \mathbb{R}^{n \times (2r+1)}$ which has rank at most $2r+1$. Let T_ℓ^i denote the entry of the i-th row and ℓ-th column, then set $T_\ell^i = a_{i\ell}, \forall i \in [n], \forall \ell \in [2r+1]$. Let T_ℓ denote the ℓ-th column of matrix T, $\forall \ell \in [2r+1]$. To guarantee a linear combination of those $2r+1$ columns always outputs a nonnegative vector, we can just choose coefficients $1, x, x^2, \cdots, x^{2r}$. Let S denote a set of all possible vectors formed by the following linear combination,

$$T(x) = \sum_{\ell=1}^{2r+1} x^{\ell-1} T_\ell \in \mathbb{R}^{n \times 1}$$

Moreover, we have

$$\begin{aligned} T(x) &= \sum_{\ell=1}^{2r+1} x^{\ell-1} T_\ell = \sum_{\ell=1}^{2r+1} x^{\ell-1} \begin{bmatrix} a_{1\ell} & a_{2\ell} & \cdots & a_{n\ell} \end{bmatrix}^\top \\ &= \begin{bmatrix} \sum_{\ell=1}^{2r+1} x^{\ell-1} a_{1\ell} & \sum_{\ell=1}^{2r+1} x^{\ell-1} a_{2\ell} & \cdots & \sum_{\ell=1}^{2r+1} x^{\ell-1} a_{n\ell} \end{bmatrix}^\top \\ &= \begin{bmatrix} p_1(x) & p_2(x) & \cdots & p_n(x) \end{bmatrix}^\top, \end{aligned}$$

where the second equality follows by the definition of T_ℓ and the last equality follows by the definition of $p_i(x)$. Let $T^j(x)$ denote the jth entry of column vector $T(x) \in \mathbb{R}^{n \times 1}$. For any

column vector W_i, we assign $T(i)$ to it,

$$W_i \leftarrow T(i)$$

which has the following property: for every $1 \leq i \leq n$, the entry at the i-th column and $j-$th row satisfies

$$W_i^j = \begin{cases} T^j(i) = p_i(j) = 0 & \text{if } j \in z_i, \\ T^j(i) = p_i(j) > 0 & \text{if } j \in [n] \backslash z_i. \end{cases}$$

Note that for any column vector W_i, we know that $W_i \in S$ and $\text{rank}(S) = 2r + 1$. Thus, $\text{rank}(W) = 2r + 1$.

16.8 Few distinct columns

In this section we show how to improve the running time from $n^{\mathrm{poly}(k,r,1/\epsilon)}$ to $\mathrm{poly}(n) \cdot 2^{\mathrm{poly}(k,r,1/\epsilon)}$ under the following assumptions: (1) $\Delta = \mathrm{poly}(n)\delta$; and (2) $\|UV\|_F^2 \leq (\Delta/\delta)^{n^\gamma}$, for an arbitrarily small constant $\gamma > 0$. In Section 16.8.1, as a warmup we assume that W has r *distinct columns* and r *distinct rows*, while in Section 16.8.2 and 16.8.3 we give our main result assuming only that W has r *distinct columns*.

A crucial observation is that the term $n^{\mathrm{poly}(k,r,1/\epsilon)}$ shows up in the "rank-r" algorithm due to the fact that the degree of polynomials we optimize is $\Omega(n)$. The reason for this is that entries of $\widehat{U}$ and $\widehat{V}$ are rational functions with $\Omega(n)$ potentially different denominators. When we combine them in a single rational function that corresponds to $\|(\widehat{U}\widehat{V} - A) \circ W\|_F^2$, we get a denominator of degree $\Omega(n)$.

16.8.1 Few Distinct Rows and Columns

In this subsection, as a warmup we assume that W has r distinct rows *and* r distinct columns. Then, we get rid of the dependence on n in the degree. Indeed, now we have only $2r$ distinct denominators (w.l.o.g., assume the first r columns are distinct and the first r rows are distinct),

$$\begin{aligned} g_i(x) &= \det((SD_{W_i}U)_{P_i}^{\top}(SD_{W_i}U)_{P_i}), \forall i \in [r] \\ f_i(x) &= \det((VD_{W^i}S)^{Q_i}((VD_{W^i}S)^{Q_i}))^{\top}), \forall i \in [r] \end{aligned}$$

where P_i and Q_i are maximal linearly independent subsets. Then we can write down the following optimization problem,

$$\begin{aligned} \min_{x \in \mathbb{R}^l} \quad & p(x)/q(x) \\ s.t. \quad & g_i^2(x) \neq 0, f_i^2(x) \neq 0, \forall i \in [r], \\ & q(x) = \prod_{i=1}^{r} g_i^2(x) f_i^2(x) \end{aligned}$$

where $q(x)$ has degree $O(rk)$, the maximum coefficient in absolute value is $(\Delta/\delta)^{O(rkn^{\gamma})}$, and the number of variables $O(rk^2/\epsilon)$. Using the same argument as in the rank-r case and applying Theorem 16.2.2, we can achieve the following minimum nonzero cost: $(\Delta/\delta)^{-n^{\gamma}2^{\widetilde{O}(rk^2/\epsilon)}}$. Now, using the approach described in section 16.6, we can find the solution in time

$$(\mathrm{nnz}(A) + \mathrm{nnz}(W))n^{\gamma} + n2^{\widetilde{O}(rk^2/\epsilon)} \log^{O(1)}(\Delta/(\delta\tau))$$

within a multiplicative factor of $1+\epsilon$ and additive factor of τ.

One can adjust the lower bound on OPT accordingly, and conclude that an algorithm for approximating OPT within a multiplicative factor of $1+\epsilon$ can be done in time

$$(\mathrm{nnz}(A) + \mathrm{nnz}(W))n^{\gamma} + n2^{\widetilde{O}(rk^2/\epsilon)} \log^{O(1)}(\Delta/\delta)$$

where

$$\mathrm{OPT} = \min_{\substack{U,V \\ \|UV\|_F^2 \le (\Delta/\delta)^{n^\gamma}}} \|(UV - A) \circ W\|_F^2.$$

16.8.2 Few Distinct Columns When OPT $= 0$

This section, we explain how to find the solution to the weighted low rank approximation problem when W has at most r distinct columns and OPT $= 0$.

The key observation is that for any matrix A and $W \in \mathbb{R}_{\geq 0}^{n \times n}$, if there exists a solution of an $n \times k$ matrix U and a $k \times n$ matrix V such that,

$$\|W \circ (UV - A)\|_F^2 = \text{OPT},$$

then there exists another matrix $W' \in \{0,1\}^{n \times n}$ such that

$$\|W' \circ (UV - A)\|_F^2 = \text{OPT}$$

where $W'_{i,j} = 0$ if $W_{i,j} = 0$ and $W'_{i,j} = 1$ if $W_{i,j} > 0$.

The above observation states that modifying the weight matrix to be Boolean does not change the optimal cost. Since W has r distinct columns, now that it is Boolean it has at most 2^r distinct rows. Indeed, each row of W is completely determined after fixing its values on the r distinct columns, and there are only 2^r possibly fixings. W.l.o.g. we assume that the first r columns are distinct. Instead of having at most $2r$ distinct denominators as in Section 16.8.1, we have at most $r + 2^r$ distinct denominators. We create l variables for $\{SD_{W_1}U, \cdots, SD_{W_r}U\}$. Then we can write down $\widehat{V}$ in the following way,

$$\widehat{V}_j = (SD_{W_j}U)^\dagger \cdot SD_{W_j}A_j = \left(((SD_{W_j}U)_{P_i})^\top \cdot (SD_{W_j}U)_{P_i}\right)^{-1} \cdot ((SD_{W_j}U)_{P_i})^\top SD_{W_j}A_j$$

where P_i denotes a subset of rows. For all D_{W_j}s in the group Z_i, they share the same P_i, where for any $j \in Z_i$, $D_{W_j} = D_{W_i}$.

Thus to express $\widehat{V}$, there are only r distinct denominators $g_i(x)$ which are the determinants of $((SD_{W_j}U)_{P_i})^\top \cdot (SD_{W_j}U)_{P_i}$. In order to remove these denominators, we can create a new variable x_{l+i} and add a new equality constaint $g_i(x)x_{l+i} - 1 = 0$. Therefore, we do not have any denominators in $\widehat{V}$.

W.l.o.g., we assume that the first 2^r rows of W are distinct. Using $\widehat{V}$ we can write down $\widehat{U}$ in the following way,

$$\begin{aligned}\widehat{U}^j &= A^j D_{W^j}(\widehat{V}D_{W^j})^\dagger \\ &= A^j D_{W^j}((\widehat{V}D_{W^j})^{Q_i})^\top \left((\widehat{V}D_{W^j})^{Q_i}((\widehat{V}D_{W^j})^{Q_i})^\top\right)^{-1}\end{aligned}$$

where Q_i denotes a subset of columns, where all D_{W^j}s in the group Z_i' can share the same Q_i, and for any $j \in Z_i'$, $D_{W^j} = D_{W^i}$.

Thus, to express $\widehat{U}$, there are only 2^r distinct denominators $f_j(x)$ which are the determinants of the matrices $(\widehat{V}D_{W^j})^{Q_i}((\widehat{V}D_{W^j})^{Q_i})^\top$.

Finally, we can use a small number of variables to represent all the entries of $\widehat{U}$ and $\widehat{V}$. It allows us to write the following optmization problem,

$$\begin{aligned}\min_{x\in\mathbb{R}^{l+r}} \quad & p(x)/q(x) \\ s.t. \quad & g_i(x)x_{l+i} - 1 = 0, \forall i \in [r] \\ & f_j^2(x) \neq 0, \forall j \in [2^r] \\ & q(x) = \prod_{j=1}^{2^r} f_j^2(x)\end{aligned}$$

where $q(x)$ has degree $O(2^r k^2)$, maximum coefficients bounded in absolute value by $(\Delta/\delta)^{O(2^r k n^\gamma)}$, $l = O(rk^2/\epsilon)$ and the number of variables $O(rk^2/\epsilon)$. Using the same argument as for the

rank-r case and applying Theorem 16.2.2, we have the following minimum nonzero cost: $(\Delta/\delta)^{-n^\gamma 2^{\widetilde{O}(r^2k^2/\epsilon)}}$.

Using the approach described in section 16.6, we can find the solution achieving zero cost in time

$$(\mathrm{nnz}(A) + \mathrm{nnz}(W))n^\gamma + n2^{\widetilde{O}(r^2k^2/\epsilon)} \log^{O(1)}(\Delta/\delta)$$

16.8.3 Few Distinct Columns When OPT $\neq 0$

Lower Bound Let U, V denote the optimal solution A, W, which gives nonzero cost. We can modify W to a new matrix W' in the following sense, $W'_{i,j} = \delta$ if $W_{i,j} \neq 0$ and $W'_{i,j} = 0$ if $W_{i,j} = 0$. Then we know that

$$\|W' \circ (UV - A)\|_F^2 \leq \|W \circ (UV - A)\|_F^2 \neq 0$$

Note that if problem A, W' has a zero cost solution, then problem A, W also has a zero cost solution, which contradicts our assumption in this section. Thus problem A, W' does not have a zero cost solution. It follows from previous sections that the minimum nonzero cost of $\min_{U,V} \|W' \circ (UV - A)\|_F^2$ is at least $(\Delta/\delta)^{-n^\gamma 2^{\tilde{O}(r^2k^2/\epsilon)}}$. Let U', V' denote the optimal solution of problem A, W'. Thus we have

$$\|W \circ (UV - A)\|_F^2 \geq \|W' \circ (UV - A)\|_F^2 \geq \|W' \circ (U'V' - A)\|_F^2$$

which is at least $(\Delta/\delta)^{-n^\gamma 2^{\tilde{O}(r^2k^2/\epsilon)}}$.

Algorithm For notational convenience, let $\delta = 1$. Then each entry of the input weight matrix W' is in $\{0, 1, 2, \cdots, \text{poly}(n)\}$. For each entry $W'_{i,j}$, we round it to the smallest $(1+\epsilon)^x$ such that $W'_{i,j} \leq (1+\epsilon)^x$ where x is an integer. Because W' is bounded, the total number of choices for the power x is $O(\log(n)/\epsilon)$. Define W to be the matrix after rounding. Define OPT to be $\min_{U,V} \|W' \circ (UV - A)\|_F^2$. Then W has the following properties

1. W has r distinct columns,
2. W has $R := (\log(n)/\epsilon)^{O(r)}$ distinct rows,
3. $\text{OPT} \leq \min_{U,V} \|W \circ (UV - A)\|_F^2 \leq (1+\epsilon)^2 \,\text{OPT}$.

We prove the above three properties one by one.

The rounding is a deterministic procedure: if two values are the same in W', then they are the same in W. Hence, Property 1 holds.

To prove Property 2, take the r distinct columns $i_1, ..., i_r$. Then every other column can be labeled j in $\{i_1, ..., i_r\}$. If you fix the values on entries $i_1, ..., i_r$ in a row, this fixes the values on every other column. So the number of distinct rows is the number of fixings to the values on $i_1, ..., i_r$. Each entry has $\log_{1+\epsilon} \text{poly}(n) = O((\log n)/\epsilon)$ possibilities, so there are $O((\log n)/\epsilon)^r$ distinct rows.

Because of the rounding procedure, each $W'_{i,j}$ satisifies that $W'_{i,j} \leq W_{i,j} \leq (1+\epsilon)W'_{i,j}$, which implies Property 3.

We use the same approach as in Section 16.8.2 to create variables, write down the polynomial systems and add not equal constraints. Instead of having $r + 2^r$ distinct denominators, we have $r + R$, where $R = O((\log n)/\epsilon)^r$. We create $l = O(rk^2/\epsilon)$ variables for $\{SD_{W_1}U, \cdots, SD_{W_r}U\}$, then we can write down $\widehat{V}$ with r distinct denominators $g_i(x)$. Each $g_i(x)$ is non-zero in an optimal solution using the perturbation argument in Section 16.4. We create new variables x_{i+l} to remove the denominators $g_i(x)$. Then the entries of $\widehat{V}$ are polynomials as opposed to rational functions. Using $\widehat{V}$ we can express $\widehat{U}$ with $R = (\log(n)/\epsilon)^{O(r)}$ distinct denominators $f_i(x)$, which are also non-zero by using the perturbation argument in 16.4, and using that W has at most this number of distinct rows. Finally we can write the

following optimization problem,

$$\begin{aligned} \min_{x \in \mathbb{R}^{l+r}} \quad & p(x)/q(x) \\ s.t. \quad & g_i(x)x_{l+i} - 1 = 0, \forall i \in [r] \\ & f_j^2(x) \neq 0, \forall j \in [R] \\ & q(x) = \prod_{j=1}^{R} f_j^2(x) \end{aligned}$$

We then determine if there exists a solution to the above semi-algebraic set in time $(k^2R)^{O(rk^2/\epsilon)} = (\log(n)/\epsilon)^{O(r^2k^2/\epsilon)}$. Combining the binary search explained in section 16.5 and 16.6 with the lower bound we obtained, we can find the solution for the original problem in time

$$(\text{nnz}(A) + \text{nnz}(W))n^{\gamma} + n2^{\widetilde{O}(r^2k^2/\epsilon)} \log^{O(1)}(\Delta/\delta).$$

Note that there is no $\log\log n$ in the exponent $2^{\widetilde{O}(r^2k^2/\epsilon)}$ since either $r^2k^2/\epsilon = o(\log n/\log\log n)$, in which case this term is dominated by $n^{1+\gamma}$, or $\log(r^2k^2/\epsilon) = \Omega(\log\log n)$.

16.9 Hardness

The Maximum Edge Biclique problem [AMS11] is defined as:

Input: An n by n bipartite graph G.

Output: A k_1 by k_2 complete bipartite subgraph of G.

Objective Function: Maximize $k_1 \cdot k_2$.

We use the Maximum Edge Biclique problem under the R4SAT assumption in [GL04], which extends the previous work done by Feige [Fei02] under the R3SAT assumption. That hardness result [GL04] shows under the R4SAT assumption there exist two constants $\epsilon_1 > \epsilon_2 > 0$ such that no efficient algorithm is able to distinguish between bipartite graphs $G(U, V, E)$ with $|U| = |V| = n$ which have a clique of size $\geq (n/16)^2(1+\epsilon_1)$ and those in which all bipartite cliques are of size $\leq (n/16)^2(1+\epsilon_2)$. Using the reduction of [GL04], one can show there exists a constant c such that for any instance of R4SAT with $\widetilde{n}$ variables and $c\widetilde{n}$ clauses, the corresponding bipartite graph G created in [GL04] has at least tn^2 edges with large probability, for a constant t, e.g. $t = 9/10$.

To construct a weighted low-rank appoximation problem from a given bipartite graph, for a given bipartite graph $G(U, V, E)$, we generate the matrix A and W as in [GG11]: $A_{ij} = 1$ if edge $(U_i, V_j) \in E$, $A_{ij} = 0$ if edge $(U_i, V_j) \notin E$. $W_{ij} = 1$ if edge $(U_i, V_j) \in E$, $W_{ij} = \text{poly}(n)$ if edge $(U_i, V_j) \notin E$. One can then show if there exists a biclique in G such the number of remaining edges is at most $tn^2 - (n/16)^2(1+\epsilon_1)$, then the solution to $\min \|W \circ \widehat{A} - W \circ A\|_F^2$ has cost at most $tn^2 - (n/16)^2(1+\epsilon_1)$. On the other hand, if there does not exist a biclique that has more than $(n/16)^2(1+\epsilon_2)$ edges, which leads to the number of remaining edges being at least $tn^2 - (n/16)^2(1+\epsilon_2)$, then any solution to $\min \|W \circ \widehat{A} - W \circ A\|_F^2$ has cost at

least $tn^2 - (n/16)^2(1 + \epsilon_2)$.

16.10 Bicriteria Approximation

16.10.1 Rank r and Binary Weights W

This section, we explain how to get a polynomial time bicriteria algorithm when weighted matrix is boolean.

Lemma 16.10.1. *Given matrix $A \in \mathbb{R}^{n\times n}$ and rank-r weighted matrix $W \in \mathbb{R}^{n\times n}_{\geq 0}$. We can find some rank-$rk$ matrix $B \in \mathbb{R}^{n\times n}$ such that*

$$\|B - W \circ A\|_F^2 \leq (1+\epsilon) \min_{\mathrm{rank}(B')=rk} \|B' - W \circ A\|_F^2.$$

in $O(\mathrm{nnz}(A) + \mathrm{nnz}(W) + n \cdot \mathrm{poly}(rk/\epsilon))$ time.

Proof. It directly follows by the input sparsity low-rank approximation result in [CW13]. □

Lemma 16.10.2. *For any matrix $W, A \in \mathbb{R}^{n\times n}$ and $\mathrm{rank}(W) = r$, we have*

$$\min_{\mathrm{rank}(B')=rk} \|B' - W \circ A\|_F^2 \leq \min_{\mathrm{rank}(C')=k} \|W \circ C' - W \circ A\|_F^2.$$

Proof. For any rank-k matrix C', matrix $W \circ C'$ has rank at most rk. Then, for any rank-k matrix C', there must exists a rank-rk matrix B' such that

$$\|B' - W \circ A\|_F^2 \leq \|W \circ C' - W \circ A\|_F^2$$

□

Theorem 16.10.3. *Given two matrices $W \in \mathbb{F}_2^{n\times n}$ and $A \in \mathbb{R}^{n\times n}$, where $\mathrm{rank}(W) = r$. Define $A_k^* = \arg\min_{\mathrm{rank}(A')=k} \|A' - A\|_W$. We can find a matrix B that has rank rk and such that*

$$\|B - A\|_W^2 \leq (1+\epsilon)\|A_k^* - A\|_W^2$$

in $O(\mathrm{nnz}(A) + \mathrm{nnz}(W) + n \cdot \mathrm{poly}(kr/\epsilon))$ time.

Proof. Let matrix B denote the output of Lemma 16.10.1, let Ω denote the support set of weighted matrix W, $\Omega = \{(i,j)|W_{i,j} > 0\}$.

$$
\begin{aligned}
& \|B - A\|_W^2 \\
= \; & \|W \circ B - W \circ A\|_F^2 \\
= \; & \sum_{(i,j)\in\Omega} W_{ij}^2 (B_{ij} - A_{ij})^2 + \sum_{(i,j)\in[n]^2\setminus\Omega} W_{ij}^2 (B_{ij} - A_{ij})^2 \\
= \; & \sum_{(i,j)\in\Omega} 1 \cdot (B_{ij} - A_{ij})^2 + \sum_{(i,j)\in[n]^2\setminus\Omega} 0 \cdot (B_{ij} - A_{ij})^2 \\
\leq \; & \sum_{(i,j)\in\Omega} 1 \cdot (B_{ij} - A_{ij})^2 + \sum_{(i,j)\in[n]^2\setminus\Omega} 1 \cdot (B_{ij})^2 \\
= \; & \|B - W \circ A\|_F^2 \\
\leq \; & (1+\epsilon) \min_{\mathrm{rank}(B')=rk} \|B' - W \circ A\|_F^2 \text{ by Lemma 16.10.1} \\
\leq \; & (1+\epsilon) \min_{\mathrm{rank}(C')=k} \|W \circ C' - W \circ A\|_F^2 \text{ by Lemma 16.10.2}
\end{aligned}
$$

□

16.10.2 Modulo p Integer Weights W

Theorem 16.10.4. *Given two matrices $W \in \mathbb{F}_p^{n\times n}$ and $A \in \mathbb{R}^{n\times n}$, where $\mathrm{rank}(W) = r$. Define $A_k^* = \arg\min_{\mathrm{rank}(A')=k} \|A' - A\|_W$. We can find a matrix A' that has rank $p^r \cdot k$ and satisfies the following*

$$\|A' - A\|_W^2 \leq (1+\epsilon)\|A_k^* - A\|_W^2$$

in $O(\mathrm{nnz}(A) + \mathrm{nnz}(W) + p^r \cdot n \cdot \mathrm{poly}(k/\epsilon))$ time.

Proof. Since each entry of weight matrix W is chosen from $\{0, 1, \cdots, p-1\}$ and has rank r. Thus, for any given r linearly independent basis, weight matrix W has at most p^r distinct columns. For any column vector A_j in A_{Z_i}, its weighted column vector W_j is equal to W_i. Then we can reduce the original problem to

$$\sum_{i=1}^{g} \min_{\mathrm{rank}(A_i')=k} \|D_{W_i} A_i' - D_{W_i} A_{Z_i}\|_F^2 \tag{16.8}$$

where $g \leq p^r$, $A_{Z_i} \in \mathbb{R}^{n\times|Z_i|}$, $\sum_{i=1}^{g} |Z_i| = n$. Since these g problems are independent, we can just solve them in parallel. Let Ω_i denote the support set of rows of D_{W_i}, ignoring the zero rows of $D_{W_i} A_{Z_i}$, we can have a new matrix $B_i \in \mathbb{R}^{|\Omega_i|\times|Z_i|}$. Consider the following low rank approximation problem

$$\min_{\mathrm{rank}(B_i')=k} \|B_i' - B_i\|_F^2$$

By the input sparsity low-rank approximation result in [CW13], in time $O(\mathrm{nnz}(B)+\max(|\Omega_i|, |Z_i|)\cdot \mathrm{poly}(k/\epsilon))$, we can find some rank-$k$ matrix $B_i' \in \mathbb{R}^{|\Omega_i|\times|Z_i|}$ such that

$$\|B_i' - B\|_F^2 \leq (1+\epsilon) \min_{\mathrm{rank}(B_i^*)=k} \|B_i^* - B_i\|_F^2$$

Since D_{W_i} is diagonal matrix, we can recover a rank-k matrix $A_i' \in \mathbb{R}^{n\times|Z_i|}$ by using matrix B_i' and D_{W_i} in the follwoing way, for jth row of $n \times |Z_i|$ matrix A_i', if jth entry of W_i is zero,

then make jth row matrix A'_i zero everywhere; otherwise, copy the corresponding row from B'_i and rescale it by 1 / (jth entry of W_i). Then the $n \times |Z_i|$ matrix A'_i we obtained has the following property

$$\begin{aligned}
& \|D_{W_i} A'_i - D_{W_i} A_{Z_i}\|_F^2 \\
= \; & \|B'_i - B_i\|_F^2 \\
\leq \; & (1+\epsilon) \min_{\mathrm{rank}(B_i^*)=k} \|B_i^* - B_i\|_F^2 \\
\leq \; & (1+\epsilon) \min_{\mathrm{rank}(A_i^*)=k} \|D_{W_i} A_i^* - D_{W_i} A_{Z_i}\|_F^2 \text{ by Lemma 16.10.2}
\end{aligned}$$

Since all the g subproblems are independent, then we can solve them separately and merge all the A'_i to a matrix A' that has rank-$p^r k$. The entire procedure takes $O(\mathrm{nnz}(A)+\mathrm{nnz}(W)+ p^r \cdot n \cdot \mathrm{poly}(k/\epsilon))$. □

16.10.3 r Distinct Columns Weights W

Theorem 16.10.5. *Given two matrices $W \in \mathbb{R}^{n\times n}_{\geq 0}$ and $A \in \mathbb{R}^{n\times n}$, W has r distinct columns. Define $A^*_k = \underset{\mathrm{rank}(A')=k}{\arg\min} \|A' - A\|_W$. We can find a matrix $A' \in \mathbb{R}^{n\times n}$ that has rank $r \cdot k$ and satisfies the following*

$$\|A' - A\|^2_W \leq (1+\epsilon)\|A^*_k - A\|^2_W$$

in $O(\mathrm{nnz}(A) + \mathrm{nnz}(W) + nr \cdot \mathrm{poly}(k/\epsilon))$ time.

Proof. In previous proof, we have p^r distinct columns in W. But now, we only have r distinct columns in W. We still use the same algorithm to solve each subproblem. Since the total numbe of subproblems is r, thus the running time doesn't have exponential dependence for r any more. □

16.11 Weighted Nonnegative Matrix Factorization Problem

Arora, Ge, Moitra and Kannan [AGKM12] provided the first provably result for nonnegative matrix factorization. Later, Moitra [Mad13] improved it to almost optimal. This section explains the details of getting an algorithm for weighted nonnegative matrix factorization. We combine our new technique "guess the sketch" with previous work done by Moitra [Mad13] to write down a low degree polynomial system with some number of inequalities in terms of small number of variables. Next, we can use polynomial solver [Ren92a, Ren92b, Ren92c] to determine if there exists a nonnegative factorization of target matrix A under weighted matrix W. The slover takes $(md)^{O(v)}$ time to run, if m is the number of inequality constraints, d is the maximum degree of polynomials and v is the number of variables. We first show an algorithm that needs try $2^{k^{O(r)}}$ guesses, the running time of which has double exponential dependence in r. Then we expalin how to write down a slightly bigger polynomial systems without $2^{k^{O(r)}}$ guesses, which reduces the double exponential of r down to single exponential dependence.

Notations Let $W \in \mathbb{R}_{\geq 0}^{n \times n}$ denote the nonnegative weight matrix, let A denote the target $n \times n$ matrix, our goal is to factorize A into two low-dimensional nonnegative matrices $B \in \mathbb{R}_{\geq 0}^{n \times k}$ and $C \in \mathbb{R}_{\geq 0}^{k \times n}$. Let A_i denote the ith column of matrix A and A^j denote the jth row of matrix A. Let $A \circ W$ denote the entry-wise product of two matrices A and W, and let $u \circ v$ denote the entry-wise product of two vectors A and W. Let D_{lev} denote the leverage score matrix. Let D_{W_i} denote the diagonal matrix, where each entry on diagonal is from the vector W_i, similarly for D_{W^j}.

Definition 16.11.1. The nonnegative weighted rank $\mathrm{rank}^+(A)$ is defined to be the smallest

k such that A can be written as

$$A_{ij} = \begin{cases} B^i C_j = (BC)_{ij} & \text{if } W_{ij} > 0 \\ \text{arbitrary} & \text{otherwise} \end{cases} \tag{16.9}$$

where B and C are nonnegative and have dimension $n \times k$ and $k \times n$ respectively, W has rank r.

We use the notations $\text{aff}(A)$ and lexicographic ordering from [Mad13] directly, and extend the stable definition and addmissible definition into weighted version. The standard lexicographic ordering is usually for the subsets that have the same size, additionally, we assume the smaller size subset has early order than larger size subset.

Definition 16.11.2 (Affine Hull)**.** Given $n \times n$ matrix A and let $S \subseteq [n]$. Define

$$\text{aff}(A_S) = \{\sum_{i \in S} \alpha_i A_i | \forall i, \alpha_i \geq 0\}.$$

Definition 16.11.3 (Weighted Stable)**.** $\forall i \in [n]$, let $S_i \subseteq [k]$ be the lexicographically first admissible subset (of columns of $B \in \mathbb{R}^{n \times k}$) for A_i. $\forall j \in [n]$, , let $T^j \subseteq [k]$ be the lexicographically first admissible subset (of rows of $C \in \mathbb{R}^{k \times n}$) for A^j. We call $W \circ A = W \circ (BC)$ **weighted stable** if:

1. $\forall i \in [n]$, C_i is supported in $S_i \subseteq [k]$
2. $\forall j \in [n]$, B^j is supported in $T^j \subseteq [k]$

Definition 16.11.4 (Weighted Admissible)**.** Given a weighted vector $w \in \mathbb{R}^n_{\geq 0}$ and a vector $v \in \mathbb{R}^n$, let S denote a subset of columns of A, S is **weighted admissible** if there exists some $u \in \text{aff}(A_S)$ such that $w \circ v = w \circ u$.

Another interpretation of weighted admissible is thinking of we have $*$ entry in vector v instead of thinking there is antoher weighted vector. Given a vector $v \in \{\mathbb{R}, *\}^n$, let $q \subseteq [n]$ denote the subset of coordinates that contain $*$, we will call a subset S of columns of A admissible if there exists some $u \in \text{aff}(A_S)$ such that, $\forall i \notin q$, $v_i = u_i$.

Lemma 16.11.1. *Given matrices $A \in \mathbb{R}^{n\times n}$ and $W \in \mathbb{R}^{n\times n}_{\geq 0}$. If there exist some nonnegative inner-dimension k matrices B and C such that $W \circ A = W \circ (BC)$, then there exist $\widetilde{B}$ and $\widetilde{C}$ such that:*

1. *$W \circ A = W \circ (\widetilde{B}\widetilde{C})$, $\widetilde{B}$ and $\widetilde{C}$ are nonnegative and have inner-dimension k;*
2. *$W \circ A = W \circ (\widetilde{B}\widetilde{C})$ is weighted stable.*

Proof. In this proof, we modify the matrix A according to the zero position of matrix W, $A_{ij} = *$ if $W_{ij} = 0$. At the beginning, we have some B and C such that A and BC are entry-wise consistent except the $*$ positions. Then each update phase will alternately switching between B-updating phase and C-updating phase. In the C-updating phase, for each column vector $A_i \in \{\mathbb{R}, *\}^{n\times 1}$, let S_i be the lexicographically first subset of columns of B that is admissible for A_i. If $S_i \subseteq [k]$ is lexicographically (strictly) earlier than the support of column vector $C_i \in \mathbb{R}^{k\times 1}$, then we can find a column vector $\widetilde{C}_i \in \mathbb{R}^{k\times 1}_{\geq 0}$, $\text{supp}(\widetilde{C}_i) \subseteq S_i$ satisfies that A_i is entry-wise consistent with $B\widetilde{C}_i$ except $*$ position. Otherwise, we choose $\widetilde{C}_i = C_i$. Since, we don't change anything for matrix B and $C_{[n]\setminus i}$, then A is still entry-wise consistent with $B\widetilde{C}$ except the $*$ positions. The last step of this C-updating phase is updating C by $\widetilde{C}$. Similarly, we can define the B-updating phase. During the overall updating, (1) the lexicographically order of support monotonically decrease, if B^j or C_i got updated. (2) the

matrices B and C always satisfy that A is entry-wise consistent with BC except $*$ position, in other words. Thus, the overall updating phases will terminate with $W \circ A = W \circ (BC)$. $\square$

16.11.1 Combining with Our Techniques

Here we explain how to adapt our technique for solving the exact case to weighted non-negative matrix factorization. (Note that there exists a low-rank matrix A' to make the optimal cost 0, but it doesn't mean A is low-rank.) We first do leverage score sampling on the LHS of the problem, there exists some diagonal matrix D_{lev} respect to $\text{span}(D_{W_1}B, D_{W_2}B, \cdots, D_{W_n}B)$ such that

$$\min_{B,C} \sum_{i=1}^{n} \|D_{lev}D_{W_i}BC_i\|_2^2 \leq (1+\epsilon)\min_{B,C} \sum_{i=1}^{n} \|D_{W_i}BC_i\|_2^2$$

If we know matrix B, then we can compute the leverage sampling matrix deterministically and exactly. Here, we don't know the B, thus, we have to either guess those nonzero probabilities or creat variables for nonzero probabilities. Let t denote the number of nonzero probabilities in leverage score sampling matrix, then

Claim 16.11.2. *There are $O(n^t)$ leverage score sampling matrix we need to guess.*

Since D_{lev} is the leverage score sampling matrix that has $t = (kr/\epsilon^2)$ nonzero probability on diagonal. Thus, the nonzero position of D_{lev} will determine the set of rows of B. We create variables for the rows of B which are chosen by D_{lev}. There are t such rows, thus we need tr variables in total. To write down $D_{lev}D_{W_i}B$ by a small number of variables, we also need to create t variables for the nonzero probability of D_{lev}. Thus,

Claim 16.11.3. *$\forall i \in [n]$, $t \times k$ matrix $D_{lev}D_{W_i}B$ can expressed as $O(tr)$ variables, where each entry of that matrix is single monomial that has degree at most 2.*

In order to write down C_i by these $O(tr)$ small number of variables, we need to group C_i by looking at the zero-pattern of $D_{lev}D_{W_i}$. Let g denote the number of different

zero-patterns, let z_i denote the set of indices belong to the same group,

$$\min_{B,C} \sum_{i=1}^{n} \|D_{lev} D_{W_i} B C_i\|_2^2 = \min_{B,C} \sum_{\ell=1}^{g} \sum_{i \in z_\ell} \|D_{lev} D_{W_i} B C_i\|_2^2$$

By the similar result from previous section, there are only $\binom{t}{r} = k^r$ different zero-patterns. Let $D_{lev} D_{W'_\ell}$ denote the zero-pattern of group $z_\ell, \forall \ell \in [g]$. Let $\text{rank}(D_{lev} D_{W'_\ell}) = s_\ell$. For each group, we first guess s_ℓ which is the size of maximal linearly independent of rows of $D_{lev} D_{W'_\ell} B$, it has k possibilities. Second we need to guess the maximal linearly independent set of rows of $D_{lev} D_{W'_\ell} B$, let U_ℓ denote the subset of rows of $D_{lev} D_{W'_\ell} B$. Then we define $S_1, S_2, \cdots, S_p$ to be the full list of sets of s_ℓ linearly independent columns of $D_{lev} D_{W'_\ell} B$ in lexicographic order, where $p \leq \binom{k}{s_\ell} \leq 2^k$. By the definition of U_ℓ and S_i, we have the property that each $s_\ell \times s_\ell$ submatrix $(D_{lev} D_{W'_\ell} B)_{S_i}^{U_\ell}$ is full rank and invertible.

Claim 16.11.4. *If $D_{lev} D_{W_i}$ and $D_{lev} D_{W_j}$ belong to the same zero pattern group z_ℓ, then they must have the same rank. There are k possibilities for the rank of $D_{lev} D_{W'_\ell} B, \forall \ell \in [k^r]$. In total, there are $O(k^{k^r})$ guesses need to try.*

Claim 16.11.5. *If $D_{lev} D_{W_{i_1}}$ and $D_{lev} D_{W_{i_2}}$ belong to the same zero pattern group z_ℓ, then they must have the same U_ℓ. There are $r^{O(k)}$ possibilities for row subset U_ℓ of $D_{lev} D_{W'_\ell} B, \forall \ell \in [k^r]$. In total, there are $2^{k^{O(r)}}$ guesses need to try. Fix a guess of U_ℓ, there are at most 2^k possibilities for column subset S_j of $D_{lev} D_{W'_\ell} B, \forall \ell \in [k^r]$. In total, there are $2^{k^{O(r)}}$ guesses need to try.*

16.11.2 Few Entries Determine B and C

We extend Lemma 2.7 in [Mad13] to the the following weighted version.

Lemma 16.11.6. *For each column vector $A_i \in \mathbb{R}^{n\times 1}$, let $D_{lev}D_{W_i}$ belong to the group z_ℓ, then among the set of vectors*

$$\mathcal{S} = \left\{ \widehat{B}_1^{i,\ell}(D_{lev}D_{W_i}A_i)^{U_\ell}, \widehat{B}_2^{i,\ell}(D_{lev}D_{W_i}A_i)^{U_\ell}, \cdots, \widehat{B}_p^{i,\ell}(D_{lev}D_{W_i}A_i)^{U_\ell} \right\}$$

column vector $C_i \in \mathbb{R}^{k\times 1}$ is the unique vector with lexicographically minimal support among all nonnegative vectors in the above set. Note that $(D_{lev}D_{W_i}B)^{U_\ell}_{S_j} \in \mathbb{R}^{s_\ell \times s_\ell}$, $((D_{lev}D_{W_i}B)^{U_\ell}_{S_j})^\dagger \in \mathbb{R}^{s_\ell\times s_\ell}$, $\widehat{B}_j^{i,\ell} \in \mathbb{R}^{k\times s_\ell}, \forall j \in [p]$,

$$\widehat{B}_j^{i,\ell} = \underbrace{P_{\pi:[s_\ell]\to[k]}}_{k\times s_\ell} \cdot ((D_{lev}D_{W_i}B)^{U_\ell}_{S_j})^\dagger, \forall i \in [n]$$

$P_{\pi:[s]\to[k]}$ denotes a permutation matrix that has exact one 1 in each column, and there are s out of k rows has exact one 1, everywhere else are all 0.

Proof. We already shown that the weighted stable C_i belongs to the set $\mathcal{S}$. Thus, there must exist some $j^* \in [p]$ such that $C_i = \widehat{B}_{j^*}^{i,\ell}(D_{lev}D_{W_i}A_i)^{U_\ell}$. Then, for any $j \neq j^*$, consider the nonnegative vector $\widehat{B}_j^{i,\ell}(D_{lev}D_{W_i}A_i)^{U_\ell} = v$. We need to show that the support of v is lexicographically later than the support of C_i.

First, we claim that if $v \neq C_i$ then the support of C_i is not the same as the support of v. Let's prove it by getting a contradiction. Suppose $v \neq C_i$ and both of them have support R_i. Indeed R_i must correspond to a linearly independent set of columns of $D_{W_i}B$. By Claim 16.11.8, we obtain that $(D_{W_i}B(v-C_i))^{\Omega_i} = (\overrightarrow{0})^{\Omega_i}$. By $v - C_i \neq \overrightarrow{0}$ and support of $v - C_i$ contained in R_i, we get $(D_{W_i}B(v-C_i))^{\Omega_i} \neq (\overrightarrow{0})^{\Omega_i}$. Thus, we get a contradiction.

So the support C_i and v are not identical and one of these must be lexicographically earlier. Suppose (for contradiction) that the support of v is earlier. By Claim 16.11.7, we have that the support of C_i is a weighted admissible set of columns of B for A_i. This contradicts stability (because we could update C_i to v), and so we can conclude that the support of C_i is lexicographically earlier. □

It remains to prove Claim 16.11.7 and Claim 16.11.8, which are the weighted version of Lemma 2.8 and Lemma 2.9 in [Mad13].

Claim 16.11.7. *For each column vector $C_i \in \mathbb{R}^{k\times 1}$, it is contained in the set $\mathcal{S}$.*

Proof. Let R_i denote the support of column vector $C_i \in \mathbb{R}^{k\times 1}$. Then R_i must correspond to a linearly independent set of columns of B - otherwise we could find a nonnegative $\widetilde{C}_i$ whose support is a strict subset of R_i such that $W_i \circ (B\widetilde{C}_i) = W_i \circ A_i$, but this would violate the condition of stability.

Suppose $D_{lev}D_{W_i}$ belongs to zero pattern z_ℓ, let U_ℓ denote maximal linearly indepedent set of rows of $D_{lev}D_{W'_\ell}B$ and s_ℓ is the rank. Because the sets of linearly independent columns of $D_{lev}D_{W_i}B \in \mathbb{R}^{n\times k}$ are a matroid, there is a set $S_j \subset [k]$ of s_ℓ linearly independent columns of $D_{lev}D_{W_i}B$ for which $R_i \subset S_j$, hence

$$\begin{aligned}
& \widehat{B}_j^{i,\ell}(D_{lev}D_{W_i}A_i)^{U_\ell} \\
= \;& \widehat{B}_j^{i,\ell}(D_{lev}D_{W_i}BC_i)^{U_\ell} \text{ by } A_i = BC_i \\
= \;& \widehat{B}_j^{i,\ell}(D_{lev}D_{W_i}B)^{U_\ell}C_i \\
= \;& P_{\pi:[s_\ell]\to[k]} \cdot ((D_{lev}D_{W_i}B)_{S_j}^{U_\ell})^\dagger \cdot (D_{lev}D_{W_i}B)_{S_j}^{U_\ell} \cdot C_i \\
= \;& v
\end{aligned}$$

Note that $\widehat{B}_j^{i,\ell}$ is zero on rows outside the set S_j and support C_i is contained in S_j, then we have $C_i = v$ $\square$

Claim 16.11.8. *For each column vector $\widehat{B}_j^{i,\ell}(D_{lev}D_{W_i}A_i)^{U_\ell} \in \mathbb{R}^{k\times 1}$, we have*

$$W_i \circ (B\widehat{B}_j^{i,\ell}(D_{lev}D_{W_i}A_i)^{U_\ell}) = W_i \circ A_i$$

or equivalently

$$D_{W_i}(B\widehat{B}_j^{i,\ell}(D_{lev}D_{W_i}A_i)^{U_\ell}) = D_{W_i}A_i$$

Proof. Let Ω_i denote the support of W_i. Define $v = B\widehat{B}_j^{i,\ell}(D_{lev}D_{W_i}A_i)^{U_\ell,\Omega_i} \in \mathbb{R}^{n\times 1}$. First, we prove that $v^{U_\ell,\Omega_i} = A_i^{U_\ell,\Omega_i}$. Since $\widehat{B}_j^{i,\ell} \in \mathbb{R}^{k\times|U_\ell\cap\Omega_i|}$ is zero on rows outside the set S_j, we have

$$\underbrace{B}_{n\times k}\ \underbrace{\widehat{B}_j^{i,\ell}}_{k\times|U\cap\Omega_i|} = B_{S_j}(\widehat{B}_j^{i,\ell})^{S_j} = B_{S_j}((D_{lev}D_{W_i}B)_{S_j}^{U_\ell})^\dagger$$

Thus

$$\begin{aligned}
v^{U_\ell,\Omega_i} &= (B\widehat{B}_j^{i,\ell}(D_{lev}D_{W_i}A_i)^{U_\ell,\Omega_i})^{U_\ell,\Omega_i} \\
&= (B\widehat{B}_j^{i,\ell})^{U_\ell,\Omega_i}(D_{lev}D_{W_i}A_i)^{U_\ell,\Omega_i} \\
&= B^{U_\ell,\Omega_i}\widehat{B}_j^{i,\ell}(D_{lev}D_{W_i}A_i)^{U_\ell,\Omega_i} \\
&= B_{S_j}^{U_\ell,\Omega_i}((D_{lev}D_{W_i}B)_{S_j}^{U_\ell})^\dagger(D_{lev}D_{W_i}A_i)^{U_\ell,\Omega_i} \\
&= A_i^{U_\ell,\Omega_i}
\end{aligned}$$

Second, we prove that $v^{\overline{U_\ell},\Omega_i} = A_i^{\overline{U_\ell},\Omega_i}$. Since U_ℓ is the maximal linearly independent set of rows of $D_{lev}D_{W_i}B$ and D_{lev} preserves the rank of $D_{W_i}B$. For any $t \in \overline{U_\ell}\cap\Omega_i$, the row vector $B^t \in \mathbb{R}^{1\times k}$ can be written as a linear combination of rows in B in the set $U_\ell \cap \Omega_i$:

$$B^t = \sum_{t'\in U_\ell\cap\Omega_i} \alpha_{t,t'}B^{t'}$$

Note that $W_i \circ (BC_i) = W_i \circ A_i$ implies $(BC_i)^{\Omega_i} = (A_i)^{\Omega_i}$. Then we have for $t \in \overline{U_\ell} \cap \Omega_i$, $A_i^t = B^t C_i = \sum_{t' \in U_\ell \cap \Omega_i} \alpha_{t,t'} B^{t'} C_i = \sum_{t' \in U_\ell \cap \Omega_i} \alpha_{t,t'} A_i^{t'}$ and hence:

$$\begin{aligned} v^t &= (B\widehat{B}_j^{i,\ell}(D_{lev} D_{W_i} A_i)^{U_\ell, \Omega_i})^t \\ &= B^t \widehat{B}_j^{i,\ell}(D_{lev} D_{W_i} A_i)^{U_\ell, \Omega_i} \\ &= \sum_{t' \in U_\ell \cap \Omega_i} \alpha_{t,t'} B^{t'} \widehat{B}_j^{i,\ell}(D_{lev} D_{W_i} A_i)^{U_\ell, \Omega_i} \\ &= \sum_{t' \in U_\ell \cap \Omega_i} \alpha_{t,t'} v^{t'} \\ &= \sum_{t' \in U_\ell \cap \Omega_i} \alpha_{t,t'} A_i^{t'} \\ &= A_i^t \end{aligned}$$

□

We still need to show that leverage score sampling matrix doesn't destroy first lexicographically order property.

Claim 16.11.9. *If $\widetilde{C} \in \mathbb{R}^{k \times n}$ is the first lexicographically order solution of the original problem $A = BC$ under W, then it is also a solution to the problem $D_{lev} A = D_{lev} BC$ under W.*

Proof. Subspace embedding preserves the equality. For each $i \in [n]$, $D_{W_i} A_i = D_{W_i} B\widetilde{C}_i$ implies that $D_{lev} D_{W_i} A_i = D_{lev} D_{W_i} B\widetilde{C}_i$. □

Claim 16.11.10. *If $C' \in \mathbb{R}^{k \times n}$ is the first lexicographically order solution of the new problem $D_{lev} A = D_{lev} BC$ under W, then the C' has to be equal to $\widetilde{C}$.*

Proof. Let's prove it by contradiction. Suppose the order of C' is early than $\widetilde{C}$. For each $i \in [n]$, we know that $D_{lev}D_{W_i}A_i = D_{lev}D_{W_i}BC'_i$. Since we also know that $D_{lev}D_{W_i}A_i = D_{lev}D_{W_i}B\widetilde{C}_i$. Combing the above equation gives that $D_{lev}D_{W_i}BC'_i = D_{lev}D_{W_i}B\widetilde{C}_i$, since $C' \neq \widetilde{C}$, then there must exist one i such that $C'_i \neq \widetilde{C}_i$, which means $D_{W_i}BC'_i \neq D_{W_i}B\widetilde{C}_i$.

By leverage score sampling, if $D_{W_i}BC'_i \neq D_{W_i}B\widetilde{C}_i$, then $D_{lev}D_{W_i}BC'_i \neq D_{lev}D_{W_i}B\widetilde{C}_i$

□

16.11.3 A Semi-Algebraic Set with Double Exponential Depence in r

Here, we explain the details of constraints should be added into the polynomials system solver.

Constraints 1 Define first($\mathcal{S}$) to be the function that takes a collection of vectors as input and outputs the vector with lexicographically minimal support among all nonnegative vectors in $\mathcal{S}$. For each k-dimensional column vector $C_i, i \in [n]$, we need to add nonnegative constraints to it,

$$C_i \geq \overrightarrow{0}, \forall i \in [n]$$

where $C_i = \text{first}(\{\widehat{B}_1^{i,\ell}(D_{lev}D_{W_i}A_i)^{U_\ell}, \widehat{B}_2^{i,\ell}(D_{lev}D_{W_i}A_i)^{U_\ell}, \cdots, \widehat{B}_p^{i,\ell}(D_{lev}D_{W_i}A_i)^{U_\ell}\})$ and $D_{lev}D_{W_i}$ belong to the zero-pattern z_ℓ.

Similarly, we can choose a leverage score sampling matrix $D_{lev'}$ on the RHS of the original problem and create variables for $C^{\text{supp}(D_{lev'})}$. Thus, for each k-dimensional row vector $B^j, j \in [n]$, we also need to add nonnegative constraints to it,

$$B^j \geq \overrightarrow{0}, \forall j \in [n]$$

where $B^j = \text{first}(\{(A^jD_{W^j}D_{lev'})^{U_\ell}\widehat{C}_1^{j,\ell}, (A^jD_{W^j}D_{lev'})^{U_\ell}\widehat{C}_2^{j,\ell}, \cdots, (A^jD_{W^j}D_{lev'})^{U_\ell}\widehat{C}_p^{j,\ell}\})$ and $D_{W^j}D_{lev'}$ belong to the zero-pattern z_ℓ.

Constraints 2 Since we know the representation of C_i, B^j and the exact value of A_i^j, then we need to add n^2 equality constraints,

$$B^jC_i = A_i^j, \text{ if } W_i^j \neq 0, \forall i \in [n], \forall j \in [n]$$

where we need to clean up the denominator of B^j and C_i when writing down this constraint.

Constraints 3 We also need to write down the inequality constraints for the denominators of every $\widehat{B}_j^{i,\ell}$, by definition, the denominator is from $((D_{lev}D_{W_i}B)_{S_j}^{U_\ell})^\dagger$. To guarantee the denominator is nonzero, we need to add this constraint,

$$\text{the denominator of } ((D_{lev}D_{W_i}B)_{S_j}^{U_\ell})^\dagger \neq 0.$$

where the number of such constraints is

$$\#D_{W_i} \cdot \#S_j \leq n \cdot 2^k$$

which is same for the other side C.

Polynomial system Claim 2.12 in [Mad13] is able to write the explicit Boolean fucntion $\mathbb{P}$ for the unweighted case of nonnegative matrix factorization problem. Note that $\mathbb{P}$ is a function of sign constraints on polynomials. Here, we extend that the Boolean function to a weighted case of nonnegative matrix factorization.

$$\bigwedge_{\ell\in[g]}\bigwedge_{\ell'\in[g']}\left(\bigwedge_{i\in[z_\ell]}\bigwedge_{j\in[z_{\ell'}]}\left(\bigvee_{i_1\in[\binom{k}{s_\ell}]}\bigvee_{j_1\in[\binom{k}{\omega_{\ell'}}]}(f_1\wedge f_2\wedge f_3\wedge f_4\wedge f_5\wedge f_6\wedge f_7)\right)\right)$$

where

$$f_1 : \left((A^j D_{W^j} D_{lev'})_{V_{\ell'}} \widehat{C}_{j_1}^{j,\ell'} \cdot \widehat{B}_{i_1}^{i,\ell}(D_{lev}D_{W_i}A_i)^{U_\ell,} - A_j^i\right) = 0$$

$$f_2 := \left(\widehat{B}_{i_1}^{i,\ell}(D_{lev}D_{W_i}A_i)^{U_\ell}\right) \geq 0$$

$$f_3 := \left((A^j D_{W^j} D_{lev'})_{V_{\ell'}} \widehat{C}_{j_1}^{j,\ell'}\right) \geq 0$$

$$f_4 := \left(\widehat{B}_{i_1}^{i,\ell}(D_{lev}D_{W_i}A_i)^{U_\ell} \text{ is the first out of } \mathcal{S}^i\right)$$

$$f_5 := \left((A^j D_{W^j} D_{lev'})_{V_{\ell'}} \widehat{C}_{j_1}^{j,\ell'} \text{ is the first out of } \mathcal{T}^j\right)$$

$$f_6 := \left(\text{denominator polynomial of } \widehat{B}_{i_1}^{i,\ell}\right) \neq 0$$

$$f_7 := \left(\text{denominator polynomial of } \widehat{C}_{j_1}^{j,\ell'}\right) \neq 0$$

where the sign of the polynomial in each constraint can be recovered as a Boolean function of signs of degree at most poly(kr).

Theorem 16.11.11. *Given matrix $A \in \mathbb{R}^{n\times n}$ and rank-r weighted matrix $W \in \mathbb{R}_{\geq 0}^{n\times n}$. It takes $n^{O(rk^2)}2^{2^{O(r\log k)}}$ time to determine if there exists some matrices $B \in \mathbb{R}_{\geq 0}^{n\times k}$ and $C \in \mathbb{R}_{\geq 0}^{k\times n}$ such that $W \circ (BC) = W \circ A$, which means existing a weighted nonnegative matrix factorization.*

Proof. The final running time comes from two parts, (1) solving the polynomial system, it is known that the running time is

$$(\text{degree} \cdot \#\text{constraints})^{\#\text{variables}}$$

The number of variables is $O(tk) = O(rk^2)$. The degree is increasing by using Cramer rule to compute the inverse of full rank square matrix, the degree is at most poly(kr). The number of constraints is at most $n^2 \cdot 2^{\text{poly}(kr)}$. Thus, running time of polynomial system solver is at most $n^{O(rk^2)}2^{\text{poly}(kr)}$. (2) The number of guesses for leverage score sampling matrix is $n^{O(t)}$ and the number of guesses for each group's maximum linearly independent rows in B is $2^{k^{O(r)}}$. Thus, we need to rerun the solver for $n^{O(t)}2^{k^{O(r)}}$ different polynomial systems. In summary, the entire running is $n^{O(rk^2)}2^{k^{O(r)}}$ by plugging $t = O(kr)$. □

16.11.4 A Semi-Algebraic Set with Single Exponential Dependence in r

The intuition of improving double exponential dependence to single exponential dependence is, instead of guessing a possibility of rank and maximum linearly independent rows for each group at a time, we can write down all the possibilities into a slightly bigger polynomial system.

We define

$$\begin{aligned}
&\mathcal{S}^{i,s_\ell,p_{s_\ell}} = \\
&\{\widehat{B}^{i,\ell}_{1,1}(D_{lev}D_{W_i}A_i)^{U_{s_\ell,1}}, \cdots, \widehat{B}^{i,\ell}_{1,\binom{k}{s_\ell}}(D_{lev}D_{W_i}A_i)^{U_{s_\ell,1}} \\
&\widehat{B}^{i,\ell}_{2,1}(D_{lev}D_{W_i}A_i)^{U_{s_\ell,2}}, \cdots, \widehat{B}^{i,\ell}_{2,\binom{k}{s_\ell}}(D_{lev}D_{W_i}A_i)^{U_{s_\ell,2}}, \\
&\cdots, \\
&\widehat{B}^{i,\ell}_{p_{s_\ell},1}(D_{lev}D_{W_i}A_i)^{U_{s_\ell,p_{s_\ell}}}, \cdots, \widehat{B}^{i,\ell}_{p_{s_\ell},\binom{k}{s_\ell}}(D_{lev}D_{W_i}A_i)^{U_{s_\ell,p_{s_\ell}}}\}
\end{aligned}$$

where z_ℓ is corresponding to the zero-pattern of $D_{lev}D_{W_i}$, s_ℓ is the rank of $D_{lev}D_{W'_\ell}$, $U_{s_\ell,i}, \forall i \in [p_{s_\ell}]$ is a set of indices of s_ℓ rows of submatrix $D_{lev}D_{W'_\ell}$, $p_{s_\ell} = \binom{t}{s_\ell} \leq \binom{t}{k} = O(r^k)$. Then we define

$$\mathcal{S}^i = \bigcup_{s_\ell=1}^{k} \mathcal{S}^{i,s_\ell,p_{s_\ell}}$$

where the number of entries in set S^i is at most $k \cdot r^k \cdot 2^k$.

Then the Constraints 3 is slightly changing to the following,

Constraints 3' We also need to write down the inequality constraints for the denominators of every $\widehat{B}^{i,\ell}_{i_1,i_2}$, by definition, the denominator is from $((D_{lev}D_{W_i}B)^{U_{s_\ell,i_1}}_{S_{i_2}})^\dagger$. To guarantee the

denominator is nonzero, we need to add this constraint,

$$\text{the denominator of } ((D_{lev} D_{W_i} B)^{U_{s_\ell, i_1}}_{S_{i_2}})^\dagger \neq 0.$$

where the number of such constraints is

$$\#D_{W_i} \cdot \#s_\ell \cdot \#i_1 \cdot \#S_{i_2} \leq n \cdot k \cdot r^{O(k)} \cdot 2^k = n \cdot 2^{O(k \log r)}$$

which is same for the other side C.

Polynomial System Finally, we can write down the boolean function $\mathbb{P}$ over the polynomial inequality constraints,

$$\bigwedge_{\ell \in [g]} \bigwedge_{\ell' \in [g']} \left(\bigvee_{s_\ell \in [k]} \bigvee_{\omega_{\ell'} \in [k]} \bigvee_{i_1 \in [p_{s_\ell}]} \bigvee_{j_1 \in [q_{\omega_{\ell'}}]} \left(\bigwedge_{i \in [z_\ell]} \bigwedge_{j \in [z_{\ell'}]} \left(\bigvee_{i_2 \in [\binom{k}{s_\ell}]} \bigvee_{j_2 \in [\binom{k}{\omega_{\ell'}}]} (f_1 \wedge f_2 \wedge \cdots \wedge f_6 \wedge f_7) \right) \right) \right)$$

where

$$f_1 := \left((A^j D_{W^j} D_{lev'})_{V_{\omega_{\ell'}, j_1}} \widehat{C}^{j, \ell'}_{j_1, j_2} \cdot \widehat{B}^{i, \ell}_{i_1, i_2} (D_{lev} D_{W_i} A_i)^{U_{s_\ell}, i_1} - A^i_j \right) = 0$$

$$f_2 := \left(\widehat{B}^{i, \ell}_{i_1, i_2} (D_{lev} D_{W_i} A_i)^{U_{s_\ell}, i_1} \right) \geq 0$$

$$f_3 := \left((A^j D_{W^j} D_{lev'})_{V_{\omega_{\ell'}, j_1}} \widehat{C}^{j, \ell'}_{j_1, j_2} \right) \geq 0$$

$$f_4 := \left(\widehat{B}^{i, \ell}_{i_1, i_2} (D_{lev} D_{W_i} A_i)^{U_{s_\ell}, i_1} \text{ is the first out of } \mathfrak{S}^i \right)$$

$$f_5 := \left((A^j D_{W^j} D_{lev'})_{V_{\omega_{\ell'}, j_1}} \widehat{C}^{j, \ell'}_{j_1, j_2} \text{ is the first out of } \mathfrak{T}^j \right)$$

$$f_6 := \left(\text{denominator polynomial of } \widehat{B}^{i,\ell}_{i_1,i_2}\right) \neq 0$$

$$f_7 := \left(\text{denominator polynomial of } \widehat{C}^{j,\ell'}_{j_1,j_2}\right) \neq 0$$

Note that we only need to adding the functions f_1, f_2, f_3, f_4, f_5 into the this big polynomial system when $W_{ji} \neq 0$.

Theorem 16.11.12. *Given matrix $A \in \mathbb{R}^{n\times n}$ and rank-r weighted matrix $W \in \mathbb{R}^{n\times n}_{\geq 0}$. It takes $n^{O(rk^2)}2^{\widetilde{O}(rk^3)}$ time to determine if there exists some matrices $B \in \mathbb{R}^{n\times k}_{\geq 0}$ and $C \in \mathbb{R}^{k\times n}_{\geq 0}$ such that $W \circ (BC) = W \circ A$, which means existing a weighted nonnegative matrix factorization.*

Chapter 17

Entry-wise L1 Low Rank Approximation

We study the ℓ_1-low rank approximation problem, where for a given $n \times d$ matrix A and approximation factor $\alpha \geq 1$, the goal is to output a rank-k matrix $\widehat{A}$ for which

$$\|A - \widehat{A}\|_1 \leq \alpha \cdot \min_{\text{rank-}k \text{ matrices } A'} \|A - A'\|_1,$$

where for an $n \times d$ matrix C, we let $\|C\|_1 = \sum_{i=1}^{n} \sum_{j=1}^{d} |C_{i,j}|$. This error measure is known to be more robust than the Frobenius norm in the presence of outliers and is indicated in models where Gaussian assumptions on the noise may not apply. The problem was shown to be NP-hard by Gillis and Vavasis and a number of heuristics have been proposed. It was asked in multiple places if there are any approximation algorithms.

We give the first provable approximation algorithms for ℓ_1-low rank approximation, showing that it is possible to achieve approximation factor $\alpha = (\log d) \cdot \text{poly}(k)$ in $\text{nnz}(A) + (n + d)\,\text{poly}(k)$ time, where $\text{nnz}(A)$ denotes the number of non-zero entries of A. If k is constant, we further improve the approximation ratio to $O(1)$ with a $\text{poly}(nd)$-time algorithm. Under the Exponential Time Hypothesis, we show there is no $\text{poly}(nd)$-time algorithm achieving a $(1 + \frac{1}{\log^{1+\gamma}(nd)})$-approximation, for $\gamma > 0$ an arbitrarily small constant, even when $k = 1$.

17.1 Introduction

Two well-studied problems in numerical linear algebra are regression and low rank approximation. In regression, one is given an $n \times d$ matrix A, and an $n \times 1$ vector b, and one seeks an $x \in \mathbb{R}^d$ which minimizes $\|Ax - b\|$ under some norm. For example, for least squares regression one minimizes $\|Ax - b\|_2$. In low rank approximation, one is given an $n \times d$ matrix A, and one seeks a rank-k matrix $\widehat{A}$ which minimizes $\|A - \widehat{A}\|$ under some norm. For example, in Frobenius norm low rank approximation, one minimizes $\|A - \widehat{A}\|_F = \left(\sum_{i,j}(A_{i,j} - \widehat{A}_{i,j})^2\right)^{1/2}$. Algorithms for regression are often used as subroutines for low rank approximation. Indeed, one of the main insights of [DMM06c, DMM06b, Sar06, DMM08, CW09] was to use results for generalized least squares regression for Frobenius norm low rank approximation. Algorithms for ℓ_1-regression, in which one minimizes $\|Ax - b\|_1 = \sum_i |(Ax)_i - b_i|$, were also used [BD13, SW11] to fit a set of points to a hyperplane, which is a special case of entrywise ℓ_1-low rank approximation, the more general problem being to find a rank-k matrix $\widehat{A}$ minimizing $\sum_{i,j} |A_{i,j} - \widehat{A}_{i,j}|$.

Randomization and approximation were introduced to significantly speed up algorithms for these problems, resulting in algorithms achieving relative error approximation with high probability. Such algorithms are based on sketching and sampling techniques; we refer to [Woo14b] for a survey. For least squares regression, a sequence of work [Sar06, CW13, MM13, NN13a, LMP13, BDN15, Coh16a] shows how to achieve algorithms running in $\text{nnz}(A) + \text{poly}(d)$ time. For Frobenius norm low rank approximation, using the advances for regression this resulted in $\text{nnz}(A) + (n + d)\,\text{poly}(k)$ time algorithms. For ℓ_1-regression, sketching and sampling-based methods [Cla05, SW11, CDMI+13, CW13, MM13, LMP13, WZ13, CW15b, CP15] led to an $\text{nnz}(A) + \text{poly}(d)$ time algorithm.

Just like Frobenius norm low rank approximation is the analogue of least squares regression, entrywise ℓ_1-low rank approximation is the analogue of ℓ_1-regression. Despite this analogy, *no non-trivial upper bounds with provable guarantees* are known for ℓ_1-low rank approximation. Unlike Frobenius norm low rank approximation, which can be solved exactly using the singular value decomposition, no such algorithm or closed-form solution is known for ℓ_1-low rank approximation. Moreover, the problem was recently shown to be NP-hard [GV15]. A major open question is whether there exist approximation algorithms, sketching-based or otherwise, for ℓ_1-low rank approximation. Indeed, the question of obtaining betters algorithms was posed in section 6 of [GV15], in [Exc13], and as the second part of open question 2 in [Woo14b], among other places. The earlier question of NP-hardness was posed in Section 1.4 of [KV09], for which the question of obtaining approximation algorithms is a natural followup. The goal of our work is to answer this question.

We now formally define the ℓ_1-low rank approximation problem: we are given an $n \times d$ matrix A and approximation factor $\alpha \geq 1$, and we would like, with large constant probability, to output a rank-k matrix $\widehat{A}$ for which

$$\|A - \widehat{A}\|_1 \leq \alpha \cdot \min_{\text{rank-}k \text{ matrices } A'} \|A - A'\|_1,$$

where for an $n \times d$ matrix C, we let $\|C\|_1 = \sum_{i=1}^{n} \sum_{j=1}^{d} |C_{i,j}|$. This notion of low rank approximation has been proposed as a more robust alternative to Frobenius norm low rank approximation [KK03, KK05, KLC+15, Kwa08, ZLS+12, BJ12, BD13, BDB13, MXZZ13, MKP13, MKP14, MKCP16, PK16], and is sometimes referred to as ℓ_1-matrix factorization or robust PCA. ℓ_1-low rank approximation gives improved results over Frobenius norm low rank approximation since outliers are less exaggerated, as one does not square their contribution

in the objective. The outlier values are often erroneous values that are far away from the nominal data, appear only a few times in the data matrix, and would not appear again under normal system operation. These works also argue ℓ_1-low rank approximation can better handle missing data, is appropriate in noise models for which the noise is not Gaussian, e.g., it produces the maximum likelihood estimator for Laplacian noise [Gao08, KAC+08, VT01], and can be used in image processing to prevent image occlusion [YZD12].

To see that ℓ_1-low rank approximation and Frobenius norm low rank approximation can give very different results, consider the $n \times n$ matrix $A = \left[\begin{smallmatrix} n & 0 \\ 0 & B \end{smallmatrix}\right]$, where B is *any* $(n-1) \times (n-1)$ matrix with $\|B\|_F < n$. The best rank-1 approximation with Frobenius norm error is given by $\widehat{A} = n \cdot e_1 e_1^\top$, where e_1 is the first standard unit vector. Here $\widehat{A}$ ignores all but the first row and column of A, which may be undesirable in the case that this row and column represent an outlier. Note $\|A - \widehat{A}\|_1 = \|B\|_1$. If, for example, B is the all 1s matrix, then $\widehat{A} = [0, 0; 0, B]$ is a rank-1 approximation for which $\|A - \widehat{A}\|_1 = n$, and therefore this solution is a much better solution to the ℓ_1-low rank approximation problem than $n \cdot e_1 e_1^\top$, for which $\|A - n \cdot e_1 e_1^\top\|_1 = (n-1)^2$.

Despite the advantages of ℓ_1-low rank approximation, its main disadvantage is its computationally intractability. It is not rotationally invariant and most tools for Frobenius low rank approximation do not apply. To the best of our knowledge, all previous works only provide heuristics. Using that for an $n \times d$ matrix C, $\|C\|_F \leq \|C\|_1 \leq \sqrt{nd}\|C\|_F$, a Frobenius norm low rank approximation gives a $\sqrt{nd}$ approximation for ℓ_1-low rank approximation. A bit better is to use algorithms for low rank approximation with respect to the sum of distances, i.e., to find a rank-k matrix $\widehat{A}$ minimizing $\|A - \widehat{A}\|_{1,2}$, where for an $n \times d$ matrix C, $\|C\|_{1,2} = \sum_{i=1}^n \|C_i\|_2$, where C_i is the i-th row of C. A sequence of work

[DV07, FMSW10, FL11, SV12a, CW15a] shows how to obtain an $O(1)$-approximation to this problem in $\text{nnz}(A)+(n+d)\,\text{poly}(k)+\exp(k)$ time, and using that $\|C\|_{1,2} \leq \|C\|_1 \leq \sqrt{d}\|C\|_{1,2}$ results in an $O(\sqrt{d})$-approximation.

17.1.1 Our Results

We give the first efficient algorithms for ℓ_1-low rank approximation with provable approximation guarantees. By symmetry of the problem, we can assume $d \leq n$. We first give an algorithm which runs in $O(\text{nnz}(A)) + n \cdot \text{poly}(k)$ time and solves the ℓ_1-low rank approximation problem with approximation factor $(\log d) \cdot \text{poly}(k)$. This is an exponential improvement over the previous approximation factor of $O(\sqrt{d})$, provided k is not too large, and is polynomial time for every k. Moreover, provided $\text{nnz}(A) \geq n \cdot \text{poly}(k)$, our time is optimal up to a constant factor as any relative error algorithm must spend $\text{nnz}(A)$ time. We also give a hard instance for our algorithm ruling out $\frac{\log d}{k \log k} + k^{1/2-\gamma}$ approximation for arbitrarily small constant $\gamma > 0$, and hard instances for a general class of algorithms based on linear sketches, ruling out $k^{1/2-\gamma}$ approximation.

Via a different algorithm, we show how to achieve an $\widetilde{O}(k)$-approximation factor in $\text{poly}(n) d^{\widetilde{O}(k)} 2^{\widetilde{O}(k^2)}$ time. This is useful for constant k, for which it gives an $O(1)$-approximation in $\text{poly}(n)$ time, improving the $O(\log d)$-approximation for constant k of our earlier algorithm. The approximation ratio of this algorithm, although $O(1)$ for constant k, depends on k. We also show one can find a rank-$2k$ matrix $\widehat{A}$ in $\text{poly}(n)$ time for constant k for which $\|A - \widehat{A}\|_1 \leq C \min_{\text{rank-}k \text{ matrices } A'} \|A - A'\|_1$, where $C > 1$ is an absolute constant independent of k. We refer to this as a bicriteria algorithm. Finally, one can output a rank-k matrix $\widehat{A}$, instead of a rank-$2k$ matrix $\widehat{A}$, in $\text{poly}(n)$ time with the same absolute constant C approximation factor, under an additional assumption that the entries of $\widehat{A}$ are integers in the range $\{-b, -b+1, \ldots, b\}$ for an integer $b \leq \text{poly}(n)$. Unlike our previous algorithms, this very last algorithm has a bit complexity assumption, and runs in $\text{poly}(b)$ time instead of $\text{poly}(\log(b))$ time.

We also give a number of results for variants of ℓ_1-low rank approximation which are studied for Frobenius norm low rank approximation; prior to our work nothing was known about these problems.

Column Subset Selection and CUR Decomposition: In the column subset selection problem, one seeks a small subset C of columns of A for which there is a matrix X for which $\|CX - A\|$ is small, under some norm. The matrix CX provides a low rank approximation to A which is often more interpretable, since it stores actual columns of A, preserves sparsity, etc. These have been extensively studied when the norm is the Frobenius or operator norm (see, e.g., [BMD09, DR10, BDM11] and the references therein). We initiate the study of this problem with respect to the ℓ_1-norm. We first prove an existence result, namely, that there exist matrices A for which any subset C of $\mathrm{poly}(k)$ columns satisfies $\min_X \|CX - A\|_1 \geq k^{1/2-\gamma} \cdot \min_{\text{rank-}k \text{ matrices } A'} \|A - A'\|_1$, where $\gamma > 0$ is an arbitrarily small constant. This result is in stark contrast to the Frobenius norm for which for every matrix there exist $O(\frac{k}{\epsilon})$ columns for which the approximation factor is $1+\epsilon$. We also show that our bound is nearly optimal in this regime, by showing for every matrix there exists a subset of $O(k \log k)$ columns providing an $O(\sqrt{k \log k})$-approximation. One can find such columns in $\mathrm{poly}(n) d^{O(k \log k)}$ time by enumerating and evaluating the cost of each subset. Although this is exponential in k, we show it is possible to find $O(k \log k)$ columns providing an $O(\sqrt{k \log k} \log d)$-approximation in polynomial time for every k.

We extend these results to the CUR decomposition problem (see, e.g., [DMM08, BW14]), in which one seeks a factorization CUR for which C is a subset of columns of A, R is a subset of rows of A, and $\|CUR - A\|$ is as small as possible. In the case of Frobenius norm, one can choose $O(k/\epsilon)$ columns and rows, have $\mathrm{rank}(U) = k$, have $\|CUR - A\|_F$ be at most

$(1+\epsilon)$ times the optimal cost, and find the factorization in $\text{nnz}(A)\log n + n \cdot \text{poly}((\log n)k/\epsilon)$ time [BW14]. Using our column subset selection results, we give an $\text{nnz}(A) + n \cdot \text{poly}(k)$ time algorithm choosing $O(k \log k)$ columns and rows, for which $\text{rank}(U) = k$, and for which $\|CUR - A\|_1$ is $\text{poly}(k) \log d$ times the cost of any rank-k approximation to A.

17.1.2 Technical Overview

Initial Algorithm and Optimizations: Let A^* be a rank-k matrix for which $\|A - A^*\|_1 = \min_{\text{rank-}k \text{ matrices } A'} \|A - A'\|_1$. Let $A^* = U^*V^*$ be a factorization for which U^* is $n \times k$ and V^* is $k \times d$. Suppose we somehow knew U^* and consider the multi-response ℓ_1-regression problem $\min_V \|U^*V - A\|_1 = \min_V \sum_{i=1}^d \|U^*V_i - A_i\|_1$, where V_i, A_i denote the i-th columns of V and A, respectively. We could solve this with linear programming though this is not helpful for our argument here.

Instead, inspired by recent advances in sketching for linear algebra (see, e.g., [Woo14b] for a survey), we could choose a random matrix S and solve $\min_V \|SU^*V - SA\|_1 = \min_V \sum_{i=1}^d \|(SU^*)V_i - SA_i\|_1$. If V is an approximate minimizer of the latter problem, we could hope V is an approximate minimizer of the former problem. If also S has a small number t of rows, then we could instead solve $\min_V \sum_{i=1}^d \|(SU^*)V_i - SA_i\|_2$, that is, minimize the sum of Euclidean norms rather than the sum of ℓ_1-norms. Since $t^{-1/2}\|(SU^*)V_i - SA_i\|_1 \leq \|(SU^*)V_i - SA_i\|_2 \leq \|(SU^*)V_i - SA_i\|_1$, we would obtain a $\sqrt{t}$-approximation to the problem $\min_V \|SU^*V - SA\|_1$. A crucial observation is that the solution to $\min_V \sum_{i=1}^d \|(SU^*)V_i - SA_i\|_2$ is given by $V = (SU^*)^\dagger SA$, which implies that V is in the row span of SA. If also S were *oblivious* to U^*, then we could compute SA without ever knowing U^*. Having a low-dimensional space containing a good solution in its span is our starting point.

For this to work, we need a distribution on oblivious matrices S with a small number of rows, for which an approximate minimizer V to $\min_V \|SU^*V - SA\|_1$ is also an approximate minimizer to $\min_V \|U^*V - A\|_1$. It is *unknown* if there exists a distribution on S with this property. What is known is that if S has $O(d \log d)$ rows, then the Lewis weights (see, e.g., [CP15] and references therein) of the concatenated matrix $[U^*, A]$ give a distribution for

which the optimal V for the latter problem is a $(1+\epsilon)$-approximation to the former problem; see also earlier work on ℓ_1-leverage scores [Cla05, DDH+09] which have poly(d) rows and the same $(1+\epsilon)$-approximation guarantee. Such distributions are not helpful here as (1) they are not oblivious, and (2) the number $O(d \log d)$ of rows gives an $O(\sqrt{d \log d})$ approximation factor, which is much larger than what we want.

There are a few oblivious distributions S which are useful for *single-response* ℓ_1-regression $\min \|U^*v - a\|_1$ for column vectors $v, a \in \mathbb{R}^k$ [SW11, CDMI+13, WZ13]. In particular, if S is an $O(k \log k) \times n$ matrix of i.i.d. Cauchy random variables, then the solution v to $\min \|SU^*v - Sa\|_1$ is an $O(k \log k)$-approximation to $\min \|U^*v - a\|_1$ [SW11]. The important property of Cauchy random variables is that if X and Y are independent Cauchy random variables, then $\alpha X + \beta Y$ is distributed as a Cauchy random variable times $|\alpha| + |\beta|$, for any scalars $\alpha, \beta \in \mathbb{R}$. The $O(k \log k)$ approximation arises because all possible regression solutions are in the column span of $[U^*, a]$ which is $(k+1)$-dimensional, and the sketch S gives an approximation factor of $O(k \log k)$ to preserve every vector norm in this subspace. If we instead had a multi-response regression problem $\min \|SU^*V^* - SA\|_1$ the dimension of the column span of $[U^*, A]$ would be $d + k$, and this approach would give an $O(d \log d)$-approximation. Unlike Frobenius norm multi-response regression $\min \|SU^*V^* - SA\|_F$, which can be bounded if S is a subspace embedding for U^* and satisfies an approximate matrix product theorem [Sar06], there is no convenient linear-algebraic analogue for the ℓ_1-norm.

We first note that since regression is a minimization problem, to obtain an $O(\alpha)$-approximation by solving the sketched version of the problem, it suffices that (1) for the optimal V^*, we have $\|SU^*V^* - SA\|_1 \leq O(\alpha)\|U^*V^* - A\|_1$, and (2) for all V, we have $\|SU^*V - SA\|_1 \geq \Omega(1) \cdot \|U^*V - A\|_1$.

We show (1) holds for $\alpha = O(\log d)$ and any number of rows of S. Our analysis follows by truncating the Cauchy random variables $(SU^*V_j^* - SA_j)_i$ for $i \in [O(k \log k)]$ and $j \in [d]$, so that their expectation exists, and applying linearity of expectation across the d columns. This is inspired from an argument of Indyk [Ind06] for embedding a vector into a lower-dimensional vector while preserving its ℓ_1-norm; for *single-response* regression this is the statement that $\|SU^*v^* - Sa\|_1 = \Theta(1)\|U^*v - a\|_1$, implied by [Ind06]. However, for *multi-response* regression we have to work entirely with expectations, rather than the tail bounds in [Ind06], since the Cauchy random variables $(SU^*V_j - SA_j)_i$, while independent across i, are dependent across j. Moreover, our $O(\log d)$-approximation factor is not an artifact of our analysis - we show in Section 17.6 that there is an $n \times d$ input matrix A for which with probability $1 - 1/\operatorname{poly}(k)$, *there is no k-dimensional space in the span of SA achieving a $\left(\frac{\log d}{t \log t} + k^{1/2-\gamma}\right)$-approximation*, for S a Cauchy matrix with t rows, where $\gamma > 0$ is an arbitrarily small constant. This shows $(k \log d)^{\Omega(1)}$-inapproximability. Thus, the fact that we achieve $O(\log d)$-approximation instead of $O(1)$ is fundamental for a matrix S of Cauchy random variables or any scaling of it.

While we cannot show (2), we instead show for all V, $\|SU^*V - SA\|_1 \geq \|U^*V - A\|_1/2 - O(\log d)\|U^*V^* - A\|_1$ if S has $O(k \log k)$ rows. This suffices for regression, since the only matrices V for which the cost is much smaller in the sketch space are those providing an $O(\log d)$ approximation in the original space. The guarantee follows from the triangle inequality: $\|SU^*V - SA\|_1 \geq \|SU^*V - SU^*V^*\|_1 - \|SU^*V^* - SA\|_1$ and the fact that S is known to not contract any vector in the column span of U^* if S has $O(k \log k)$ rows [SW11]. Because of this, we have $\|SU^*V - SU^*V^*\|_1 = \Omega(1)\|U^*V - U^*V^*\|_1 = \Omega(1)(\|U^*V - A\|_1 - \|U^*V^* - A\|_1)$, where we again use the triangle inequality. We also bound the additive term

$\|SU^*V^* - SA\|_1$ by $O(\log d)\|U^*V^* - A\|_1$ using (1) above.

Given that SA contains a good rank-k approximation in its row span, our algorithm with a slightly worse poly(n) time and poly$(k\log(n))$-approximation can be completely described here. Let S and T_1 be independent $O(k\log k)\times n$ matrices of i.i.d. Cauchy random variables, and let R and T_2 be independent $d\times O(k\log k)$ matrices of i.i.d. Cauchy random variables. Let

$$X = (T_1AR)^\dagger((T_1AR)(T_1AR)^\dagger(T_1AT_2)(SAT_2)(SAT_2)^\dagger)_k(SAT_2)^\dagger,$$

which is the rank-k matrix minimizing $\|T_1ARXSAT_2 - T_1AT_2\|_F$, where for a matrix C, C_k is its best rank-k approximation in Frobenius norm. Output $\widehat{A} = ARXSA$ as the solution to ℓ_1-low rank approximation of A. We show with constant probability that $\widehat{A}$ is a poly$(k\log(n))$-approximation.

To improve the approximation factor, after computing SA, we ℓ_1-project each of the rows of A onto SA using linear programming or fast algorithms for ℓ_1-regression [CW13, MM13], obtaining an $n\times d$ matrix B of rank $O(k\log k)$. We then apply the algorithm in the previous paragraph with A replaced by B. This ultimately leads to a $\log d\cdot$ poly(k)-approximation.

To improve the running time from poly(n) to nnz$(A) + n\cdot$ poly(k), we show a similar analysis holds for the sparse Cauchy matrices of [MM13]; see also the matrices in [WZ13].

CUR Decompositions: To obtain a CUR decomposition, we first find a $\log d\cdot$ poly(k)-approximate rank-k approximation $\widehat{A}$ as above. Let B_1 be an $n\times k$ matrix whose columns span those of $\widehat{A}$, and consider the regression $\min_V \|B_1V - A\|_1$. Unlike the problem $\min_V \|U^*V -$

$A\|_1$ where U^* was unknown, we *know* B_1 so can compute its Lewis weights efficiently, sample by them, and obtain a regression problem $\min_V \|D_1(B_1V - A)\|_1$ where D_1 is a sampling and rescaling matrix. Since

$$\|D_1(B_1V - A)\|_1 \leq \|D_1(B_1V - B_1V^*)\|_1 + \|D_1(B_1V^* - A)\|_1,$$

where $V^* = \text{argmin}_V\|B_1V - A\|_1$, we can bound the first term by $O(\|B_1V - B_1V^*\|_1)$ using that D_1 is a subspace embedding if it has $O(k \log k)$ rows, while the second term is $O(1)\|B_1V^* - A\|_1$ by a Markov bound. Note that

$$\|B_1V^* - A\|_1 \leq (\log d) \cdot \text{poly}(k) \min_{\text{rank-}k \text{ matrices } A'} \|A - A'\|_1.$$

By switching to ℓ_2 as before, we see that $\widehat{V} = (D_1B_1)^\dagger D_1A$ contains a $(\log d)\,\text{poly}(k)$-approximation in its span. Here D_1A is an actual subset of rows of A, as required in a CUR decomposition. Moreover the subset size is $O(k \log k)$. We can sample by the Lewis weights of $\widehat{V}$ to obtain a subset C of $O(k \log k)$ rescaled columns of A, together with a rank-k matrix U for which

$$\|CUR - A\|_1 \leq (\log d)\,\text{poly}(k) \min_{\text{rank-}k \text{ matrices } A'} \|A - A'\|_1.$$

Algorithm for Small k: Our CUR decomposition shows how we might obtain an $O(1)$-approximation for constant k in $\text{poly}(n)$ time. If we knew the Lewis weights of U^*, an α-approximate solution to the problem $\min_V \|D_1(U^*V - A)\|_1$ would be an $O(\alpha)$-approximate solution to the problem $\min_V \|U^*V - A\|_1$, where D_1 is a sampling and rescaling matrix of $O(k \log k)$ rows of A. Moreover, an $O(\sqrt{k \log k})$-approximate solution to $\min_V \|D_1(U^*V -$

$A)\|_1$ is given by $V = (D_1U^*)^\dagger D_1A$, which implies the $O(k \log k)$ rows of D_1A contain an $O(\sqrt{k \log k})$-approximation. For small k, we can guess every subset of $O(k \log k)$ rows of A in $n^{O(k \log k)}$ time (if $d \ll n$, by taking transposes at the beginning one can replace this with $d^{O(k \log k)}$ time). For each guess, we set up the problem $\min_{\text{rank-}k\ U} \|U(D_1A) - A\|_1$. If D_2 is a sampling and rescaling matrix according to the Lewis weights of D_1A, then by a similar triangle inequality argument as for our CUR decomposition, minimizing $\|U(D_1A)D_2 - AD_2\|_1$ gives an $O(\sqrt{k \log k})$ approximation. By switching to ℓ_2, this implies there is an $O(k \log k)$-approximation of the form AD_2WD_1A, where W is an $O(k \log^2 k) \times O(k \log k)$ matrix of rank k. By setting up the problem $\min_{\text{rank-}k\ W} \|AD_2WD_1A - A\|_1$, one can sample from Lewis weights on the left and right to reduce this to a problem independent of n and d, after which one can use polynomial optimization to solve it in $\exp(\text{poly}(k))$ time. One of our guesses D_1A will be correct, and for this guess we obtain an $\widetilde{O}(k)$-approximation. For each guess we can compute its cost and take the best one found. This gives an $O(1)$-approximation for constant k, removing the $O(\log d)$-factor from the approximation of our earlier algorithm.

Existential Results for Subset Selection: In our algorithm for small k, the first step was to show there exist $O(k \log k)$ rows of A which contain a rank-k space which is an $O(\sqrt{k \log k})$-approximation.

While for Frobenius norm one can find $O(k)$ rows with an $O(1)$-approximation in their span, one of our main negative results for ℓ_1-low rank approximation is that this is impossible, showing that the best approximation one can obtain with $\text{poly}(k)$ rows is $k^{1/2-\gamma}$ for an arbitrarily small constant $\gamma > 0$. Our hard instance is an $r \times (r + k)$ matrix A in which the first k columns are i.i.d. Gaussian, and the remaining r columns are an identity

matrix. Here, r can be twice the number of rows one is choosing. The optimal ℓ_1-low rank approximation has cost at most r, obtained by choosing the first k columns.

Let $R \in \mathbb{R}^{r/2 \times k}$ denote the first k entries of the $r/2$ chosen rows, and let y denote the first k entries of an unchosen row. For $r/2 > k$, there exist many solutions $x \in \mathbb{R}^{r/2}$ for which $x^\top R = y$. However, we can show the following tradeoff:

$$\textit{whenever } \|x^\top R - y\|_1 < \tfrac{\sqrt{k}}{\mathrm{poly}(\log k)}, \textit{ then } \|x\|_1 > \tfrac{\sqrt{k}}{\mathrm{poly}(\log k)}.$$

Then no matter which linear combination $x^\top$ of the rows of R one chooses to approximate y by, either one incurs a $\frac{\sqrt{k}}{\mathrm{poly}(\log k)}$ cost on the first k coordinates, or since A contains an identity matrix, one incurs cost $\|x\|_1 > \frac{\sqrt{k}}{\mathrm{poly}(\log k)}$ on the last r coordinates of $x^\top R$.

To show the tradeoff, consider an $x \in \mathbb{R}^{r/2}$. We decompose $x = x^0 + \sum_{j \geq 1} x^j$, where x^j agrees with x on coordinates which have absolute value in the range $\frac{1}{\sqrt{k}\log^c k} \cdot [2^{-j}, 2^{-j+1}]$, and is zero otherwise. Here, $c > 0$ is a constant, and x^0 denotes the restriction of x to all coordinates of absolute value at least $\frac{1}{\sqrt{k}\log^c k}$. Then $\|x\|_1 < \frac{\sqrt{k}}{\log^c k}$, as otherwise we are done. Hence, x^0 *has small support.* Thus, one can build a small net for all x^0 vectors by choosing the support, then placing a net on it. For x^j for $j > 0$, the support sizes are increasing so the net size needed for all x^j vectors is larger. However, since x^j has all coordinates of roughly the same magnitude on its support, its ℓ_2*-norm is decreasing in* j. Since $(x^j)^\top R \sim N(0, \|x^j\|_2^2 I_k)$, this makes it much less likely that individual coordinates of $(x^j)^\top R$ can be large. Since this probability goes down rapidly, we can afford to union bound over the larger net size. What we show is that for any sum of the form $\sum_{j \geq 1} x^j$, at most $\frac{k}{10}$ of its coordinates are at least $\frac{1}{\log k}$ in magnitude.

For $\|x^\top R - y\|_1$ to be at most $\frac{\sqrt{k}}{\log^c k}$, for at least $\frac{k}{2}$ coordinates i, we must have $|(x^\top R - y)_i| < \frac{2}{\sqrt{k}\log^c k}$. With probability $1 - 2^{-\Omega(k)}$, $|y_i| \geq \frac{1}{100}$ on at least $\frac{2k}{3}$ coordinates. From the previous paragraph, it follows there are at least $\frac{k}{2} - \frac{k}{10} - \frac{k}{3} = \Omega(k)$ coordinates i of x for which (1) $|(x^\top R - y)_i| < \frac{2}{\sqrt{k}\log^c k}$, (2) $|\sum_{j\geq 1} x_i^j| < \frac{1}{\log k}$, and (3) $|y_i| \geq \frac{1}{100}$. On these i, $(x^0)^\top R_i$ must be in an interval of width $\frac{1}{\log k}$ at distance at least $\frac{1}{100}$ from the origin. Since $(x^0)^\top R \sim N(0, \|x^0\|_2^2 I_k)$, for any value of $\|x^0\|_2^2$ the probability this happens on $\Omega(k)$ coordinates is at most $2^{-\Theta(k)}$. Since the net size for x^0 is small, we can union bound over every sequence $x^0, x^1, \ldots,$ coming from our nets.

Some care is needed to union bound over all possible subsets R of rows which can be chosen. We handle this by conditioning on a few events of A itself, which imply corresponding events *for every subset of rows*. These events are such that if R is the chosen set of half the rows, and S the remaining set of rows of A, then the event that a constant fraction of rows in S are close to the row span of R is $2^{-\Theta(kr)}$, which is small enough to union bound over all choices of R.

Curiously, we also show there are some matrices $A \in \mathbb{R}^{n\times d}$ for which any ℓ_1 rank-k approximation in the entire row span of A cannot achieve better than a $(2 - \Theta(1/d))$-approximation.

Bicriteria Algorithm: Our algorithm for small k gives an $O(1)$-approximation in $\mathrm{poly}(n)$ time for constant k, but the approximation factor depends on k. We show how one can find a rank-$2k$ matrix $\widehat{A}$ for which $\|A - \widehat{A}\|_1 \leq C \cdot \mathrm{OPT}$, where C is an absolute constant, and $\mathrm{OPT} = \min_{\text{rank-}k \text{ matrices } A'} \|A - A'\|_1$. We first find a rank-$k$ matrix B^1 for which $\|A - B^1\|_1 \leq p \cdot \mathrm{OPT}$ for a factor $1 \leq p \leq \mathrm{poly}(n)$. We can use any of our algorithms above

for this.

Next consider the problem $\min_{V \in \mathbb{R}^{2k \times d}} \|U^*V - (A - B^1)\|_1$, and let U^*V^* be a best ℓ_1-low rank-$2k$ approximation to $A - B^1$; we later explain why we look at this problem. We can assume V^* is an ℓ_1 *well-conditioned basis* [Cla05, DDH+09], since we can replace U^* with U^*R^{-1} and V^* with RV^* for any invertible linear transformation R. For any vector x we then have $\frac{\|x\|_1}{f} \leq \|x^\top V^*\|_1 \leq e\|x\|_1$, where $1 \leq e, f \leq \text{poly}(k)$. This implies all entries of U^* are at most $2f\|A - B\|_1$, as otherwise one could replace U^* with $0^{n \times 2k}$ and reduce the cost. Also, any entry of U^* smaller than $\frac{\|A-B\|_1}{100enkp}$ can be replaced with 0 as this incurs additive error $\frac{\text{OPT}}{100}$. If we round the entries of U^* to integer multiples of $\frac{\|A-B\|_1}{100enkp}$, then we only have $O(enkpf)$ possibilities for each entry of U^*, and still obtain an $O(1)$-approximation. We refer to the rounded U^* as U^*, abusing notation.

Let D be a sampling and rescaling matrix with $O(k \log k)$ non-zero diagonal entries, corresponding to sampling by the Lewis weights of U^*. We do not know D, but handle this below. By the triangle inequality, for any V,

$$\begin{aligned} \|D(U^*V - (A - B^1))\|_1 &= \|D(U^*V - U^*V^*)\|_1 \pm \|D(U^*V^* - (A - B^1))\|_1 \\ &= \Theta(1)\|U^*V - U^*V^*\|_1 \pm O(1)\|U^*V^* - (A - B^1)\|_1, \end{aligned}$$

where the Lewis weights give $\|D(U^*V - U^*V^*)\|_1 = \Theta(1)\|U^*V - U^*V^*\|_1$ and a Markov bound gives $\|D(U^*V^* - (A - B^1))\|_1 = O(1)\|U^*V^* - (A - B^1)\|_1$. Thus, minimizing $\|DU^*V - D(A - B^1)\|_1$ gives a fixed constant factor approximation to the problem $\min_{V \in \mathbb{R}^{2k \times d}} \|U^*V - (A - B^1)\|_1$. The non-zero diagonal entries of D can be assumed to be integers between 1 and n^2.

We guess the entries of DU^* and note for each entry there are only $O(enkpf \log(n^2))$

possibilities. One of our guesses corresponds to Lewis weight sampling by U^*. We solve for V and by the guarantees of Lewis weights, the row span of this V provides an $O(1)$-approximation. We can find the corresponding U via linear programming. As mentioned above, we do not know D, but can enumerate over all D and all possible DU^*. The total time is $n^{\text{poly}(k)}$.

After finding U, which has $2k$ columns, we output the rank-$3k$ space formed by the column span of $[U, B^1]$. By including the column span of B^1, we ensure our original transformation of the problem $\min_{V\in\mathbb{R}^{k\times d}} \|U^*\cdot V - A\|_1$ to the problem $\min_{V\in\mathbb{R}^{2k\times d}} \|U^*\cdot V - (A - B^1)\|_1$ is valid, since we can first use the column span of B^1 to replace A with $A - B^1$. Replacing A with $A - B^1$ ultimately results in a rank-$3k$ output. Had we used A instead of $A - B^1$ our output would have been rank k but would have additive error $\frac{\|A\|_1}{\text{poly}(k/\epsilon)}$. If we assume the entries of A are in $\{-b, -b+1, \ldots, b\}$, then we can lower bound the cost $\|U^*V - A\|_1$, given that it is non-zero, by $(ndb)^{-O(k)}$ (if it is zero then we output A) using Lemma 4.1 in [CW09] and relating entrywise ℓ_1-norm to Frobenius norm. We can go through the same arguments above with $A - B$ replaced by A and our running time will now be $(ndb)^{\text{poly}(k)}$.

Hard Instances for Cauchy Matrices and More General Sketches: We consider a $d \times d$ matrix $A = I_d + (\log d)e_1^\top e$, where $e_1 = (1, 0, \ldots, 0)$ and $e = (1, 1, \ldots, 1)$ and I_d is the $d \times d$ identity. For an $O(k \log k) \times d$ matrix S of i.i.d. Cauchy random variables, $SA = S + (\log d)S_1^\top e$, where S_1 is the first column of S. For a typical column of SA, all entries are at most $\text{poly}(k) \log d$ in magnitude. Thus, in order to approximate the first row of A, which is $(\log d)e$, by $x^\top SA$ for an $x \in \mathbb{R}^{k \log k}$, we need $\|x\|_1 \geq \frac{1}{\text{poly}(k)}$. Also $\|x^\top S\|_1 = \Omega(\|x\|_1 d \log d)$ with $1 - \exp(-k \log k)$ probability, for d large enough, so by a net

argument $\|x\|_1 \leq \text{poly}(k)$ for all x.

However, *there are* entries of SA that are very large, i.e., about one which is $r = \Theta(dk \log k)$ in magnitude, and in general about 2^i entries about $r2^{-i}$ in magnitude. These entries typically occur in columns C_j of SA for which all other entries in the column are bounded by $\text{poly}(k)$ in magnitude. Thus, $|x^\top C_j| \approx r2^{-i}$ for about 2^i columns j. For each such column, if $r2^{-i} \gg \log d$, then we incur cost $\frac{r2^{-i}}{\text{poly}(k)}$ in approximating the first row of A. In total the cost is $\frac{r \log r}{\text{poly}(k)} = \frac{d \log d}{\text{poly}(k)}$, but the optimal cost is at most d, giving a $\frac{\log d}{\text{poly}(k)}$ lower bound. We optimize this to a $\frac{\log d}{k \log^2 k}$ lower bound.

When k is large this bound deteriorates, but we also show a $k^{1/2-\gamma}$ lower bound for arbitrarily small constant $\gamma > 0$. This bound applies to any oblivious sketching matrix. The idea is similar to our row subset selection lower bound. Let A be as in our row subset selection lower bound, consider SA, and write $S = U\Sigma V^\top$ in its full SVD. Then SA is in the row span of the top $O(k \log k)$ rows of $V^\top A$, since Σ only has $O(k \log k)$ non-zero singular values. Since the first k columns of A are rotationally invariant, $V^\top A$ has first k columns i.i.d. Gaussian and remaining columns equal to $V^\top$. Call the first $O(k \log k)$ rows of $V^\top A$ the matrix B. We now try to approximate a row of A by a vector in the row span of B. There are two issues that make this setting different from row subset selection: (1) B no longer contains an identity submatrix, and (2) the rows of B depend on the rows of A. We handle the first issue by building nets for subsets of coordinates of $x^\top V^\top$ rather than x as before; since $\|x^\top V^\top\|_2 = \|x\|_2$ similar arguments can be applied. We handle the second issue by observing that if the number of rows of B is considerably smaller than that of A, then the distribution of B had we replaced a random row of A with zeros would be statistically close to i.i.d. Gaussian. Hence, typical rows of A can be regarded as being independent of

B.

Theorem 17.1.1 (Informal Version of Theorem 17.4.6)**.** *Given $A \in \mathbb{R}^{n\times d}$, there is an algorithm which in $\mathrm{nnz}(A) + (n+d)\cdot \mathrm{poly}(k)$ time, outputs a (factorization of a) rank-k matrix A' such that with probability $9/10$, $\|A' - A\|_1 \leq (\log d)\,\mathrm{poly}(k) \min_{U\in\mathbb{R}^{n\times k}, V\in\mathbb{R}^{k\times d}} \|UV - A\|_1$.*

Theorem 17.1.2 (Informal Version of Theorem 17.4.7)**.** *Given $A \in \mathbb{R}^{n\times d}$, there is an algorithm that takes $\mathrm{poly}(n) d^{\widetilde{O}(k)} 2^{\widetilde{O}(k^2)}$ time and outputs a rank-k matrix A' such that, with probability $9/10$, $\|A' - A\|_1 \leq \widetilde{O}(k) \min_{U\in\mathbb{R}^{n\times k}, V\in\mathbb{R}^{k\times d}} \|UV - A\|_1$. In addition, A' is a CUR decomposition.*

Theorem 17.1.3 (Informal Version of Theorem 17.6.26)**.** *For any $k \geq 1$, and any constant $c \geq 1$, let $n = k^c$. There exists a matrix A such that for any matrix A' in the span of $n/2$ rows of A, $\|A' - A\|_1 = \Omega(k^{0.5-\alpha}) \min_{U\in\mathbb{R}^{n\times k}, V\in\mathbb{R}^{k\times d}} \|UV - A\|_1$, where $\alpha > 0$ is an arbitrarily small constant.*

Road map Section 17.2 introduces some notation and definitions. Section 17.3 includes several useful tools. We provide several ℓ_1-low rank approximation algorithms in Section 17.4. Section 17.5 contains the no contraction and no dilation analysis for our main algorithm.

We provide our existential hardness results for Cauchy matrices, row subset selection and oblivious subspace embeddings in Section 17.6.

17.2 Notation

Let $\mathbb{N}_+$ denote the set of positive integers. For any $n \in \mathbb{N}_+$, let $[n]$ denote the set $\{1, 2, \cdots, n\}$. For any $p \in [1, 2]$, the ℓ_p-norm of a vector $x \in \mathbb{R}^d$ is defined as

$$\|x\|_p = \big(\sum_{i=1}^{d} |x_i|^p\big)^{1/p}.$$

For any $p \in [1, 2)$, the ℓ_p-norm of a matrix $A \in \mathbb{R}^{n \times d}$ is defined as

$$\|A\|_p = \big(\sum_{i=1}^{n} \sum_{j=1}^{d} |A_{ij}|^p\big)^{1/p}.$$

Let $\|A\|_F$ denote the Frobenius norm of matrix A. Let $\mathrm{nnz}(A)$ denote the number of nonzero entries of A. Let $\det(A)$ denote the determinant of a square matrix A. Let $A^\top$ denote the transpose of A. Let $A^\dagger$ denote the Moore-Penrose pseudoinverse of A. Let A^{-1} denote the inverse of a full rank square matrix. We use A_j to denote the j^{th} column of A, and A^i to denote the i^{th} row of A. For an $n \times d$ matrix A, for S a subset of $[n]$ and T a subset of $[d]$, we let A^S denote the $|S| \times d$ submatrix of A with rows indexed by S, while A_T denotes the $n \times |T|$ submatrix of A with columns indexed by T, and A_T^S denote the $|S| \times |T|$ submatrix A with rows in S and columns in T.

For any function f, we define $\widetilde{O}(f)$ to be $f \cdot \log^{O(1)}(f)$. In addition to $O(\cdot)$ notation, for two functions f, g, we use the shorthand $f \lesssim g$ (resp. $\gtrsim$) to indicate that $f \leq Cg$ (resp. $\geq$) for an absolute constant C. We use $f \eqsim g$ to mean $cf \leq g \leq Cf$ for constants c, C. We use OPT to denote $\min_{\mathrm{rank}-k\ A_k} \|A_k - A\|_1$, unless otherwise specified.

17.3 Preliminaries

17.3.1 Polynomial system verifier

Renegar [Ren92a, Ren92b] and Basu *et al.* [BPR96] independently provided an algorithm for the decision problem for the existential theory of the reals, which is to decide the truth or falsity of a sentence $(x_1, \cdots, x_v)F(f_1, \cdots, f_m)$ where F is a quantifier-free Boolean formula with atoms of the form $\text{sign}(f_i) = \sigma$ with $\sigma \in \{0, 1, -1\}$. Note that this problem is equivalent to deciding if a given semi-algebraic set is empty or not. Here we formally state that theorem. For a full discussion of algorithms in real algebraic geometry, we refer the reader to [BPR05] and [Bas14].

Theorem 17.3.1 (Decision Problem [Ren92a, Ren92b, BPR96])**.** *Given a real polynomial system $P(x_1, x_2, \cdots, x_v)$ having v variables and m polynomial constraints*

$$f_i(x_1, x_2, \cdots, x_v)\Delta_i 0, \forall i \in [m],$$

where Δ_i is any of the "standard relations": $\{>, \geq, =, \neq, \leq, <\}$, let d denote the maximum degree of all the polynomial constraints and let H denote the maximum bitsize of the coefficients of all the polynomial constraints. Then in

$$(md)^{O(v)}\,\text{poly}(H),$$

time one can determine if there exists a solution to the polynomial system P.

Recently, this technique has been used to solve a number of low-rank approximation and matrix factorization problems [AGKM12, Mad13, CW15a, BDL16, RSW16].

17.3.2 Cauchy and p-stable transform

Definition 17.3.1 (Dense Cauchy transform)**.** Let $S = \sigma \cdot C \in \mathbb{R}^{m \times n}$ where σ is a scalar, and each entry of $C \in \mathbb{R}^{m \times n}$ is chosen independently from the standard Cauchy distribution. For any matrix $A \in \mathbb{R}^{n \times d}$, SA can be computed in $O(m \cdot \text{nnz}(A))$ time.

Definition 17.3.2 (Sparse Cauchy transform)**.** Let $\Pi = \sigma \cdot SC \in \mathbb{R}^{m \times n}$, where σ is a scalar, $S \in \mathbb{R}^{m \times n}$ has each column chosen independently and uniformly from the m standard basis vectors of $\mathbb{R}^m$, and $C \in \mathbb{R}^{n \times n}$ is a diagonal matrix with diagonals chosen independently from the standard Cauchy distribution. For any matrix $A \in \mathbb{R}^{n \times d}$, ΠA can be computed in $O(\text{nnz}(A))$ time.

Definition 17.3.3 (Dense p-stable transform)**.** Let $p \in (1, 2)$. Let $S = \sigma \cdot C \in \mathbb{R}^{m \times n}$ where σ is a scalar, and each entry of $C \in \mathbb{R}^{m \times n}$ is chosen independently from the standard p-stable distribution. For any matrix $A \in \mathbb{R}^{n \times d}$, SA can be computed in $O(m \,\text{nnz}(A))$ time.

Definition 17.3.4 (Sparse p-stable transform)**.** Let $p \in (1, 2)$. Let $\Pi = \sigma \cdot SC \in \mathbb{R}^{m \times n}$, where σ is a scalar, $S \in \mathbb{R}^{m \times n}$ has each column chosen independently and uniformly from the m standard basis vectors of $\mathbb{R}^m$, and $C \in \mathbb{R}^{n \times n}$ is a diagonal matrix with diagonals chosen independently from the standard p-stable distribution. For any matrix $A \in \mathbb{R}^{n \times d}$, ΠA can be computed in $O(\text{nnz}(A))$ time.

17.3.3 Lewis weights

We follow the exposition of Lewis weights from [CP15].

Definition 17.3.5. For a matrix A, let a_i denote i^{th} row of A, and $a_i (= (A^i)^\top)$ is a column vector. The statistical leverage score of a row a_i is

$$\tau_i(A) \stackrel{\text{def}}{=} a_i^\top (A^\top A)^{-1} a_i = \|(A^\top A)^{-1/2} a_i\|_2^2.$$

For a matrix A and norm p, the ℓ_p Lewis weights w are the unique weights such that for each row i we have

$$w_i = \tau_i(W^{1/2-1/p} A).$$

or equivalently

$$a_i^\top (A^\top W^{1-2/p} A)^{-1} a_i = w_i^{2/p}.$$

Lemma 17.3.2 (Lemma 2.4 of [CP15] and Lemma 7 of [CLM+15]). *Given a matrix $A \in \mathbb{R}^{n \times d}$, $n \geq d$, for any constant $C > 0, 4 > p \geq 1$, there is an algorithm which can compute C-approximate ℓ_p Lewis weights for every row i of A in $O((nnz(A) + d^\omega \log d) \log n)$ time, where $\omega < 2.373$ is the matrix multiplication exponent[Str69, CW87, Wil12].*

Lemma 17.3.3 (Theorem 7.1 of [CP15]). *Given matrix $A \in \mathbb{R}^{n \times d}$ ($n \geq d$) with ℓ_p ($4 > p \geq 1$) Lewis weights w, for any set of sampling probabilities p_i, $\sum_i p_i = N$,*

$$p_i \geq f(d, p) w_i,$$

if $S \in \mathbb{R}^{N \times n}$ has each row chosen independently as the i^{th} standard basis vector, times $1/p_i^{1/p}$, with probability p_i/N, then with probability at least 0.999,

$$\forall x \in \mathbb{R}^d, \frac{1}{2}\|Ax\|_p^p \leq \|SAx\|_p^p \leq 2\|Ax\|_p^p$$

Furthermore, if $p = 1$, $N = O(d \log d)$. *If* $1 < p < 2$, $N = O(d \log d \log \log d)$. *If* $2 \leq p < 4$, $N = O(d^{p/2} \log d)$.

Given a matrix $A \in \mathbb{R}^{n \times d}$ $(n \geq d)$, by Lemma 17.3.3 and Lemma 17.3.2, we are able to compute a sampling/rescaling matrix S in $O((nnz(A) + d^{\omega} \log d) \log n)$ with $\widetilde{O}(d)$ nonzero entries such that

$$\forall x \in \mathbb{R}^d, \frac{1}{2}\|Ax\|_p^p \leq \|SAx\|_p^p \leq 2\|Ax\|_p^p.$$

Sometimes, $\mathrm{poly}(d)$ is much smaller than $\log n$. In this case, we are able to compute the such sampling/rescaling matrix S in $n\,\mathrm{poly}(d)$ time in the following way: basically we can run one of the input sparsity ℓ_p embedding algorithm (see e.g. [MM13]) to compute a well conditioned basis U of column span of A in $n\,\mathrm{poly}(d)$ time. By sampling according to the well conditioned basis (see e.g. [Cla05, DDH+09, Woo14b]), we can compute a sampling/rescaling matrix S_1 such that $(1-\epsilon)\|Ax\|_p^p \leq \|S_1 Ax\|_p^p \leq (1+\epsilon)\|Ax\|_p^p$ where $\epsilon \in (0,1)$ is an arbitrary constant. Notice that S_1 has $\mathrm{poly}(d)$ nonzero entries, thus $S_1 A$ has size $\mathrm{poly}(d)$. Now, we apply Lewis weights sampling according to $S_1 A$, we can get a sampling/rescaling matrix S such that

$$\forall x \in \mathbb{R}^d, (1 - \frac{1}{3})\|S_1 Ax\|_p^p \leq \|SS_1 Ax\|_p^p \leq (1 + \frac{1}{3})\|S_1 Ax\|_p^p.$$

It means that

$$\forall x \in \mathbb{R}^d, \frac{1}{2}\|Ax\|_p^p \leq \|SS_1 Ax\|_p^p \leq 2\|Ax\|_p^p.$$

Note that SS_1 is still a sampling/rescaling matrix according to A, and the number of non-zero entries is $\widetilde{O}(d)$. And the total running time is thus $n\,\mathrm{poly}(d)$.

17.3.4 Frobenius norm and ℓ_2 relaxation

Theorem 17.3.4 (Generalized rank-constrained matrix approximations, Theorem 2 in [FT07])**.** *Given matrices $A \in \mathbb{R}^{n\times d}$, $B \in \mathbb{R}^{n\times p}$, and $C \in \mathbb{R}^{q\times d}$, let the SVD of B be $B = U_B\Sigma_B V_B^\top$ and the SVD of C be $C = U_C\Sigma_C V_C^\top$. Then,*

$$B^\dagger(U_B U_B^\top A V_C C_C^\top)_k C^\dagger = \underset{\text{rank}-k\ X\in\mathbb{R}^{p\times q}}{\arg\min} \|A - BXC\|_F,$$

where $(U_B U_B^\top A V_C V_C^\top)_k \in \mathbb{R}^{p\times q}$ is of rank at most k and denotes the best rank-k approximation to $U_B U_B^\top A V_C V_C^\top \in \mathbb{R}^{p\times d}$ in Frobenius norm.

Claim 17.3.5 (ℓ_2 relaxation of ℓ_p-regression)**.** *Let $p \in [1, 2)$. For any $A \in \mathbb{R}^{n\times d}$ and $b \in \mathbb{R}^n$, define $x^* = \arg\min_{x\in\mathbb{R}^d} \|Ax - b\|_p$ and $x' = \arg\min_{x\in\mathbb{R}^d} \|Ax - b\|_2$. Then,*

$$\|Ax^* - b\|_p \le \|Ax' - b\|_p \le n^{1/p-1/2} \cdot \|Ax^* - b\|_p.$$

Proof. The lower bound trivially holds by definition; we will focus on proving the upper bound. Because $Ax - b$ is an n-dimensional vector, $\forall x$,

$$\frac{1}{n^{1/p-1/2}} \|Ax - b\|_p \le \|Ax - b\|_2 \le \|Ax - b\|_p. \tag{17.1}$$

Then,

$$\begin{aligned}
&\|Ax' - b\|_p \\
&\le \sqrt{n}\|Ax' - b\|_2 && \text{by LHS of Equation (17.1)} \\
&\le \sqrt{n}\|Ax^* - b\|_2 && \text{by } x' = \arg\min_x \|Ax - b\|_2 \\
&\le \sqrt{n}\|Ax^* - b\|_p && \text{by RHS of Equation (17.1)}
\end{aligned}$$

This completes the proof. □

Claim 17.3.6 (Frobenius norm relaxation of ℓ_p-low rank approximation)**.** *Let $p \in [1, 2)$ and for any matrix $A \in \mathbb{R}^{n\times d}$, define $A^* = \arg\min_{\text{rank}-k\ B\in\mathbb{R}^{n\times d}} \|B - A\|_p$ and $A' = \arg\min_{\text{rank}-k\ B\in\mathbb{R}^{n\times d}} \|B - A\|_F$. Then*

$$\|A^* - A\|_p \le \|A' - A\|_p \le (nd)^{1/p-1/2}\|A^* - A\|_p. \tag{17.2}$$

Proof. The lower bound of $\|A' - A\|_p$ trivially holds by definition. We show an upper bound of $\|A' - A\|_p$ in the rest of the proof. For any $A' - A \in \mathbb{R}^{n\times d}$, we have

$$\frac{1}{(nd)^{1/p-1/2}}\|A' - A\|_p \le \|A' - A\|_F \le \|A' - A\|_p. \tag{17.3}$$

Then,

$$\begin{aligned}
&\|A' - A\|_p \\
&\le (nd)^{1/p-1/2}\|A' - A\|_F && \text{by LHS of Equation (17.3)} \\
&\le (nd)^{1/p-1/2}\|A^* - A\|_F && \text{by } A' = \arg\min_{\text{rank}-k\ B}\|B - A\|_p \\
&\le (nd)^{1/p-1/2}\|A^* - A\|_p. && \text{by RHS of Equation (17.3)}
\end{aligned}$$

□

17.3.5 Converting entry-wise ℓ_1 and ℓ_p objective functions into polynomials

Claim 17.3.7 (Converting absolute value constraints into variables)**.** *Given m polynomials $f_1(x), f_2(x), \cdots, f_m(x)$ where $x \in \mathbb{R}^v$, solving the problem*

$$\min_{x \in \mathbb{R}^v} \sum_{i=1}^{m} |f_i(x)|, \tag{17.4}$$

is equivalent to solving another minimization problem with $O(m)$ extra constraints and m extra variables,

$$\begin{aligned} \min_{x \in \mathbb{R}^v, \sigma \in \mathbb{R}^m} & \sum_{i=1}^{m} \sigma_i f_i(x) \\ \text{s.t. } & \sigma_i^2 = 1, \forall i \in [m] \\ & f_i(x)\sigma_i \geq 0, \forall i \in [m]. \end{aligned}$$

Claim 17.3.8. *(Handling ℓ_p) Given m polynomials $f_1(x), f_2(x), \cdots, f_m(x)$ where $x \in \mathbb{R}^v$ and $p = a/b$ for positive integers a and b, solving the problem*

$$\min_{x \in \mathbb{R}^v} \sum_{i=1}^{m} |f_i(x)|^p, \tag{17.5}$$

is equivalent to solving another minimization problem with $O(m)$ extra constraints and $O(m)$ extra variables,

$$\begin{aligned} \min_{x \in \mathbb{R}^v, \sigma \in \mathbb{R}^m} & \sum_{i=1}^{m} y_i \\ \text{s.t. } & \sigma_i^2 = 1, \forall i \in [m] \\ & f_i(x)\sigma_i \geq 0, \forall i \in [m] \\ & (\sigma_i f_i(x))^a = y_i^b, \forall i \in [m] \\ & y_i \geq 0, \forall i \in [m]. \end{aligned}$$

17.3.6 Converting entry-wise ℓ_1 objective function into a linear program

Claim 17.3.9. *Given any matrix $A \in \mathbb{R}^{n \times d}$ and matrix $B \in \mathbb{R}^{k \times d}$, the problem $\min_{U \in \mathbb{R}^{n \times k}} \|UB - A\|_1$ can be solved by solving the following linear program,*

$$\begin{aligned}
&\min_{U \in \mathbb{R}^{n \times k}, x \in \mathbb{R}^{n \times d}} \sum_{i=1}^{n} \sum_{j=1}^{m} x_{i,j} \\
&U_i B^j - A_{i,j} \leq x_{i,j}, \forall i \in [n], j \in [d] \\
&U_i B^j - A_{i,j} \geq -x_{i,j}, \forall i \in [n], j \in [d] \\
&x_{i,j} \geq 0, \forall i \in [n], j \in [d],
\end{aligned}$$

where the number of constraints is $O(nd)$ and the number of variables is $O(nd)$.

17.4 ℓ_1-Low Rank Approximation

This section presents our main ℓ_1-low rank approximation algorithms. Section 17.4.1 provides our three existence results. Section 17.4.2 shows an input sparsity algorithm with $\text{poly}(k)\log^2 d \log n$-approximation ratio. Section 17.4.3 improves the approximation ratio to $\text{poly}(k)\log d$. Section 17.4.4 explains how to obtain $\widetilde{O}(k)$ approximation ratio. Section 17.4.5 improves the approximation ratio to $O(1)$ by outputting a rank-$3k$ solution. Section 17.4.6 presents our algorithm for CUR decomposition. Section 17.4.7 includes some useful properties. Our ℓ_1-low rank approximation algorithm for a rank-r (where $k \leq r \leq (n,d)$) matrix is used as a black box (by setting $r = \text{poly}(k)$) in several other algorithms.

17.4.1 Existence results via dense Cauchy transforms, sparse Cauchy transforms, Lewis weights

The goal of this section is to present the existence results in Corollary 17.4.2. We first provide some bicriteria algorithms in Theorem 17.4.1 which can be viewed as a "warmup". Then the proof of our bicriteria algorithm actually implies the existence results.

Theorem 17.4.1. *Given matrix $A \in \mathbb{R}^{n\times d}$, for any $k \geq 1$, there exist bicriteria algorithms with running time T (specified below), which output two matrices $U \in \mathbb{R}^{n\times m}$, $V \in \mathbb{R}^{m\times d}$ such that, with probability* $9/10$*,*

$$\|UV - A\|_1 \leq \alpha \min_{\text{rank}-k\ A_k} \|A_k - A\|_1.$$

(I). Using a dense Cauchy transform,

$T = \text{poly}(n, d, k)$, $m = O(k \log k)$, $\alpha = O(\sqrt{k \log k} \log d)$.

(II). Using a sparse Cauchy transform,

$T = \text{poly}(n, d, k)$,$m = O(k^5 \log^5 k)$, $\alpha = O(k^{4.5} \log^{4.5} k \log d)$.

(III). Sampling by Lewis weights,

$T = (nd)^{\widetilde{O}(k)}$, $m = O(k \log k)$, $\alpha = O(\sqrt{k \log k})$.

The matrices in (I), (II), (III) here, are the same as those in (I), (II), (III), (IV) of Lemma 17.5.5. Thus, they have the properties shown in Section 17.5.2.

Proof. We define

$$\text{OPT} := \min_{\text{rank}-k\ A_k} \|A_k - A\|_1.$$

We define $U^* \in \mathbb{R}^{n \times k}, V^* \in \mathbb{R}^{k \times d}$ to be the optimal solution such that $\|U^* V^* - A\|_1 = \mathrm{OPT}$.

Part (I). Apply the dense Cauchy transform $S \in \mathbb{R}^{m \times n}$ with $m = O(k \log k)$ rows, and $\beta = O(\log d)$.

Part (II). Apply the sparse Cauchy transform $S (= \Pi \in \mathbb{R}^{m \times n})$ with $m = O(k^5 \log^5 k)$ rows, and $\beta = O(\sigma \log d) = O(k^2 \log^2 k \log d)$.

Part (III). Use S $(= D \in \mathbb{R}^{n \times k})$ to denote an $n \times n$ matrix which is a sampling and rescaling diagonal matrix according to the Lewis weights of matrix U^*. It has $m = O(k \log k)$ rows, and $\beta = O(1)$. Sometimes we abuse notation, and should regard D as a matrix which has size $m \times n$, where $m = O(k \log k)$.

We can just replace M in Lemma 17.5.5 with $U^* V^* - A$, replace U in Lemma 17.5.5 with U^*, and replace $c_1 c_2$ with $O(\beta)$. So, we can apply Lemma 17.5.5 for S. Then we can plug it in Lemma 17.5.2, we have: with constant probability, for any $c \geq 1$, for any $V' \in \mathbb{R}^{k \times d}$ which satisfies

$$\|SU^* V' - SA\|_1 \leq c \cdot \min_{V \in \mathbb{R}^{k \times d}} \|SU^* V - SA\|_1, \tag{17.6}$$

it has

$$\|U^* V' - A\|_1 \leq c \cdot O(\beta) \|U^* V^* - A\|_1. \tag{17.7}$$

Define $\widehat{V}_i = \arg\min_{V_i \in \mathbb{R}^k} \|SU^* V_i - SA_i\|_2$ for each $i \in [d]$. By using Claim 17.3.5 with

$n = m$ and $d = k$, it shows

$$\begin{aligned}\|SU^*\widehat{V} - SA\|_1 &= \sum_{i=1}^{d} \|SU^*\widehat{V}_i - SA_i\|_1 \\ &\leq \sum_{i=1}^{d} \sqrt{m}\|SU^*\widetilde{V}_i - SA_i\|_1 \\ &= \sqrt{m} \min_{V \in \mathbb{R}^{k\times d}} \|SU^*V - SA\|_1.\end{aligned}$$

which means $\widehat{V}$ is a $\sqrt{m}$-approximation solution to problem, $\min_{V\in\mathbb{R}^{k\times d}}\|SU^*V - SA\|_1$.

Now, let us look into Equation (17.6) and Equation (17.7), we can obtain that

$$\|U^*\widehat{V} - A\|_1 \leq \sqrt{m}O(\beta)\,\mathrm{OPT}\,.$$

Because $\widehat{V}_i$ is the optimal solution of the ℓ_2 regression problem, we have

$$\widehat{V}_i = (SU^*)^\dagger SA_i \in \mathbb{R}^k, \forall i \in [d], \text{ which means } \widehat{V} = (SU^*)^\dagger SA \in \mathbb{R}^{k\times d}.$$

Plugging $\widehat{V}$ into original problem, we obtain

$$\|U^*(SU^*)^\dagger \cdot SA - A\|_1 \leq \sqrt{m}O(\beta)\,\mathrm{OPT}\,.$$

It means

$$\min_{\mathrm{rank}-k\ X\in\mathbb{R}^{n\times m}} \|XSA - A\|_1 \leq \sqrt{m}O(\beta)\,\mathrm{OPT}\,. \tag{17.8}$$

If we ignore the constraint on the rank of X, we can get a bicriteria solution:

For part (I), notice that X is an $n \times m$ matrix which can be found by using a linear program, because matrices $SA \in \mathbb{R}^{m\times d}$ and $A \in \mathbb{R}^{n\times d}$ are known.

For part (II), notice that X is an $n \times m$ matrix which can be found by using a linear program, because matrices $SA \in \mathbb{R}^{m \times d}$ and $A \in \mathbb{R}^{n \times d}$ are known.

For part (III), notice that X is an $n \times m$ matrix which can be found by using a linear program, when the span of rows of $DA \in \mathbb{R}^{m \times d}$ is known. We assume that D is known in all the above discussions. But D is actually unknown. So we need to try all the possible choices of the row span of DA. Since D samples at most $m = O(k \log k)$ rows of A, then the total number of choices of selecting m rows from n rows is $\binom{n}{m} = n^{O(k \log k)}$. This completes the proof.

□

Equation (17.8) in the proof of our bicriteria solution implies the following result,

Corollary 17.4.2. *Given $A \in \mathbb{R}^{n \times d}$, there exists a* rank-$k$ *matrix $A' \in \mathbb{R}^{n \times d}$ such that $A' \in \text{rowspan}(S'A) \subseteq \text{rowspan}(A)$ and $\|A' - A\|_1 \leq \alpha \cdot \min_{\text{rank}-k\ A_k} \|A - A_k\|_1$, where $S' \in \mathbb{R}^{m \times n}$ is a sketching matrix. If S'*

(I). indicates the dense Cauchy transform, then $\alpha = O(\sqrt{k \log k} \log d)$.

(II). indicates the sparse Cauchy transform, then $\alpha = O(k^{4.5} \log^{4.5} k \log d)$.

(III). indicates sampling by Lewis weights, then $\alpha = O(\sqrt{k \log k})$.

Proof. Define $\text{OPT} = \min_{U \in \mathbb{R}^{n \times k}, V \in \mathbb{R}^{k \times d}} \|UV - A\|_1$.

Proof of (I). Choose S to be a dense Cauchy transform matrix with m rows, then

$$\min_{U \in \mathbb{R}^{n \times k}, Z \in \mathbb{R}^{k \times m}} \|UZSA - A\|_1 \leq O(\sqrt{m} \log d)\, \text{OPT},$$

where $m = O(k \log k)$. Choosing $A' = UZSA$ completes the proof.

Proof of (II). Choose $\Pi = SD \in \mathbb{R}^{m\times n}$ where $S \in \mathbb{R}^{m\times n}$ has each column chosen independently and uniformly from the m standard basis vectors of $\mathbb{R}^m$, and where D is a diagonal matrix with diagonals chosen independently from the standard Cauchy distribution, then

$$\min_{U\in\mathbb{R}^{n\times k}, Z\in\mathbb{R}^{k\times m}} \|UZ\Pi A - A\|_1 \leq O(\sqrt{m}\sigma \log d)\,\mathrm{OPT},$$

where $m = O(k^5 \log^5 k)$ and $\sigma = O(k^2 \log^2 k)$. Choosing $A' = UZ\Pi A$ completes the proof.

Proof of (III).

Choose D to be the sampling and rescaling matrix corresponding to the Lewis weights of U^*, and let it have $m = O(k \log k)$ nonzero entries on the diagonal, then

$$\min_{U\in\mathbb{R}^{n\times k}, Z\in\mathbb{R}^{k\times m}} \|UZDA - A\|_1 \leq O(\sqrt{m})\,\mathrm{OPT}\,.$$

Choosing $A' = UZDA$ completes the proof. □

17.4.2 Input sparsity time, $\mathrm{poly}(k, \log n, \log d)$-approximation for an arbitrary matrix A

The algorithm described in this section is actually worse than the algorithm described in the next section. But this algorithm is easy to extend to the distributed and streaming settings (See full version of [SWZ17]).

Algorithm 17.2 Input Sparsity Time Algorithm

procedure L1LowRankApproxInputSparsity(A, n, d, k) ▷ Theorem 17.4.3
  Set $s \leftarrow r \leftarrow t_1 \leftarrow \widetilde{O}(k^5)$, $t_2 \leftarrow \widetilde{O}(k)$.
  Choose sparse Cauchy matrices $S \in \mathbb{R}^{s \times n}$, $R \in \mathbb{R}^{d \times r}$, $T_1 \in \mathbb{R}^{t_1 \times n}$.
  Choose dense Cauchy matrices $T_2 \in \mathbb{R}^{d \times t_2}$.
  Compute $S \cdot A$, $A \cdot R$ and $T_1 \cdot A \cdot T_2$.
  Compute $XY = \arg\min_{X,Y} \|T_1 ARXYSAT_2 - T_1 AT_2\|_F$.
  return ARX, YSA.
end procedure

Theorem 17.4.3. *Given matrix $A \in \mathbb{R}^{n \times d}$, for any $k \geq 1$, there exists an algorithm which takes $O(\mathrm{nnz}(A)) + (n+d) \cdot \mathrm{poly}(k)$ time and outputs two matrices $U \in \mathbb{R}^{n \times k}$, $V \in \mathbb{R}^{k \times d}$ such that*

$$\|UV - A\|_1 \leq O(\mathrm{poly}(k) \log n \log^2 d) \min_{\mathrm{rank}-k \ A_k} \|A_k - A\|_1$$

holds with probability $9/10$.

Proof. Choose a Cauchy matrix $S \in \mathbb{R}^{s \times n}$ (notice that S can be either a dense Cauchy transform matrix or a sparse Cauchy transform matrix). Using Corollary 17.4.2, we have

$$\min_{U \in \mathbb{R}^{n \times k}, Z \in \mathbb{R}^{k \times s}} \|UZSA - A\|_1 \leq \alpha_s \, \mathrm{OPT},$$

where α_s is the approximation by using matrix S. If S is a dense Cauchy transform matrix, then due to Part (I) of Corollary 17.4.2, $\alpha_s = O(\sqrt{k \log k} \log d)$, $s = O(k \log k)$, and computing SA takes $O(s \operatorname{nnz}(A))$ time. If S is a sparse Cauchy transform matrix, then due to Part II of Corollary 17.4.2, $\alpha_s = \widetilde{O}(k^{4.5} \log d)$, $s = \widetilde{O}(k^5)$, and computing SA takes $\operatorname{nnz}(A)$ time.

We define $U^*, Z^* = \arg\min_{U,Z} \|UZSA - A\|_1$. For the fixed $Z^* \in \mathbb{R}^{k \times s}$, choose a Cauchy matrix $R \in \mathbb{R}^{d \times r}$ (note that R can be either a dense Cauchy transform matrix or a sparse Cauchy transform matrix) and sketch on the right of $(UZSA - A)$. If R is a dense Cauchy transform matrix, then $\alpha_r = O(\log n)$, $r = O(k \log k)$, computing AR takes $O(r \cdot \operatorname{nnz}(A))$ time. If R is a sparse Cauchy transform matrix, then $\alpha_r = \widetilde{O}(k^2) \log n$, $r = \widetilde{O}(k^5)$, computing AR takes $O(\operatorname{nnz}(A))$ time.

Define a row vector $\widehat{U}^j = A^j R((Z^*SA)R)^\dagger \in \mathbb{R}^k$. Then

$$\forall j \in [n], \|\widehat{U}^j Z^* SAR - A^j R\|_2 = \min_{x \in \mathbb{R}^k} \|x^\top Z^* SAR - A^j R\|_2.$$

Recall that r is the number of columns of R. Due to Claim 17.3.5,

$$\sum_{j=1}^n \|A^j R((Z^*SA)R)^\dagger Z^* SAR - A^j R\|_1 \leq O(\sqrt{r}) \sum_{j=1}^n \min_{U^j \in \mathbb{R}^k} \|U^j Z^* SAR - A^j R\|_1,$$

which is equivalent to

$$\|AR((Z^*SA)R)^\dagger Z^* SAR - AR\|_1 \leq O(\sqrt{r}) \min_{U \in \mathbb{R}^{n \times k}} \|UZ^* SAR - AR\|_1,$$

where AR is an $n \times r$ matrix and SA is an $s \times d$ matrix.

Using Lemma 17.5.2, we obtain,

$$\|AR((Z^*SA)R)^\dagger Z^* SA - A\|_1 \leq O(\sqrt{r}\alpha_r) \min_{U \in \mathbb{R}^{n \times k}} \|UZ^* SA - A\|_1.$$

We define $X^* \in \mathbb{R}^{r\times k}$, $Y^* \in \mathbb{R}^{k\times s}$,

$$X^*, Y^* = \arg\min_{X\in\mathbb{R}^{r\times k}, Y\in\mathbb{R}^{k\times s}} \|ARXYSA - A\|_1.$$

Then,

$$\begin{aligned}
\|ARX^*Y^*SA - A\|_1 &\leq \|AR((Z^*SA)R)^\dagger Z^*SA - A\|_1 \\
&\leq O(\sqrt{r}\alpha_r) \min_{U\in\mathbb{R}^{n\times k}} \|UZ^*SA - A\|_1 \\
&= O(\sqrt{r}\alpha_r) \min_{U\in\mathbb{R}^{n\times k}, Z\in\mathbb{R}^{k\times s}} \|UZSA - A\|_1 \\
&\leq O(\sqrt{r}\alpha_r\alpha_s)\,\mathrm{OPT}\,.
\end{aligned}$$

It means that ARX^*, Y^*SA gives an $O(\alpha_r\alpha_s\sqrt{r})$-approximation to the original problem.

Thus it suffices to use Lemma 17.4.4 to solve

$$\min_{X\in\mathbb{R}^{r\times k}, Y\in\mathbb{R}^{k\times s}} \|ARXYSA - A\|_1,$$

by losing an extra $\mathrm{poly}(k)\log d$ factor in the approximation ratio.

By using a sparse Cauchy transform (for the place discussing the two options), combining the approximation ratios and running times all together, we can get $\mathrm{poly}(k)\log(n)\log^2(d)$-approximation ratio with $O(\mathrm{nnz}(A)) + (n+d)\,\mathrm{poly}(k)$ running time. This completes the proof. □

Lemma 17.4.4. *Given matrices $A \in \mathbb{R}^{n\times d}$, $SA \in \mathbb{R}^{s\times n}$,$RA \in \mathbb{R}^{r\times d}$ where $S \in \mathbb{R}^{s\times n}$, $R \in \mathbb{R}^{d\times r}$ with $\min(n,d) \geq \max(r,s)$. For any $1 \leq k \leq \min(r,s)$, there exists an algorithm that takes $O(\mathrm{nnz}(A)) + (n+d)\,\mathrm{poly}(s,r,k)$ time to output two matrices $X' \in \mathbb{R}^{r\times k}, Y' \in \mathbb{R}^{k\times s}$ such that*

$$\|ARX' \cdot Y'SA - A\|_1 \leq \mathrm{poly}(r,s)\log(d) \min_{X\in\mathbb{R}^{r\times k}, Y\in\mathbb{R}^{k\times s}} \|ARXYSA - A\|_1$$

holds with probability at least .999.

Proof. Choose sketching matrices $T_1 \in \mathbb{R}^{t_1 \times n}$ to sketch on the left of $(ARXYSA - A)$ (note that S can be either a dense Cauchy transform matrix or a sparse Cauchy transform matrix). If T_1 is a dense Cauchy transform matrix, then $t_1 = O(r \log r)$, $\alpha_{t_1} = O(\log d)$, and computing $T_1 A$ takes $O(t_1 \cdot \text{nnz}(A))$ time. If T_1 is a sparse Cauchy transform matrix, then $t_1 = \widetilde{O}(r^5)$, $\alpha_{t_1} = \widetilde{O}(r^2) \log d$, and computing $T_1 A$ takes $\text{nnz}(A)$ time.

Choose dense Cauchy matrices $T_2^\top \in \mathbb{R}^{t_2 \times d}$ to sketch on the right of $T_1(ARXYSA - A)$ with $t_2 = O((t_1 + s)\log(t_1 + s))$. We get the following minimization problem,

$$\min_{X \in \mathbb{R}^{r \times k}, Y \in \mathbb{R}^{k \times s}} \|T_1 ARXYSAT_2 - T_1 AT_2\|_1. \tag{17.9}$$

Define X', Y' to be the optimal solution of

$$\min_{X \in \mathbb{R}^{r \times k}, Y \in \mathbb{R}^{k \times s}} \|T_1 ARXYSAT_2 - T_1 AT_2\|_F.$$

Due to Claim 17.3.6,

$$\|T_1 ARX'Y'SAT_2 - T_1 AT_2\|_1 \leq \sqrt{t_1 t_2} \min_{X \in \mathbb{R}^{r \times k}, Y \in \mathbb{R}^{k \times s}} \|T_1 ARXYSAT_2 - T_1 AT_2\|_1.$$

Due to Lemma 17.5.4

$$\|ARX'Y'SA - A\|_1 \leq \sqrt{t_1 t_2}\alpha_{t_1} \log t_1 \min_{X \in \mathbb{R}^{r \times k}, Y \in \mathbb{R}^{k \times s}} \|ARXYSA - A\|_1.$$

It remains to solve

$$\min_{X \in \mathbb{R}^{r \times k}, Y \in \mathbb{R}^{k \times s}} \|T_1 ARXYSAT_2 - T_1 AT_2\|_F.$$

By using Theorem 17.3.4 and choosing T_1 to be a sparse Cauchy transform matrix, we have that the optimal rank-k solution $X'Y'$ is $(T_1AR)^\dagger(U_BU_B^\top(T_1AT_2)V_CV_C^\top)_k(SAT_2)$ which can be computed in $O(\mathrm{nnz}(A)) + (n+d)\,\mathrm{poly}(s,r,k)$ time. Here, U_B are the left singular vectors of T_1AR. V_C are the right singular vectors of SAT_2. □

An alternative way of solving Equation (17.9) is using a polynomial system verifier. Note that a polynomial system verifier does not allow absolute value constraints. Using Claim 17.3.7, we are able to remove these absolute value constraints by introducing new constraints and variables. Thus, we can get a better approximation ratio but by spending exponential running time in k. In the previous step, we should always use a dense Cauchy transform to optimize the approximation ratio.

Corollary 17.4.5. *Given $A \in \mathbb{R}^{n\times d}$, there exists an algorithm which takes $nd \cdot \mathrm{poly}(k) + (n+d)\cdot 2^{\widetilde{O}(k^2)}$ time and outputs two matrices $U \in \mathbb{R}^{n\times k}$, $V \in \mathbb{R}^{k\times d}$ such that*

$$\|UV - A\|_1 \leq O(\mathrm{poly}(k)\log n \log^2 d) \min_{\mathrm{rank}-k\ A_k} \|A_k - A\|_1$$

holds with probability $9/10$.

The $\mathrm{poly}(k)$ factor in the above corollary is much smaller than that in Theorem 17.4.3.

17.4.3 $\mathrm{poly}(k, \log d)$-approximation for an arbitrary matrix A

In this section, we explain how to get an $O(\log d) \cdot \mathrm{poly}(k)$ approximation.

Algorithm 17.3 $\mathrm{poly}(k) \log d$-approximation Algorithm

procedure L1LowRankApproxPolykLogd(A, n, d, k) ▷ Theorem 17.4.6
  Set $s \leftarrow \widetilde{O}(k^5)$.
  Choose sparse Cauchy matrices $S \in \mathbb{R}^{s \times n}$ and compute $S \cdot A$.
  Implicitly obtain $B = U_B V_B$ by finding $V_B = SA \in \mathbb{R}^{s \times d}$ and $U_B \in \mathbb{R}^{n \times s}$ where $\forall i \in [n]$, row vector $(U_B)^i$ gives an $O(1)$ approximation to $\min_{x \in \mathbb{R}^{1 \times s}} \|xSA - A^i\|_1$.
  $U, V \leftarrow$L1LowRankApproxB(U_B, V_B, n, d, k, s). ▷ Theorem 17.4.19
  return U, V.
end procedure

Intuitively, our algorithm has two stages. In the first stage, we just want to find a low rank matrix B which is a good approximation to A. Then, we can try to find a rank-k approximation to B. Since now B is a low rank matrix, it is much easier to find a rank-k approximation to B. The procedure L1LowRankApproxB(U_B, V_B, n, d, k, s) corresponds to Theorem 17.4.19.

Theorem 17.4.6. *Given matrix $A \in \mathbb{R}^{n \times d}$, for any $k \geq 1$, there exists an algorithm which takes $\mathrm{nnz}(A) + (n + d) \cdot \mathrm{poly}(k)$ time to output two matrices $U \in \mathbb{R}^{n \times k}$, $V \in \mathbb{R}^{k \times d}$ such that*

$$\|UV - A\|_1 \leq \mathrm{poly}(k) \log d \min_{\mathrm{rank}-k \ A_k} \|A_k - A\|_1$$

holds with probability $9/10$.

Proof. We define

$$\mathrm{OPT} := \min_{\mathrm{rank}-k \ A_k} \|A_k - A\|_1.$$

The main idea is to replace the given $n \times d$ matrix A with another low rank matrix B which also has size $n \times d$. Choose $S \in \mathbb{R}^{s \times n}$ to be a Cauchy matrix, where $s \leq \text{poly}(k)$ (note that, if S is a dense Cauchy transform matrix, computing SA takes $O(s \,\text{nnz}(A))$ time, while if S is a sparse Cauchy transform matrix, computing SA takes $O(\text{nnz}(A))$ time). Then B is obtained by taking each row of A and replacing it with its closest point (in ℓ_1-distance) in the row span of SA. By using Part II of Corollary 17.4.2, we have,

$$\min_{U \in \mathbb{R}^{n \times k}, Z \in \mathbb{R}^{k \times s}} \|UZSA - A\|_1 \leq O(\sqrt{s}\,\text{poly}(k) \log d)\,\text{OPT}\,.$$

We define B to be the product of two matrices $U_B \in \mathbb{R}^{n \times s}$ and $V_B \in \mathbb{R}^{s \times d}$. We define V_B to be SA and U_B to be such that for any $i \in [n]$, $(U_B)^i$ gives an $O(1)$-approximation to problem $\min_{x \in \mathbb{R}^{1 \times s}} \|xSA - A^i\|_1$, i.e.,

$$\|(U_B)^i SA - A^i\|_1 \leq O(1) \min_{x \in \mathbb{R}^{1 \times s}} \|xSA - A^i\|_1, \forall i \in [n],$$

which means

$$\|U_B SA - A\|_1 \leq O(1) \min_{X \in \mathbb{R}^{n \times s}} \|XSA - A\|_1.$$

For a fixed $SA \in \mathbb{R}^{s \times d}$, we can compute $D \in \mathbb{R}^{d \times d}$, which is a sampling and rescaling matrix corresponding to Lewis weights of $(SA)^\top$, and let $m = O(s \log s)$ be the number of nonzero entries on the diagonal of D.

Define $\widehat{X} = \arg\min_{X \in \mathbb{R}^{n \times s}} \|XSAD - AD\|_1$, thus by Lemma 17.5.5 and Lemma 17.5.2, we have

$$\|\widehat{X}SA - A\|_1 \leq O(1) \min_{X \in \mathbb{R}^{n \times s}} \|XSA - A\|_1.$$

Notice that computing Lewis weights takes $d\,\mathrm{poly}(s)$ time. We can use ℓ_1-regression solver and linear programming to find $\widehat{X} \in \mathbb{R}^{n\times s}$ in $(n+d)\,\mathrm{poly}(s)$ time. Thus U_B can be found in $O(\mathrm{nnz}(A)) + (n+d)\,\mathrm{poly}(s)$ time.

By the definition of B, it is an $n \times d$ matrix. Naïvely we can write down B after finding U_B and V_B. The time for writing down B is $O(nd)$. To avoid this, we can just keep a factorization U_B and V_B. We are still able to run algorithm L1LowRankApproxB. Because $s = \mathrm{poly}(k)$, the running time of algorithm L1LowRankApproxB is still $O(\mathrm{nnz}(A)) + (n+d)\,\mathrm{poly}(k)$.

By the definition of B, we have that B has rank at most s. Suppose we then solve ℓ_1-low rank approximation problem for rank-s matrix B, finding a rank-k g-approximation matrix UV. Due to Lemma 17.4.15, we have that if B is an f-approximation solution to A, then UV is also an $O(fg)$-approximation solution to A,

$$\|UV - A\|_1 \leq O(\log d) \cdot \mathrm{poly}(k) \cdot g\,\mathrm{OPT}\,.$$

Using Theorem 17.4.19 we have that $g = \mathrm{poly}(s)$, which completes the proof.

□

17.4.4 $\widetilde{O}(k)$-approximation for an arbitrary matrix A

Algorithm 17.4 $\widetilde{O}(k)$-approximation Algorithm

procedure L1LowRankApproxK(A, n, d, k) ▷ Theorem 17.4.7
  $r \leftarrow O(k \log k), m \leftarrow t_1 \leftarrow O(r \log r), t_2 \leftarrow O(m \log m)$.
  Guess a diagonal matrix $R \in \mathbb{R}^{d \times d}$ with only r 1s. ▷ R selects r columns of $A \in \mathbb{R}^{n \times d}$.
  Compute a sampling and rescaling matrix $D \in \mathbb{R}^{n \times n}, T_1 \in \mathbb{R}^{n \times n}$ corresponding to the Lewis weights of AR, and let them have m, t_1 nonzero entries on the diagonals, respectively.
  Compute a sampling and rescaling matrix $T_2^\top \in \mathbb{R}^{d \times d}$ according to the Lewis weights of $(DA)^\top$, and let it have t_2 nonzero entries on the diagonal.
  Solve $\min_{X,Y} \|T_1 ARXYDAT_2 - T_1 AT_2\|_1$.
  Take the best solution X, Y over all guesses of R.
  return ARX, YDA.
end procedure

Theorem 17.4.7. *Given matrix $A \in \mathbb{R}^{n \times d}$, there exists an algorithm that takes $\mathrm{poly}(n) \cdot d^{\widetilde{O}(k)} \cdot 2^{\widetilde{O}(k^2)}$ time and outputs two matrices $U \in \mathbb{R}^{n \times k}$, $V \in \mathbb{R}^{k \times d}$ such that*

$$\|UV - A\|_1 \leq \widetilde{O}(k) \min_{\mathrm{rank}-k\ A_k} \|A_k - A\|_1$$

holds with probability $9/10$.

Proof. We define

$$\mathrm{OPT} := \min_{\mathrm{rank}-k\ A_k} \|A_k - A\|_1.$$

Let $U^* \in \mathbb{R}^{n \times k}, V^* \in \mathbb{R}^{k \times d}$ satisfy

$$\|U^* V^* - A\|_1 = \mathrm{OPT}\,.$$

Let $S^\top \in \mathbb{R}^{d\times d}$ denote the sampling and rescaling matrix corresponding to the Lewis weights of $(V^*)^\top$, where the number of nonzero entries on the diagonal of S is $s = r = O(k \log k)$. Let $R^\top \in \mathbb{R}^{d\times d}$ denote a diagonal matrix such that $\forall i \in [d]$, if $S_{i,i} \neq 0$, then $R_{i,i} = 1$, and if $S_{i,i} = 0$, then $R_{i,i} = 0$. Since $\mathrm{rowspan}(R^\top A^\top) = \mathrm{rowspan}(S^\top A^\top)$,

$$\min_{Z\in\mathbb{R}^{m\times k}, V\in\mathbb{R}^{k\times d}} \|ASZV - A\|_1 = \min_{Z\in\mathbb{R}^{m\times k}, V\in\mathbb{R}^{k\times d}} \|ARZV - A\|_1.$$

Combining with Part III of Corollary 17.4.2, there exists a rank-k solution in the column span of AR, which means,

$$\min_{Z\in\mathbb{R}^{m\times k}, V\in\mathbb{R}^{k\times d}} \|ARZV - A\|_1 \leq O(\sqrt{r})\,\mathrm{OPT}\,. \tag{17.10}$$

Because the number of 1s of R is r, and the size of the matrix is $d \times d$, there are $\binom{d}{r} = d^{\widetilde{O}(k)}$ different choices for locations of 1s on the diagonal of R. We cannot compute R directly, but we can guess all the choices of locations of 1s. Regarding R as selecting r columns of A, then there are $d^{\widetilde{O}(k)}$ choices. There must exist a "correct" way of selecting a subset of columns over all all choices. After trying all of them, we will have chosen the right one.

For a fixed guess R, we can compute $D \in \mathbb{R}^{n\times n}$, which is a sampling and rescaling matrix corresponding to the Lewis weights of AR, and let $m = O(k \log^2 k)$ be the number of nonzero entries on the diagonal of D.

By Equation (17.10), there exists a $W \in \mathbb{R}^{r\times k}$ such that,

$$\min_{V\in\mathbb{R}^{k\times d}} \|ARWV - A\|_1 \leq O(\sqrt{r})\,\mathrm{OPT}\,. \tag{17.11}$$

We define $\widehat{V}_i = \arg\min_{V_i\in\mathbb{R}^{k\times d}} \|DARWV_i - DA_i\|_2$, $\forall i \in [d]$, which means $\widehat{V}_i = (DARW)^\dagger DA_i \in \mathbb{R}^k$. Then $\widehat{V} = (DARW)^\dagger DA \in \mathbb{R}^{k\times d}$. We define $V^* = \arg\min_{V\in\mathbb{R}^{k\times d}} \|ARWV - A\|_1$. Then, by

Claim 17.3.5, it has

$$\|DARW\widehat{V} - DA\|_1 \leq O(\sqrt{m}) \min_{V \in \mathbb{R}^{k \times d}} \|DARWV - DA\|_1.$$

By applying Lemma 17.5.5, Lemma 17.5.2 and Equation (17.11), we can show

$$\|ARW\widehat{V} - A\|_1 \leq O(\sqrt{m}) \|ARWV^* - A\|_1 \leq O(\sqrt{mr})\,\mathrm{OPT} \leq \widetilde{O}(k)\,\mathrm{OPT}\,.$$

Plugging $\widehat{V} = (DARW)^\dagger DA$ into $\|ARW\widehat{V} - A\|_1$, we obtain that

$$\|ARW(DARW)^\dagger DA - A\|_1 \leq \widetilde{O}(k)\,\mathrm{OPT}\,.$$

and it is clear that,

$$\min_{X \in \mathbb{R}^{r \times k}, Y \in \mathbb{R}^{k \times m}} \|ARXYDA - A\|_1 \leq \|ARW(DARW)^\dagger DA - A\|_1 \leq \widetilde{O}(k)\,\mathrm{OPT}\,.$$

Recall that we guessed R, so it is known. We can compute $T_1 \in \mathbb{R}^{n \times n}$, which is a sampling and rescaling diagonal matrix corresponding to the Lewis weights of AR, and $t_1 = O(r \log r)$ is the number of nonzero entries on the diagonal of T_1.

Also, DA is known, and the number of nonzero entries in D is $m = O(k \log^2 k)$. We can compute $T_2^\top \in \mathbb{R}^{d \times d}$, which is a sampling and rescaling matrix corresponding to the Lewis weights of $(DA)^\top$, and $t_2 = O(m \log m)$ is the number of nonzero entries on the diagonal of T_2.

Define $X^*, Y^* = \arg\min_{X \in \mathbb{R}^{r \times k}, Y \in \mathbb{R}^{k \times m}} \|T_1(AR)XY(DA)T_2 - T_1AT_2\|_1$. Thus, using Lemma 17.5.4, we have

$$\|(AR)X^*Y^*(DA) - A\|_1 \leq \widetilde{O}(k)\,\mathrm{OPT}\,.$$

To find X^*, Y^*, we need to solve this minimization problem

$$\min_{X \in \mathbb{R}^{r \times k}, Y \in \mathbb{R}^{k \times m}} \|T_1(AR)XY(DA)T_2 - T_1AT_2\|_1,$$

which can be solved by a polynomial system verifier (see more discussion in Section 17.3.1 and 17.3.5).

In the next paragraphs, we explain how to solve the above problem by using a polynomial system verifier. Notice that $T_1(AR)$ is known and $(DA)T_2$ is also known. First, we create $r \times k$ variables for the matrix X, i.e., one variable for each entry of X. Second, we create $k \times m$ variables for matrix Y, i.e., one variable for each entry of Y. Putting it all together and creating $t_1 \times t_2$ variables $\sigma_{i,j}, \forall i \in [t_1], j \in [t_2]$ for handling the unknown signs, we write down the following optimization problem

$$\begin{aligned} \min_{X,Y} \ & \sum_{i=1}^{t_1} \sum_{j=1}^{t_2} \sigma_{i,j} (T_1(AR)XY(DA)T_2)_{i,j} \\ \text{s.t } & \sigma_{i,j}^2 = 1, \forall i \in [t_1], j \in [t_2] \\ & \sigma_{i,j} \cdot (T_1(AR)XY(DA)T_2)_{i,j} \geq 0, \forall i \in [t_1], j \in [t_2]. \end{aligned}$$

Notice that the number of constraints is $O(t_1 t_2) = \widetilde{O}(k^2)$, the maximum degree is $O(1)$, and the number of variables $O(t_1 t_2 + km + rk) = \widetilde{O}(k^2)$. Thus the running time is,

$$(\#\,\text{constraints} \cdot \#\text{degree})^{O(\#\,\text{variables})} = 2^{\widetilde{O}(k^2)}.$$

To use a polynomial system verifier, we need to discuss the bit complexity. Suppose that all entries are multiples of δ, and the maximum is Δ, i.e., each entry

$$\in \{-\Delta, \cdots, -2\delta, -\delta, 0, \delta, 2\delta, \cdots, \Delta\},$$

and $\Delta/\delta = 2^{\text{poly}(nd)}$. Then the running time is $O(\text{poly}(\Delta/\delta)) \cdot 2^{\widetilde{O}(k^2)} = \text{poly}(nd)2^{\widetilde{O}(k^2)}$.

Also, a polynomial system verifier is able to tell us whether there exists a solution in a semi-algebraic set. In order to find the solution, we need to do a binary search over the cost C. In each step of the binary search we use a polynomial system verifier to determine if there exists a solution in,

$$\begin{aligned}
&\sum_{i=1}^{t_1}\sum_{j=1}^{t_2}\sigma_{i,j}(T_1(AR)XY(DA)T_2)_{i,j} \leq C \\
&\sigma_{i,j}^2 = 1, \forall i \in [t_1], j \in [t_2] \\
&\sigma_{i,j} \cdot (T_1(AR)XY(DA)T_2)_{i,j} \geq 0, \forall i \in [t_1], j \in [t_2].
\end{aligned}$$

In order to do binary search over the cost, we need to know an upper bound on the cost and also a lower bound on the minimum nonzero cost. The upper bound on the cost is $C_{\max} = O(nd\Delta)$, and the minimum nonzero cost is $C_{\min} = 2^{-\Omega(\text{poly}(nd))}$. Thus, the total number of steps for binary search is $O(\log(C_{\max}/C_{\min}))$. Overall, the running time is

$$nd^{\widetilde{O}(k)} \cdot 2^{\widetilde{O}(k^2)} \cdot \log(\Delta/\delta) \cdot \log(C_{\max}/C_{\min}) = \text{poly}(n)d^{\widetilde{O}(k)}2^{\widetilde{O}(k^2)}.$$

This completes the proof. □

Instead of solving an ℓ_1 problem at the last step of L1LowRankApproxK by using a polynomial system verifier, we can just solve a Frobenius norm minimization problem. This slightly improves the running time and pays an extra $\text{poly}(k)$ factor in the approximation ratio. Thus, we obtain the following corollary,

Corollary 17.4.8. *Given matrix $A \in \mathbb{R}^{n \times d}$, there exists an algorithm that takes $\mathrm{poly}(n) \cdot d^{\widetilde{O}(k)}$ time which outputs two matrices $U \in \mathbb{R}^{n \times k}$, $V \in \mathbb{R}^{k \times d}$ such that*

$$|UV - A\|_1 \leq \mathrm{poly}(k) \min_{\mathrm{rank}-k \ A_k} \|A_k - A\|_1$$

holds with probability $9/10$.

17.4.5 Rank-$3k$ and $O(1)$-approximation algorithm for an arbitrary matrix A

In this section, we show how to output a rank-$3k$ solution that is able to achieve an $O(1)$-approximation.

Algorithm 17.5 Bicriteria $O(1)$-approximation Algorithm

procedure L1LowRankApproxBicriteria(A, n, d, k) ▷ Theorem 17.4.9
  $U_B, V_B \leftarrow \min_{U \in \mathbb{R}^{n \times k}, V \in \mathbb{R}^{k \times d}} \|UV - A\|_F$.
  $r \leftarrow O(k \log k)$.
  Guess a diagonal matrix $D \in \mathbb{R}^{n \times n}$ with r nonzero entries.
  Guess matrix $DU \in \mathbb{R}^{r \times 2k}$.
  Find V_A by solving $\min_V \|DUV - D(A - B)\|_1$.
  Find U_A by solving $\min_U \|UV_A - (A - B)\|_1$.
  Take the best solution $\begin{bmatrix} U_A & U_B \end{bmatrix}, \begin{bmatrix} V_A \\ V_B \end{bmatrix}$ over all guesses.
  return $\begin{bmatrix} U_A & U_B \end{bmatrix}, \begin{bmatrix} V_A \\ V_B \end{bmatrix}$.
end procedure

Theorem 17.4.9. *Given matrix $A \in \mathbb{R}^{n \times d}$, for any $k \geq 1$, there exists an algorithm which takes $(nd)^{\widetilde{O}(k^2)}$ time to output two matrices $U \in \mathbb{R}^{n \times 3k}$, $V \in \mathbb{R}^{3k \times d}$,*

$$\|UV - A\|_1 \lesssim \min_{\text{rank}-k \ A_k} \|A_k - A\|_1,$$

holds with probability $9/10$.

Proof. We define OPT to be

$$\arg\min_{U \in \mathbb{R}^{n \times k}, V \in \mathbb{R}^{k \times d}} \|UV - A\|_1$$

Solving the Frobenius norm problem, we can find a factorization of a rank-k matrix $B = U_B V_B$ where $U_B \in \mathbb{R}^{n \times k}, V_B \in \mathbb{R}^{k \times d}$, and B satisfies $\|A - B\|_1 \leq \alpha_B \, \mathrm{OPT}$ for an $\alpha_B = \sqrt{nd}$.

We define $U^* \in \mathbb{R}^{n\times 2k}, V^* \in \mathbb{R}^{2k\times d}$ to be the optimal solution, i.e.,

$$U^*V^* = \arg\min_{U\in\mathbb{R}^{n\times 2k}, V\in\mathbb{R}^{2k\times d}} \|UV - (A-B)\|_1.$$

Let D be a sampling and rescaling diagonal matrix corresponding to the Lewis weights of U^*, and let the number of nonzero entries on the diagonal be $t = O(k\log k)$.

By Lemma 17.5.5 and Lemma 17.5.2, the solution of $\min_{V\in\mathbb{R}^{k\times d}} \|DU^*V - D(A-B)\|_1$ together with U^* gives an $O(1)$-approximation to $A-B$. In order to compute D we need to know U^*. Although we do not know U^*, there still exists a way to figure out the Lewis weights. The idea is the same as in the previous discussion Lemma 17.4.10 "Guessing Lewis weights". By Claim 17.4.11 and Claim 17.4.12, the total number of possible D is $n^{O(t)}$.

Lemma 17.4.10 tries to find a rank-k solution when all the entries in A are integers at most $\mathrm{poly}(nd)$. Here we focus on a bicriteria algorithm that outputs a rank-$3k$ matrix without such a strong bit complexity assumption. We can show a better claim 17.4.13, which is that the total number of possible DU^* is $N^{\tilde{O}(k^2)}$ where $N = \mathrm{poly}(n)$ is the number of choices for a single entry in U^*.

We explain how to obtain an upper bound on N. Consider the optimum $\|U^*V^* - (A-B)\|_1$. We can always change the basis so assume V^* is an Auerbach basis (i.e., an ℓ_1-well-conditioned basis discussed in Section 17.1), so $e\|x\|_1 \geq \|xV^*\|_1 \geq \|x\|_1/f$, where $e, f = \mathrm{poly}(k)$. Then no entry of U^* is larger than $2f\|A-B\|_1$, otherwise we could replace U^* with 0 and get a better solution. Also any entry smaller than $\|A-B\|_1/(enk\alpha_B 100)$ can be replaced with 0 as this will incur additive error at most $\mathrm{OPT}/100$. So if we round to integer multiples of $\|A-B\|_1/(enk\alpha_B 100)$ we only have $O(enk\alpha_B f)$ possibilities for each

entry of U^* and still have an $O(1)$-approximation. We will just refer to this rounded U^* as U^*, abusing notation.

Let $\mathcal{U}$ denote the set of all the matrices U that we guess. From the above discussion, we conclude that, there exists a $U \in \mathcal{U}$ such that $\|UV^* - (A-B)\|_1 \leq O(\mathrm{OPT})$.

For each guess of DU^* and D, we find V_A, U_A in the following way. We find V_A by using a linear program to solve,

$$\min_{V \in \mathbb{R}^{k \times d}} \|DU^*V - D(A-B)\|_1.$$

Given V_A and A, we write down a linear program to solve this problem,

$$\min_{U \in \mathbb{R}^{n \times k}} \|UV_A - (A-B)\|_1,$$

which takes $\mathrm{poly}(ndk)$ time. Then we obtain U_A.

Recall that V_B, U_B are the two factors of B and it is a rank-k, α_B-approximation solution to $\min_{U,V} \|UV - A\|_1$. Then we have

$$\left\| \begin{bmatrix} U_A & U_B \end{bmatrix} \begin{bmatrix} V_A \\ V_B \end{bmatrix} - A \right\|_1 = \left\| U_A V_A - (A - U_B V_B) \right\|_1 = \left\| U_A V_A - (A-B) \right\|_1.$$

Because there must exist a pair U_A, V_A satisfying $\|U_A V_A - (A-B)\|_1 \leq O(\mathrm{OPT})$, it follows that by taking the best solution $\begin{bmatrix} U_A & U_B \end{bmatrix} \begin{bmatrix} V_A \\ V_B \end{bmatrix}$ over all guesses, we obtain an $O(1)$-approximation solution.

Overall, the running time is $(nd)^{\widetilde{O}(k^2)}$. □

Lemma 17.4.10. *Given an $n \times d$ matrix A with integers bounded by $\mathrm{poly}(n)$, for any $k \geq 1$, there exists an algorithm which takes $(nd)^{\widetilde{O}(k^3)}$ time to output two matrices $U \in \mathbb{R}^{n \times k}$,*

$V \in \mathbb{R}^{k \times d}$, *such that*

$$\|UV - A\|_1 \lesssim \min_{\text{rank}-k \ A_k} \|A_k - A\|_1,$$

Proof. We define $U^* \in \mathbb{R}^{n \times k}, V^* \in \mathbb{R}^{k \times d}$ to be the optimal solution, i.e.,

$$U^*, V^* = \arg\min_{U \in \mathbb{R}^{n \times k}, V \in \mathbb{R}^{k \times d}} \|UV - A\|_1,$$

and define $\mathrm{OPT} = \|U^* V^* - A\|_1$.

Let D denote a sampling and rescaling diagonal matrix corresponding to the Lewis weights of U^*, and let the number of nonzero entries on the diagonal be $t = O(k \log k)$.

By Lemma 17.5.5 and Lemma 17.5.2, the solution to $\min_{V \in \mathbb{R}^{2k \times d}} \|DU^* V - DA\|_1$ together with U^* gives an $O(1)$-approximation to A. In order to compute D, we need to know U^*. Although we do not know U^*, there still exists a way to figure out the Lewis weights. We call the idea "Guessing Lewis weights". We will explain this idea in the next few paragraphs.

First, we can guess the nonzero entries on the diagonal, because the number of choices is small.

Claim 17.4.11. *The number of possible choice of* $\mathrm{supp}(D)$ *is at most* $n^{O(t)}$.

Proof. The matrix has dimension $n \times n$ and the number of nonzero entries is t. Thus the number of possible choices is at most $\sum_{i=1}^{t} \binom{n}{t} = n^{O(t)}$. □

Second, we can guess the value of each probability. For each probability, it is trivially at most 1. If the probability is less than $1/(\mathrm{poly}(n) k \log k)$, then we will never sample that row with high probability. It means that we can truncate the probability if it is below that

threshold. We can also round each probability to 2^{-i} which only loses another constant factor in the approximation ratio. Thus, we have:

Claim 17.4.12. *The total number of possible D is $n^{O(t)} = n^{\widetilde{O}(k)}$.*

Since $\Delta/\delta \leq \text{poly}(n)$ and the entries of A are in

$$\{-\Delta, -\Delta+\delta, \ldots, -2\delta, -\delta, 0, \delta, 2\delta, \cdots, \Delta-\delta, \Delta\},$$

we can lower bound the cost of $\|U^*V - A\|_1$ given that it is non-zero by $(nd\Delta/\delta)^{-O(k)}$ (if it is zero then A has rank at most k and we output A) using Lemma 4.1 in [CW09] and relating entrywise ℓ_1-norm to Frobenius norm. We can assume V is an ℓ_1 well-conditioned basis, since we can replace U^* with U^*R^{-1} and V with RV for any invertible linear transformation R. By properties of such basis, we can discretize the entries of U^* to integer multiples of $(nd\Delta/\delta)^{-O(k)}$ while preserving relative error. Hence we can correctly guess each entry of DU^* in $\left(n^{O(k)}\right)$ time.

Claim 17.4.13. *The total number of possible DU^* is $n^{\widetilde{O}(k^3)}$.*

In the following, let DU denote a guess of DU^*. Now the problem remaining is to solve $\min_{V \in \mathbb{R}^{k\times d}} \|DUV - DA\|_1$. Since we already know DA can be computed, and we know DU, we can solve this multiple regression problem by running linear programming. Thus the running time of this step is in $\text{poly}(nd)$. After we get such a solution V, we use a linear program to solve $\min_{U \in \mathbb{R}^{n\times k}} \|DUV - DA\|_1$. Then we can get U.

After we guess all the choices of D and DU^*, we must find a solution U, V which gives an $O(1)$ approximation. The total running time is $n^{\widetilde{O}(k)} \cdot n^{\widetilde{O}(k^3)} \cdot \text{poly}(nd) = (nd)^{\widetilde{O}(k^3)}$. □

17.4.6 CUR decomposition for an arbitrary matrix A

Algorithm 17.6 CUR Decomposition Algorithm

procedure L1LowRankApproxCUR(A, n, d, k) ▷ Theorem 17.4.14
  $U_B, V_B \leftarrow$ L1LowRankApproxPolykLogd(A, n, d, k).
  Let $D_1 \in \mathbb{R}^{n\times n}$ be the sampling and rescaling diagonal matrix corresponding to the Lewis weights of $B_1 = U_B \in \mathbb{R}^{n\times k}$, and let D_1 have $d_1 = O(k \log k)$ nonzero entries.
  Let $D_2^\top \in \mathbb{R}^{d\times d}$ be the sampling and rescaling diagonal matrix corresponding to the Lewis weights of $B_2^\top = \left((D_1 B_1)^\dagger D_1 A\right)^\top \in \mathbb{R}^{d\times k}$, and let D_2 have $d_2 = O(k \log k)$ nonzero entries.
  $C \leftarrow AD_2$, $U \leftarrow (B_2 D_2)^\dagger (D_1 B_1)^\dagger$, and $R \leftarrow D_1 A$.
  return C, U, R.
end procedure

Theorem 17.4.14. *Given matrix $A \in \mathbb{R}^{n\times d}$, for any $k \geq 1$, there exists an algorithm which takes $O(\mathrm{nnz}(A)) + (n+d)\,\mathrm{poly}(k)$ time to output three matrices $C \in \mathbb{R}^{n\times c}$ with columns from A, $U \in \mathbb{R}^{c\times r}$, and $R \in \mathbb{R}^{r\times d}$ with rows from A, such that $\mathrm{rank}(CUR) = k$, $c = O(k \log k)$, $r = O(k \log k)$, and*

$$\|CUR - A\|_1 \leq \mathrm{poly}(k) \log d \min_{\mathrm{rank}-k\ A_k} \|A_k - A\|_1,$$

holds with probability $9/10$.

Proof. We define

$$\mathrm{OPT} := \min_{\mathrm{rank}-k\ A_k} \|A_k - A\|_1.$$

Due to Theorem 17.4.6, we can output two matrices $U_B \in \mathbb{R}^{n\times k}$, $V_B \in \mathbb{R}^{k\times d}$ such that $U_B V_B$ gives a rank-k, and $\mathrm{poly}(k) \log d$-approximation solution to A, i.e.,

$$\|U_B V_B - A\|_1 \leq \mathrm{poly}(k) \log d\, \mathrm{OPT}\,. \tag{17.12}$$

By Section 17.3.3, we can compute $D_1 \in \mathbb{R}^{n\times n}$ which is a sampling and rescaling matrix corresponding to the Lewis weights of $B_1 = U_B$ in $O(n\,\mathrm{poly}(k))$ time, and there are $d_1 = O(k\log k)$ nonzero entries on the diagonal of D_1.

Define $V^* \in \mathbb{R}^{k\times d}$ to be the optimal solution of $\min_{V\in\mathbb{R}^{k\times d}} \|B_1V - A\|_1$, $\widehat{V} = (D_1B_1)^\dagger D_1A \in \mathbb{R}^{k\times d}$, $U_1 \in \mathbb{R}^{n\times k}$ to be the optimal solution of $\min_{U\in\mathbb{R}^{n\times k}} \|U\widehat{V} - A\|_1$, and V' to be the optimal solution of $\min_{V\in\mathbb{R}^{k\times d}} \|D_1A - D_1B_1V\|_1$.

By Claim 17.3.5, we have

$$\|D_1B_1\widehat{V} - D_1A\|_1 \leq \sqrt{d_1}\|D_1B_1V' - D_1A\|_1.$$

Due to Lemma 17.5.5 and Lemma 17.5.2, with constant probability, we have

$$\|B_1\widehat{V} - A\|_1 \leq \sqrt{d_1}\alpha_{D_1}\|B_1V^* - A\|_1,$$

where $\alpha_{D_1} = O(1)$.

Now, we can show,

$$\begin{aligned}
\|U_1\widehat{V} - A\|_1 \leq\ & \|B_1\widehat{V} - A\|_1 && \text{by } U_1 = \arg\min_{U\in\mathbb{R}^{n\times k}}\|U\widehat{V} - A\|_1 \\
\lesssim\ & \sqrt{d_1}\|B_1V^* - A\|_1 \\
\leq\ & \sqrt{d_1}\|U_BV_B - A\|_1 \\
\leq\ & \mathrm{poly}(k)\log d\,\mathrm{OPT}\,. && \text{by Equation (17.12)} \qquad (17.13)
\end{aligned}$$

We define $B_2 = \widehat{V}$, then we replace $\widehat{V}$ by $B_2 \in \mathbb{R}^{k\times d}$ and look at this objective function,

$$\min_{U\in\mathbb{R}^{n\times k}} \|UB_2 - A\|_1,$$

where U^* denotes the optimal solution. We use a sketching matrix to sketch the RHS of matrix $UB_2 - A \in \mathbb{R}^{n\times d}$. Let $D_2^\top \in \mathbb{R}^{d\times d}$ denote a sampling and rescaling diagonal matrix corresponding to the Lewis weights of $B_2^\top \in \mathbb{R}^{d\times k}$, and let the number of nonzero entries on the diagonal of D_2 be $d_2 = O(k \log k)$. We define $\widehat{U} = AD_2(B_2D_2)^\dagger \in \mathbb{R}^{n\times k}$, $U' \in \mathbb{R}^{n\times k}$ to be the optimal solution of $\min_{U\in\mathbb{R}^{n\times k}} \|(UB_2 - A)D_2\|_1$. Recall that $U_1 \in \mathbb{R}^{n\times k}$ is the optimal of $\min_{U\in\mathbb{R}^{n\times k}} \|UB_2 - A\|_1$.

By Claim 17.3.5, we have

$$\|\widehat{U}B_2D_2 - AD_2\|_1 \leq \sqrt{d_2}\|U'B_2D_2 - AD_2\|_1.$$

According to Lemma 17.5.2 and Lemma 17.5.5, with constant probability,

$$\|\widehat{U}B_2 - A\|_1 \leq \alpha_{D_2}\sqrt{d_2}\|U_1B_2 - A\|_1,$$

where $\alpha_{B_2} = O(1)$.

We have

$$\begin{aligned}
& \|\widehat{U}B_2 - A\|_1 \\
\leq\ & \sqrt{d_2}\alpha_{D_2}\|U_1B_2 - A\|_1 \\
=\ & \sqrt{d_2}\alpha_{D_2}\|U_1\widehat{V} - A\|_1 && \text{by } B_2 = \widehat{V} \\
\leq\ & \mathrm{poly}(k)\log(d)\,\mathrm{OPT}\,. && \text{by Equation (17.13)}
\end{aligned}$$

Notice that $\widehat{U}B_2 = AD_2(B_2D_2)^\dagger(D_1B_1)^\dagger D_1A$. Setting

$$C = AD_2 \in \mathbb{R}^{n\times d_2}, U = (B_2D_2)^\dagger(D_1B_1)^\dagger \in \mathbb{R}^{d_2\times d_1}, \text{ and } R = D_1A \in \mathbb{R}^{d_1\times d},$$

we get the desired CUR decomposition,

$$\| \underbrace{AD_2}_{C} \cdot \underbrace{(B_2D_2)^\dagger (D_1B_1)^\dagger}_{U} \cdot \underbrace{D_1A}_{R} - A\|_1 \leq \mathrm{poly}(k) \log(d)\, \mathrm{OPT}\,.$$

with $\mathrm{rank}(CUR) = k$. Overall, the running time is $O(\mathrm{nnz}(A)) + (n+d)\,\mathrm{poly}(k)$.

□

17.4.7 Rank-r matrix B

17.4.7.1 Properties

Lemma 17.4.15. *Given matrix $A \in \mathbb{R}^{n\times d}$, let $\mathrm{OPT} = \min_{\mathrm{rank}-k\ A_k} \|A - A_k\|_1$. For any $r \geq k$, if rank-r matrix $B \in \mathbb{R}^{n\times d}$ is an f-approximation to A, i.e.,*

$$\|B - A\|_1 \leq f \cdot \mathrm{OPT},$$

and $U \in \mathbb{R}^{n\times k}, V \in \mathbb{R}^{k\times d}$ is a g-approximation to B, i.e.,

$$\|UV - B\|_1 \leq g \cdot \min_{\mathrm{rank}-k\ B_k} \|B_k - B\|_1,$$

then,

$$\|UV - A\|_1 \lesssim gf \cdot \mathrm{OPT}\,.$$

Proof. We define $\widetilde{U} \in \mathbb{R}^{n\times k}, \widetilde{V} \in \mathbb{R}^{k\times d}$ to be two matrices, such that

$$\|\widetilde{U}\widetilde{V} - B\|_1 \leq g \min_{\mathrm{rank}-k\ B_k} \|B_k - B\|_1,$$

and also define,

$$\widehat{U}, \widehat{V} = \operatorname*{arg\,min}_{U\in\mathbb{R}^{n\times k}, V\in\mathbb{R}^{k\times d}} \|UV - B\|_1 \text{ and } U^*, V^* = \operatorname*{arg\,min}_{U\in\mathbb{R}^{n\times k}, V\in\mathbb{R}^{k\times d}} \|UV - A\|_1,$$

Then,

$$\begin{aligned}
\|\widetilde{U}\widetilde{V} - A\|_1 &\leq \|\widetilde{U}\widetilde{V} - B\|_1 + \|B - A\|_1 && \text{by triangle inequality} \\
&\leq g\|\widehat{U}\widehat{V} - B\|_1 + \|B - A\|_1 && \text{by definition} \\
&\leq g\|U^* V^* - B\|_1 + \|B - A\|_1 && \text{by } \|\widehat{U}\widehat{V} - B\|_1 \leq \|U^* V^* - B\|_1 \\
&\leq g\|U^* V^* - A\|_1 + g\|B - A\|_1 + \|B - A\|_1 && \text{by triangle inequality} \\
&= g\,\mathrm{OPT} + (g+1)\|B - A\|_1 && \text{by definition of OPT} \\
&\leq g\,\mathrm{OPT} + (g+1)f \cdot \mathrm{OPT} && \text{by } B \text{ is } f\text{-approximation to } A \\
&\lesssim gf\,\mathrm{OPT}\,.
\end{aligned}$$

This completes the proof. □

Lemma 17.4.16. *Given a matrix $B \in \mathbb{R}^{n \times d}$ with rank r, for any $1 \leq k < r$, for any fixed $U^* \in \mathbb{R}^{n \times k}$, choose a Cauchy matrix S with $m = O(r \log r)$ rows and rescaled by $\Theta(1/m)$. With probability .999 for all $V \in \mathbb{R}^{k \times d}$, we have*

$$\|SU^*V - SB\|_1 \geq \|U^*V - B\|_1.$$

Proof. This follows by definitions in Section 17.5 and Lemma 17.5.15. □

Lemma 17.4.17. *Given a matrix $B \in \mathbb{R}^{n \times d}$ with rank r, for any $1 \leq k < r$, for any fixed $U^* \in \mathbb{R}^{n \times k}, V^* \in \mathbb{R}^{k \times d}$, choose a Cauchy matrix S with m rows and rescaled by $\Theta(1/m)$. We have*

$$\|SU^*V^* - SB\|_1 \leq O(r \log r)\|U^*V^* - B\|_1,$$

with probability .999.

Proof. Let U denote a well-conditioned basis of $[U^*V^*, B]$, then U has $\widetilde{d} = O(r)$ columns. We have

$$\begin{aligned}
\|SU\|_1 &= \sum_{i=1}^{\widetilde{d}} \sum_{j=1}^{m} |(SU_i)_j| \\
&= \sum_{i=1}^{\widetilde{d}} \sum_{j=1}^{m} |\frac{1}{m} \sum_{l=1}^{n} S_{j,l} U_{l,i}| && \text{by } S_{j,l} \sim C(0,1) \\
&= \frac{1}{m} \sum_{i=1}^{\widetilde{d}} \sum_{j=1}^{m} |c_{i,j}| && \text{by } c_{i,j} \sim C(0, \|U_i\|_1) \\
&= \frac{1}{m} \sum_{i=1}^{\widetilde{d}} \sum_{j=1}^{m} \|U_i\|_1 \cdot w_{i+(j-1)d}, && \text{by } w_{i,j} \sim |C(0,1)|
\end{aligned}$$

where the last step follows since each w_i can be thought of as a clipped half-Cauchy random variable. Define $d' = m\widetilde{d}$. Define event ξ_i to be the situation when $w_i < D$ (we will choose D later), and define event $\xi = \xi_1 \cap \xi_2 \cap \cdots \cap \xi_{d'}$. Using a similar proof as Lemma 17.5.6, which is also similar to previous work [Ind06, SW11, CDMI+13], we obtain that

$$\Pr\left[\sum_{i=1}^{m} \|SU_i\|_1 \geq \sum_{i=1}^{m} \|U_i\|_1 t\right] \lesssim \frac{\log d'}{t} + \frac{d'}{D}.$$

Choosing $t = \Theta(\log d')$ and $D = \Theta(d')$, we have

$$\Pr\left[\sum_{i=1}^{m} \|SU_i\|_1 \geq \sum_{i=1}^{m} \|U_i\|_1 O(\log d')\right] \leq \frac{1}{C},$$

for a constant C. Condition on the above event. Let $y = Ux$, for some $x \in \mathbb{R}^d$. Then for

any y,

$$\begin{aligned}
\|Sy\|_1 = &\ \|SUx\|_1 \\
\leq &\ \sum_{j=1}^{d'} \|SU_j x_j\|_1 && \text{by triangle inequality} \\
= &\ \sum_{j=1}^{d'} |x_j| \cdot \|SU_j\|_1 \\
\lesssim &\ \|x\|_\infty \log(d') \sum_{j=1}^{d'} \|U_j\|_1 \\
\lesssim &\ r \log r \|y\|_1,
\end{aligned}$$

where the last step follows by $\sum_{j=1}^{d'} \|U_j\|_1 \leq d'$ and $\|x\|_\infty \leq \|Ux\|_1 = \|y\|_1$. Choosing $C = 1000$ completes the proof. □

Lemma 17.4.18. *Given a matrix $M \in \mathbb{R}^{n\times d}$ with rank $O(r)$, choose a random matrix $S \in \mathbb{R}^{m\times n}$ with each entry drawn from a standard Cauchy distribution and scaled by $\Theta(1/m)$. We have that*

$$\|SM\|_1 \leq O(r \log r)\|M\|_1,$$

holds with probability .999.

Proof. Let $U \in \mathbb{R}^{O(r)}$ be the well-conditioned basis of M. Then each column of M can be expressed by Ux for some x. We then follow the same proof as that of Lemma 17.4.17. □

17.4.7.2 $\mathrm{poly}(k, r)$-approximation for rank-r matrix B

Theorem 17.4.19. *Given a factorization of a* rank-r *matrix $B = U_B V_B \in \mathbb{R}^{n\times d}$, where $U_B \in \mathbb{R}^{n\times r}, V_B \in \mathbb{R}^{r\times d}$, for any $1 \leq k \leq r$ there exists an algorithm which takes $(n + d) \cdot \mathrm{poly}(k)$*

Algorithm 17.7 poly(r,k)-approximation Algorithm for Rank-r matrix B

procedure L1LowRankApproxB(U_B, V_B, n, d, k, r) ▷ Theorem 17.4.19
  Set $s \leftarrow \widetilde{O}(r), r' \leftarrow \widetilde{O}(r)$, $t_1 \leftarrow \widetilde{O}(r)$, $t_2 \leftarrow \widetilde{O}(r)$.
  Choose dense Cauchy matrices $S \in \mathbb{R}^{s\times n}$, $R \in \mathbb{R}^{d\times r'}$, $T_1 \in \mathbb{R}^{t_1\times n}$, $T_2 \in \mathbb{R}^{d\times t_2}$.
  Compute $S \cdot U_B \cdot V_B$, $U_B \cdot V_B \cdot R$ and $T_1 \cdot U_B \cdot V_B \cdot T_2$.
  Compute $XY = \arg\min_{X,Y} \|T_1 U_B V_B R X Y S U_B V_B T_2 - T_1 U_B V_B T_2\|_F$.
  return $U_B V_B R X, Y S U_B V_B$.
end procedure

time to output two matrices $U \in \mathbb{R}^{n\times k}, V \in \mathbb{R}^{k\times d}$ *such that*

$$\|UV - B\|_1 \leq \mathrm{poly}(r) \min_{\mathrm{rank}-k\ B_k} \|B_k - B\|_1,$$

holds with probability $9/10$.

Proof. We define

$$\mathrm{OPT} = \min_{\mathrm{rank}-k\ B_k} \|B_k - B\|_1.$$

Choose $S \in \mathbb{R}^{s\times n}$ to be a dense Cauchy transform matrix with $s = O(r \log r)$. Using Lemma 17.4.18, Lemma 17.5.15, and combining with Equation (17.8), we have

$$\min_{U\in\mathbb{R}^{n\times k}, Z\in\mathbb{R}^{k\times s}} \|UZSB - B\|_1 \leq \sqrt{s} O(r\log r)\,\mathrm{OPT} = O(r^{1.5}\log^{1.5} r)\,\mathrm{OPT}\,.$$

Let $\alpha_s = O(r^{1.5}\log^{1.5} r)$.

We define $U^*, Z^* = \arg\min_{U\in\mathbb{R}^{n\times k}, Z\in\mathbb{R}^{k\times d}} \|UZSB - B\|_1$. For the fixed $Z^* \in \mathbb{R}^{k\times s}$, choose a dense Cauchy transform matrix $R \in \mathbb{R}^{d\times r'}$ with $r' = O(r\log r)$ and sketch on the right of $(UZSB - B)$. We obtain the minimization problem, $\min_{U\in\mathbb{R}^{n\times k}} \|UZ^*SBR - BR\|_1$.

Define $\widehat{U}^j = B^j R((Z^*SB)R)^\dagger \in \mathbb{R}^k, \forall j \in [n]$. Then $\widehat{U} = BR((Z^*SB)R)^\dagger \in \mathbb{R}^{n\times k}$. Due to Claim 17.3.5,

$$\sum_{j=1}^n \|B^j R((Z^*SB)R)^\dagger Z^*SBR - B^j R\|_1 \leq O(\sqrt{r'}) \sum_{j=1}^n \min_{U^j\in\mathbb{R}^k} \|U^j Z^*SBR - B^j R\|_1,$$

which is equivalent to

$$\|BR((Z^*SB)R)^\dagger Z^*SBR - BR\|_1 \leq O(\sqrt{r'}) \min_{U\in\mathbb{R}^{n\times k}} \|UZ^*SBR - BR\|_1,$$

where BR is an $n \times r'$ matrix and SB is an $s \times d$ matrix. Both of them can be computed in $(n+d)\,\mathrm{poly}(r)$ time.

Using Lemma 17.5.2, Lemma 17.5.15, Lemma 17.4.18, we obtain,

$$\|BR((Z^*SB)R)^\dagger Z^*SB - B\|_1 \leq O(\sqrt{r'}\alpha_{r'}) \min_{U\in\mathbb{R}^{n\times k}} \|UZ^*SB - B\|_1$$

where $\alpha_{r'} = \widetilde{O}(r)$.

We define $X^* \in \mathbb{R}^{r\times k}$, $Y^* \in \mathbb{R}^{k\times s}$,

$$X^*, Y^* = \arg\min_{X\in\mathbb{R}^{r'\times k}, Y\in\mathbb{R}^{k\times s}} \|BRXYSB - B\|_1.$$

Then,

$$\begin{aligned}
\|BRX^*Y^*SB - B\|_1 &\leq \|BR((Z^*SB)R)^\dagger Z^*SB - B\|_1 \\
&\leq O(\sqrt{r'}\alpha_{r'}) \min_{U\in\mathbb{R}^{n\times k}} \|UZ^*SB - B\|_1 \\
&= O(\sqrt{r'}\alpha_{r'}) \min_{U\in\mathbb{R}^{n\times k}, Z\in\mathbb{R}^{k\times s}} \|UZSB - B\|_1 \\
&\leq O(\sqrt{r'}\alpha_{r'}\alpha_s)\,\mathrm{OPT}\,.
\end{aligned}$$

It means that BRX, YSB gives an $O(\alpha_{r'}\alpha_s\sqrt{r'})$-approximation to the original problem.

Thus it suffices to use Lemma 17.4.20 to solve

$$\min_{X\in\mathbb{R}^{r\times k},Y\in\mathbb{R}^{k\times s}} \|BRXYSB - B\|_1,$$

by losing an extra $\mathrm{poly}(r)$ approximation ratio. Therefore, we finish the proof. □

Lemma 17.4.20. *Suppose we are given $S \in \mathbb{R}^{s\times n}$, $R \in \mathbb{R}^{d\times r'}$, and a factorization of a* rank-r *matrix $B = U_B V_B \in \mathbb{R}^{n\times d}$, where $U_B \in \mathbb{R}^{n\times r}, V_B \in \mathbb{R}^{r\times d}$. Then for any $1 \le k \le r$, there exists an algorithm which takes $(n+d)\,\mathrm{poly}(r, r', s)$ time to output two matrices $X' \in \mathbb{R}^{r'\times k}, Y' \in \mathbb{R}^{k\times s}$ such that*

$$\|BRX' \cdot Y'SB - B\|_1 \le \mathrm{poly}(r) \min_{X\in\mathbb{R}^{r'\times k},Y\in\mathbb{R}^{k\times s}} \|BRXYSB - B\|_1$$

holds with probability at least .999.

Proof. Choosing dense Cauchy matrices $T_1 \in \mathbb{R}^{t_1\times n}, T_2^\top \in \mathbb{R}^{t_2\times d}$ to sketch on both sides, we get the problem

$$\min_{X\in\mathbb{R}^{r'\times k},Y\in\mathbb{R}^{k\times s}} \|T_1BRXYSBT_2 - T_1BT_2\|_1, \tag{17.14}$$

where $t_1 = \widetilde{O}(r)$ and $t_2 = \widetilde{O}(r)$.

Define X', Y' to be the optimal solution of

$$\min_{X\in\mathbb{R}^{r'\times k},Y\in\mathbb{R}^{k\times s}} \|T_1BRXYSBT_2 - T_1BT_2\|_F.$$

Define $\widetilde{X}, \widetilde{Y}$ to the be the optimal solution of

$$\min_{X\in\mathbb{R}^{r'\times k},Y\in\mathbb{R}^{k\times s}} \|BRXYSB - B\|_1.$$

By Claim 17.3.6,

$$\|T_1BRX'Y'SBT_2 - T_1BT_2\|_1 \leq \sqrt{t_1t_2} \min_{X\in\mathbb{R}^{r'\times k}, Y\in\mathbb{R}^{k\times s}} \|T_1BRXYSBT_2 - T_1BT_2\|_1.$$

By Lemma 17.5.4, Lemma 17.4.18 and Lemma 17.5.15, we have

$$\|BRX' \cdot Y'SB - B\|_1 \leq \sqrt{t_1t_2} \cdot \widetilde{O}(r^2)\|BR\widetilde{X} \cdot \widetilde{Y}SB - B\|_1.$$

This completes the proof. □

17.5 Contraction and Dilation Bound for ℓ_1

This section presents the essential lemmas for ℓ_1-low rank approximation. Section 17.5.1 gives some basic definitions. Section 17.5.2 shows some properties implied by contraction and dilation bounds. Section 17.5.3 presents the no dilation lemma for a dense Cauchy transform. Section 17.5.4 and 17.5.5 presents the no contraction lemma for dense Cauchy transforms. Section 17.5.6 and 17.5.7 contains the results for sparse Cauchy transforms and Lewis weights.

17.5.1 Definitions

Definition 17.5.1. Given a matrix $M \in \mathbb{R}^{n\times d}$, if matrix $S \in \mathbb{R}^{m\times n}$ satisfies

$$\|SM\|_1 \leq c_1\|M\|_1,$$

then S has at most c_1-dilation on M.

Definition 17.5.2. Given a matrix $U \in \mathbb{R}^{n\times k}$, if matrix $S \in \mathbb{R}^{m\times n}$ satisfies

$$\forall x \in \mathbb{R}^k, \|SUx\|_1 \geq \frac{1}{c_2}\|Ux\|_1,$$

then S has at most c_2-contraction on U.

Definition 17.5.3. Given matrices $U \in \mathbb{R}^{n\times k}, A \in \mathbb{R}^{n\times d}$, let $V^* = \arg\min_{V\in\mathbb{R}^{k\times d}} \|UV-A\|_1$. If matrix $S \in \mathbb{R}^{m\times n}$ satisfies

$$\forall V \in \mathbb{R}^{k\times d}, \|SUV - SA\|_1 \geq \frac{1}{c_3}\|UV - A\|_1 - c_4\|UV^* - A\|_1,$$

then S has at most (c_3, c_4)-contraction on (U, A).

Definition 17.5.4. A (c_5, c_6) ℓ_1-subspace embedding for the column space of an $n\times k$ matrix U is a matrix $S \in \mathbb{R}^{m\times n}$ for which all $x \in \mathbb{R}^k$

$$\frac{1}{c_5}\|Ux\|_1 \leq \|SUx\|_1 \leq c_6\|Ux\|_1.$$

Definition 17.5.5. Given matrices $U \in \mathbb{R}^{n\times k}, A \in \mathbb{R}^{n\times d}$, let $V^* = \arg\min_{V\in\mathbb{R}^{k\times d}} \|UV-A\|_1$. Let $S \in \mathbb{R}^{m\times n}$. If for all $c \geq 1$, and if for any $\widehat{V} \in \mathbb{R}^{k\times d}$ which satisfies

$$\|SU\widehat{V} - SA\|_1 \leq c \cdot \min_{V\in\mathbb{R}^{k\times d}} \|SUV - SA\|_1,$$

it holds that

$$\|U\widehat{V} - A\|_1 \leq c \cdot c_7 \cdot \|UV^* - A\|_1,$$

then S provides a c_7-multiple-regression-cost preserving sketch of (U, A).

Definition 17.5.6. Given matrices $L \in \mathbb{R}^{n \times m_1}, N \in \mathbb{R}^{m_2 \times d}, A \in \mathbb{R}^{n \times d}, k \geq 1$, let

$$X^* = \arg \min_{\text{rank}-k \ X} \|LXN - A\|_1.$$

Let $S \in \mathbb{R}^{m \times n}$. If for all $c \geq 1$, and if for any rank $-k$ $\widehat{X} \in \mathbb{R}^{m_1 \times m_2}$ which satisfies

$$\|SL\widehat{X}N - SA\|_1 \leq c \cdot \min_{\text{rank}-k \ X} \|SLXN - SA\|_1,$$

it holds that

$$\|L\widehat{X}N - A\|_1 \leq c \cdot c_8 \cdot \|LX^*N - A\|_1,$$

then S provides a c_8-restricted-multiple-regression-cost preserving sketch of (L, N, A, k).

17.5.2 Properties

Lemma 17.5.1. *Given matrices $A \in \mathbb{R}^{n\times d}, U \in \mathbb{R}^{n\times k}$, let $V^* = \arg\min_{V\in\mathbb{R}^{k\times d}} \|UV - A\|_1$. If $S \in \mathbb{R}^{m\times n}$ has at most c_1-dilation on $UV^* - A$, i.e.,*

$$\|S(UV^* - A)\|_1 \leq c_1\|UV^* - A\|_1,$$

and it has at most c_2-contraction on U, i.e.,

$$\forall x \in \mathbb{R}^k, \|SUx\|_1 \geq \frac{1}{c_2}\|Ux\|_1,$$

then S has at most $(c_2, c_1 + \frac{1}{c_2})$-contraction on (U, A), i.e.,

$$\forall V \in \mathbb{R}^{k\times d}, \|SUV - SA\|_1 \geq \frac{1}{c_2}\|UV - A\|_1 - (c_1 + \frac{1}{c_2})\|UV^* - A\|_1,$$

Proof. Let $A \in \mathbb{R}^{n\times d}, U \in \mathbb{R}^{n\times k}, S \in \mathbb{R}^{m\times n}$ be the same as that described in the lemma. Then $\forall V \in \mathbb{R}^{k\times d}$

$$\begin{aligned}
\|SUV - SA\|_1 &\geq \|SUV - SUV^*\|_1 - \|SUV^* - SA\|_1 \\
&\geq \|SUV - SUV^*\|_1 - c_1\|UV^* - A\|_1 \\
&= \|SU(V - V^*)\|_1 - c_1\|UV^* - A\|_1 \\
&= \sum_{j=1}^{d} \|SU(V - V^*)_j\|_1 - c_1\|UV^* - A\|_1 \\
&\geq \sum_{j=1}^{d} \frac{1}{c_2}\|U(V - V^*)_j\|_1 - c_1\|UV^* - A\|_1 \\
&= \frac{1}{c_2}\|UV - UV^*\|_1 - c_1\|UV^* - A\|_1 \\
&\geq \frac{1}{c_2}\|UV - A\|_1 - \frac{1}{c_2}\|UV^* - A\|_1 - c_1\|UV^* - A\|_1 \\
&= \frac{1}{c_2}\|UV - A\|_1 - \left((\frac{1}{c_2} + c_1)\|UV^* - A\|_1\right).
\end{aligned}$$

The first inequality follows by the triangle inequality. The second inequality follows since S has at most c_1 dilation on $UV^* - A$. The third inequality follows since S has at most c_2 contraction on U. The fourth inequality follows by the triangle inequality. □

Lemma 17.5.2. *Given matrices $A \in \mathbb{R}^{n\times d}, U \in \mathbb{R}^{n\times k}$, let $V^* = \arg\min_{V\in\mathbb{R}^{k\times d}} \|UV - A\|_1$. If $S \in \mathbb{R}^{m\times n}$ has at most c_1-dilation on $UV^* - A$, i.e.,*

$$\|S(UV^* - A)\|_1 \leq c_1\|UV^* - A\|_1,$$

and has at most c_2-contraction on U, i.e.,

$$\forall x \in \mathbb{R}^k, \|SUx\|_1 \geq \frac{1}{c_2}\|Ux\|_1,$$

then S provides a $(2c_1c_2+1)$-multiple-regression-cost preserving sketch of (U, A), i.e., for all $c \geq 1$, for any $\widehat{V} \in \mathbb{R}^{k\times d}$ which satisfies

$$\|SU\widehat{V} - SA\|_1 \leq c \cdot \min_{V\in\mathbb{R}^{k\times d}} \|SUV - SA\|_1,$$

it has

$$\|U\widehat{V} - A\|_1 \leq c \cdot (2c_1c_2 + 1) \cdot \|UV^* - A\|_1,$$

Proof. Let $S \in \mathbb{R}^{m\times n}, A \in \mathbb{R}^{n\times d}, U \in \mathbb{R}^{n\times k}, V^*, \widehat{V} \in \mathbb{R}^{k\times d}$, and c be the same as stated in the lemma.

$$\begin{aligned}
\|U\widehat{V} - A\|_1 &\leq c_2\|SU\widehat{V} - SA\|_1 + (1 + c_1c_2)\|UV^* - A\|_1 \\
&\leq c_2c \min_{V\in\mathbb{R}^{k\times d}} \|SUV - SA\|_1 + (1 + c_1c_2)\|UV^* - A\|_1 \\
&\leq c_2c\|SUV^* - SA\|_1 + (1 + c_1c_2)\|UV^* - A\|_1 \\
&\leq c_1c_2c\|UV^* - A\|_1 + (1 + c_1c_2)\|UV^* - A\|_1 \\
&\leq c \cdot (1 + 2c_1c_2)\|UV^* - A\|_1.
\end{aligned}$$

The first inequality follows by Lemma 17.5.1. The second inequality follows by the guarantee of $\widehat{V}$. The fourth inequality follows since S has at most c_1-dilation on $UV^* - A$. The fifth inequality follows since $c \geq 1$. □

Lemma 17.5.3. *Given matrices $L \in \mathbb{R}^{n \times m_1}, N \in \mathbb{R}^{m_2 \times d}, A \in \mathbb{R}^{n \times d}, k \geq 1$, let*

$$X^* = \arg \min_{\text{rank}-k \ X} \|LXN - A\|_1.$$

If $S \in \mathbb{R}^{m \times n}$ has at most c_1-dilation on $LX^*N - A$, i.e.,

$$\|S(LX^*N - A)\|_1 \leq c_1 \|LX^*N - A\|_1,$$

and has at most c_2-contraction on L, i.e.,

$$\forall x \in \mathbb{R}^{m_1} \|SLx\|_1 \geq \|Lx\|_1,$$

then S provides a $(2c_1c_2+1)$-restricted-multiple-regression-cost preserving sketch of (L, N, A, k), i.e., for all $c \geq 1$, for any rank $-k$ *$\widehat{X} \in \mathbb{R}^{m_1 \times m_2}$ which satisfies*

$$\|SL\widehat{X}N - SA\|_1 \leq c \cdot \min_{\text{rank}-k \ X} \|SLXN - SA\|_1,$$

it holds that

$$\|L\widehat{X}N - A\|_1 \leq c \cdot (2c_1c_2 + 1) \cdot \|LX^*N - A\|_1.$$

Proof. Let $S \in \mathbb{R}^{m \times n}, L \in \mathbb{R}^{n \times m_1}, \widehat{X} \in \mathbb{R}^{m_1 \times m_2}, X^* \in \mathbb{R}^{m_1 \times m_2}, N \in \mathbb{R}^{m_2 \times d}, A \in \mathbb{R}^{n \times d}$, and

$c \geq 1$ be the same as stated in the lemma.

$$\begin{aligned}
\|SL\widehat{X}N - SA\|_1 &\geq \|SL\widehat{X}N - SLX^*N\|_1 - \|SLX^*N - SA\|_1 \\
&\geq \frac{1}{c_2}\|L(\widehat{X}N - X^*N)\|_1 - c_1\|LX^*N - A\|_1 \\
&\geq \frac{1}{c_2}\|L\widehat{X}N - A\|_1 - \frac{1}{c_2}\|LX^*N - A\|_1 - c_1\|LX^*N - A\|_1 \\
&= \frac{1}{c_2}\|L\widehat{X}N - A\|_1 - (\frac{1}{c_2} + c_1)\|LX^*N - A\|_1.
\end{aligned}$$

The inequality follows by the triangle inequality. The second inequality follows since S has at most c_2-contraction on L, and it has at most c_1-dilation on $LX^*N - A$. The third inequality follows by the triangle inequality.

It follows that

$$\begin{aligned}
\|L\widehat{X}N - A\|_1 &\leq c_2\|SL\widehat{X}N - SA\|_1 + (1 + c_1c_2)\|LX^*N - A\|_1 \\
&\leq c_2c \cdot \min_{\text{rank}-k\ X} \|SLXN - SA\|_1 + (1 + c_1c_2)\|LX^*N - A\|_1 \\
&\leq c_2c \cdot \|SLX^*N - SA\|_1 + (1 + c_1c_2)\|LX^*N - A\|_1 \\
&\leq cc_1c_2 \cdot \|LX^*N - A\|_1 + (1 + c_1c_2)\|LX^*N - A\|_1 \\
&\leq c \cdot (1 + 2c_1c_2)\|LX^*N - A\|_1.
\end{aligned}$$

The first inequality directly follows from the previous one. The second inequality follows from the guarantee of $\widehat{X}$. The fourth inequality follows since S has at most c_1 dilation on $LX^*N - A$. The fifth inequality follows since $c \geq 1$. □

Lemma 17.5.4. *Given matrices $L \in \mathbb{R}^{n\times m_1}, N \in \mathbb{R}^{m_2\times d}, A \in \mathbb{R}^{n\times d}, k \geq 1$, let*

$$X^* = \arg\min_{\text{rank}-k\ X} \|LXN - A\|_1.$$

Let $T_1 \in \mathbb{R}^{t_1 \times n}$ have at most c_1-dilation on $LX^*N - A$, and at most c_2-contraction on L. Let

$$\widetilde{X} = \arg \min_{\text{rank}-k \ X} \|T_1 LXN - T_1 A\|_1.$$

Let $T_2^\top \in \mathbb{R}^{t_2 \times d}$ have at most c_1'-dilation on $(T_1 L\widetilde{X}N - T_1 A)^\top$, and at most c_2'-contraction on $N^\top$. Then, for all $c \geq 1$, for any rank $-k$ $\widehat{X} \in \mathbb{R}^{m_1 \times m_2}$ *which satisfies*

$$\|T_1(L\widehat{X}N - SA)T_2\|_1 \leq c \cdot \min_{\text{rank}-k \ X} \|T_1(LXN - A)T_2\|_1,$$

it has

$$\|L\widehat{X}N - A\|_1 \leq c \cdot (2c_1c_2 + 1)(2c_1'c_2' + 1) \cdot \|LX^*N - A\|_1.$$

Proof. Apply Lemma 17.5.3 for sketch matrix T_2. Then for any $c \geq 1$, any rank $-k$ $\widehat{X} \in \mathbb{R}^{m_1 \times m_2}$ which satisfies

$$\|T_1(L\widehat{X}N - A)T_2\|_1 \leq c \cdot \min_{\text{rank}-k \ X} \|T_1(LXN - A)T_2\|_1,$$

has

$$\|T_1(L\widehat{X}N - A)\|_1 \leq c \cdot (2c_1'c_2' + 1) \cdot \|T_1(L\widetilde{X}N - A)\|_1.$$

Apply Lemma 17.5.3 for sketch matrix T_1. Then for any $c \geq 1$, any rank $-k$ $\widehat{X} \in \mathbb{R}^{m_1 \times m_2}$ which satisfies

$$\|T_1(L\widehat{X}N - A)\|_1 \leq c(2c_1'c_2' + 1) \cdot \min_{\text{rank}-k \ X} \|T_1(L\widetilde{X}N - A)\|_1,$$

has

$$\|L\widehat{X}N - A\|_1 \leq c \cdot (2c_1c_2 + 1)(2c_1'c_2' + 1) \cdot \|LX^*N - A\|_1.$$

□

Lemma 17.5.5. *Given matrices $M \in \mathbb{R}^{n\times d}, U \in \mathbb{R}^{n\times t}$, $d \geq t = \text{rank}(U), n \geq d \geq r = \text{rank}(M)$, if sketching matrix $S \in \mathbb{R}^{m\times n}$ is drawn from any of the following probability distributions of matrices, with .99 probability S has at most c_1-dilation on M, i.e.,*

$$\|SM\|_1 \leq c_1\|M\|_1,$$

and S has at most c_2-contraction on U, i.e.,

$$\forall x \in \mathbb{R}^t,\ \|SUx\|_1 \geq \frac{1}{c_2}\|Ux\|_1,$$

where $c_1,\ c_2$ are parameters depend on the distribution over S.

(I) *$S \in \mathbb{R}^{m\times n}$ is a dense Cauchy matrix: a matrix with i.i.d. entries from the standard Cauchy distribution. If $m = O(t\log t)$, then $c_1c_2 = O(\log d)$. If $m = O((t+r)\log(t+r))$, then $c_1c_2 = O(\min(\log d, r\log r))$.*

(II) *$S \in \mathbb{R}^{m\times n}$ is a sparse Cauchy matrix: $S = TD$, where $T \in \mathbb{R}^{m\times n}$ has each column i.i.d. from the uniform distribution on standard basis vectors of $\mathbb{R}^m$, and $D \in \mathbb{R}^{n\times n}$ is a diagonal matrix with i.i.d. diagonal entries following a standard Cauchy distribution. If $m = O(t^5\log^5 t)$, then $c_1c_2 = O(t^2\log^2 t\log d)$. If $m = O((t+r)^5\log^5(t+r))$, then $c_1c_2 = O(\min(t^2\log^2 t\log d, r^3\log^3 r))$.*

(III) *$S \in \mathbb{R}^{m\times n}$ is a sampling and rescaling matrix (notation $S \in \mathbb{R}^{n\times n}$ denotes a diagonal sampling and rescaling matrix with m non-zero entries): If S samples and reweights $m = O(t\log t)$ rows of U, selecting each with probability proportional to the i^{th} row's ℓ_1 Lewis weight and reweighting by the inverse probability, then $c_1c_2 = O(1)$.*

In the above, if we replace S with $\sigma \cdot S$ where $\sigma \in \mathbb{R}\backslash\{0\}$ is any scalar, then the relation between m and $c_1 c_2$ can be preserved.

For (I), if $m = O(t \log t)$, then $c_1 c_2 = O(\log d)$ is implied by Lemma 17.5.15 and Lemma 17.5.7. If $m = O((t+r)\log(t+r))$, $c_1 c_2 = O(r \log r)$ is implied by [SW11].

For (II), if $m = O(t^5 \log^5 t)$, then $c_1 c_2 = O(t^2 \log^2 t \log d)$ is implied by Corollary 17.5.19 and Lemma 17.5.17. If $m = O((t+r)^5 \log^5(t+r))$, $c_1 c_2 = O(r^3 \log^3 r)$ is implied by [MM13].

For (III), it is implied by [CP15] and Lemma 17.5.21.

17.5.3 Cauchy embeddings, no dilation

Lemma 17.5.6. *Define $U^* \in \mathbb{R}^{n\times k}, V^* \in \mathbb{R}^{k\times d}$ to be the optimal solution of $\min_{U\in\mathbb{R}^{n\times k}, V\in\mathbb{R}^{k\times d}} \|UV - A\|_1$. Choose a Cauchy matrix S with m rows and rescaled by $\Theta(1/m)$. We have that*

$$\|SU^*V^* - SA\|_1 \leq O(\log d)\|U^*V^* - A\|_1$$

holds with probability at least 99/100.

Proof. The proof technique has been used in [Ind06] and [CDMI+13]. Fix the optimal U^* and V^*, then

$$\begin{aligned}
\|SU^*V^* - SA\|_1 &= \sum_{i=1}^{d} \|S(U^*V_i^* - A_i)\|_1 \\
&= \sum_{i=1}^{d}\sum_{j=1}^{m} |\sum_{l=1}^{n} \frac{1}{m} S_{j,l} \cdot (U^*V_i^* - A_i)_l| && \text{where } S_{j,l} \sim C(0,1) \\
&= \sum_{i=1}^{d}\sum_{j=1}^{m} \frac{1}{m}|c_{i,j}| && \text{where } c_{i,j} \sim C(0, \|U^*V_i^* - A_i\|_1) \\
&= \frac{1}{m}\sum_{i=1}^{d}\sum_{j=1}^{m} \|U^*V_i^* - A_i\|_1 \cdot w_{i+d(j-1)}. && \text{where } w_{i+d(j-1)} \sim |C(0,1)|
\end{aligned} \tag{17.15}$$

where the last step follows since each w_i can be thought of as a clipped half-Cauchy random variable. Define $d' = md$. Define event ξ_i to be the situation in which $w_i < D$ (we will decide upon D later), and define event $\xi = \xi_1 \cap \xi_2 \cap \cdots \cap \xi_{d'}$. Then it is clear that $\xi \cap \xi_i = \xi, \forall i \in [d']$.

Using the probability density function (pdf) of a Cauchy and because $\tan^{-1} x \leq x$, we can lower bound Pr[event ξ_i holds] in the following sense,

$$\Pr[\xi_i] = \frac{2}{\pi}\tan^{-1}(D) = 1 - \frac{2}{\pi}\tan^{-1}(1/D) \geq 1 - \frac{2}{\pi D}.$$

By a union bound over all $i \in [d']$, we can lower bound Pr[event ξ holds],

$$\Pr[\xi] \geq 1 - \sum_{i=1}^{d'} \Pr[\overline{\xi}_i] \geq 1 - \frac{2d'}{\pi D}. \tag{17.16}$$

By Bayes rule and $\xi = \xi \cap \xi_i$, $\Pr[\xi|\xi_i] \Pr[\xi_i] = \Pr[\xi \cap \xi_i] = \Pr[\xi]$, which implies that $\Pr[\xi|\xi_i] = \Pr[\xi] / \Pr[\xi_i]$. First, we can lower bound $\mathbb{E}[w_i|\xi_i]$,

$$\begin{aligned}
\mathbb{E}[w_i|\xi_i] =& \ \mathbb{E}[w_i|\xi_i \cap \xi] \Pr[\xi|\xi_i] + \mathbb{E}[w_i|\xi \cap \overline{\xi}] \Pr[\overline{\xi}|\xi_i] \\
\geq& \ \mathbb{E}[w_i|\xi_i \cap \xi] \Pr[\xi|\xi_i] && \text{by } w_i \geq 0 \text{ and } \Pr[] \geq 0 \\
=& \ \mathbb{E}[w_i|\xi] \Pr[\xi|\xi_i] && \text{by } \xi = \xi \cap \xi_i.
\end{aligned}$$

The above equation implies that

$$\begin{aligned}
\mathbb{E}[w_i|\xi] \leq& \frac{\mathbb{E}[w_i|\xi_i]}{\Pr[\xi|\xi_i]} \\
=& \frac{\mathbb{E}[w_i|\xi_i] \Pr[\xi_i]}{\Pr[\xi \cap \xi_i]} && \text{by Bayes rule } \Pr[\xi|\xi_i] \Pr[\xi_i] = \Pr[\xi \cap \xi_i] \\
=& \frac{\mathbb{E}[w_i|\xi_i] \Pr[\xi_i]}{\Pr[\xi]} && \text{by } \xi = \xi \cap \xi_i.
\end{aligned}$$

Using the pdf of a Cauchy, $\mathbb{E}[w_i|\xi_i] = \frac{1}{\pi} \log(1 + D^2) / \Pr[\xi_i]$ and plugging it into the lower bound of $\mathbb{E}[w_i|\xi]$,

$$\mathbb{E}[w_i|\xi] \leq \frac{\mathbb{E}[w_i|\xi_i] \Pr[\xi_i]}{\Pr[\xi]} = \frac{\frac{1}{\pi} \log(1 + D^2)}{\Pr[\xi]} \leq \frac{\frac{1}{\pi} \log(1 + D^2)}{1 - \frac{2d}{\pi D}} \lesssim \log(D),$$

where the third step follows since $\Pr[\xi] \geq 1 - \frac{2d'}{\pi D}$ and the last step follows by choosing $D = \Theta(d')$.

We can conclude

$$\begin{aligned}
\mathbb{E}[\|SU^*V^* - SA\|_1|\xi] =& \frac{1}{m} \sum_{i=1}^{d} \sum_{j=1}^{m} \|U^*V_i^* - A_i\|_1 \cdot \mathbb{E}[w_{i+d(j-1)}|\xi] \\
\lesssim& (\log d') \cdot \|U^*V^* - A\|_1.
\end{aligned} \tag{17.17}$$

For simplicity, define $X = \|SU^*V^* - SA\|_1$ and $\gamma = \|U^*V^* - A\|_1$. By Markov's inequality and because $\Pr[X \geq \gamma t|\bar{\xi}] \leq 1$, we have

$$\begin{aligned}
& \Pr[X \geq \gamma t] \\
= \; & \Pr[X \geq \gamma t|\xi] \Pr[\xi] + \Pr[X \geq \gamma t|\bar{\xi}] \Pr[\bar{\xi}] \\
\leq \; & \Pr[X \geq \gamma t|\xi] + \Pr[\bar{\xi}] \\
\leq \; & \frac{\mathbb{E}[X|\xi]}{\gamma t} + \Pr[\bar{\xi}] && \text{by Markov's inequality} \\
\leq \; & \frac{\mathbb{E}[X|\xi]}{\gamma t} + \frac{2d'}{\pi D} && \text{by Equation (17.16)} \\
\lesssim \; & \frac{\log d'}{t} + \frac{2d'}{\pi D} && \text{by Equation (17.17)} \\
\leq \; & .01,
\end{aligned}$$

where choosing $t = \Theta(\log d')$ and $D = \Theta(d')$. Since $k \leq d$ and $m = \text{poly}(k)$, we have $t = \Theta(\log d)$, which completes the proof.

□

Lemma 17.5.7. *Given any matrix $M \in \mathbb{R}^{n \times d}$, if matrix $S \in \mathbb{R}^{m \times n}$ has each entry drawn from an i.i.d. standard Cauchy distribution and is rescaled by $\Theta(1/m)$, then*

$$\|SM\|_1 \leq O(\log d)\|M\|_1$$

holds with probability at least 99/100.

Proof. Just replace the matrix $U^*V^* - A$ in the proof of Lemma 17.5.6 with M. Then we can get the result directly. □

17.5.4 Cauchy embeddings, no contraction

We prove that if we choose a Cauchy matrix S, then for a fixed optimal solution U^* of $\min_{U,V} \|UV - A\|_1$, and for all V, we have that with high probability $\|SU^*V - SA\|_1$ is lower bounded by $\|U^*V - A\|_1$ up to some constant.

Lemma 17.5.8. *Define $U^* \in \mathbb{R}^{n\times k}, V^* \in \mathbb{R}^{k\times d}$ to be the optimal solution of $\min_{U\in\mathbb{R}^{n\times k} V\in\mathbb{R}^{k\times d}} \|UV - A\|_1$, where $A \in \mathbb{R}^{n\times d}$. Let $m = O(k \log k), S \in \mathbb{R}^{m\times n}$ be a random matrix with each entry an i.i.d. standard Cauchy random variable, scaled by $\Theta(1/m)$. Then with probability at least 0.95,*

$$\forall V \in \mathbb{R}^{k\times d}, \|U^*V - A\|_1 \lesssim \|SU^*V - SA\|_1 + O(\log(d))\|U^*V^* - A\|_1.$$

Proof. This follows by Lemmas 17.5.6, 17.5.15, 17.5.1.

□

17.5.5 Cauchy embeddings, k-dimensional subspace

The goal of this section is to prove Lemma 17.5.15.

Before getting into the details, we first give the formal definition of an (α, β) ℓ_1 well-conditioned basis and ϵ-net.

Definition 17.5.7 (ℓ_1 Well-conditioned basis)**.** [DDH+09] A basis U for the range of A is (α, β)-conditioned if $\|U\|_1 \leq \alpha$ and for all $x \in \mathbb{R}^k$, $\|x\|_\infty \leq \beta \|Ux\|_1$. We will say U is well-conditioned if α and β are low-degree polynomials in k, independent of n.

Note that a well-conditioned basis implies the following result.

Fact 17.5.9. *There exist $\alpha, \beta \geq 1$ such that,*

$$\forall x \in \mathbb{R}^k, \frac{1}{k\beta}\|x\|_1 \leq \|Ux\|_1 \leq \alpha \|x\|_1.$$

Proof. The lower bound can be proved in the following sense,

$$\|Ux\|_1 \geq \frac{1}{\beta}\|x\|_\infty \geq \frac{1}{\beta}\frac{1}{k}\|x\|_1,$$

where the first step follows by the properties of a well-conditioned basis, and the second step follows since $k\|x\|_\infty \geq \|x\|_1$. Then we can show an upper bound,

$$\|Ux\|_1 \leq \|U\|_1 \cdot \|x\|_1 \leq \alpha \|x\|_1,$$

where the first step follows by $\|Ux\|_1 \leq \|U\|_1 \|x\|_1$, and the second step follows using $\|U\|_1 \leq \alpha$. □

Definition 17.5.8 (ϵ-net)**.** Define $\mathcal{N}$ to an ϵ-net where, for all the $x \in \mathbb{R}^k$ that $\|x\|_1 = 1$, for any vectors two $x, x' \in \mathcal{N}$, $\|x - x'\|_1 \geq \epsilon$, for any vector $y \notin \mathcal{N}$, there exists an $x \in \mathcal{N}$ such that $\|x - y\|_1 \leq \epsilon$. Then the size of $\mathcal{N}$ is $(\frac{1}{\epsilon})^{O(k)} = 2^{O(k \log(1/\epsilon))}$.

Lemma 17.5.10 (Lemma 6 in [SW11])**.** *There is a constant $c_0 > 0$ such that for any $t \geq 1$ and any constant $c > c_0$, if S is a $t \times n$ matrix whose entries are i.i.d. standard Cauchy random variables scaled by c/t, then, for any fixed $y \in \mathbb{R}^n$,*

$$\Pr[\|Sy\|_1 < \|y\|_1] \leq 1/2^t$$

Lemma 17.5.11. *Suppose we are given a well-conditioned basis $U \in \mathbb{R}^{n \times k}$. If S is a $t \times n$ matrix whose entries are i.i.d. standard Cauchy random variables scaled by $\Theta(1/t)$, then with probability $1 - 2^{-\Omega(t)}$, for all vectors $x \in \mathcal{N}$ we have that $\|SUx\|_1 \geq \|Ux\|_1$.*

Proof. First, using Lemma 17.5.10, we have for any fixed vector $y \in \mathbb{R}^n$, $\Pr[\|Sy\| < \|y\|_1] \leq 1/2^t$. Second, we can rewrite $y = Ux$. Then for any fixed $x \in \mathcal{N}$, $\Pr[\|SUx\| < \|Ux\|_1] \leq 1/2^t$. Third, choosing $t \gtrsim k \log(1/\epsilon)$ and taking a union bound over all the vectors in the ϵ-net $\mathcal{N}$ completes the proof. □

Lemma 17.5.12 (Lemma 7 in [SW11])**.** *Let S be a $t \times n$ matrix whose entries are i.i.d standard Cauchy random variables, scaled by c/t for a constant c, and $t \geq 1$. Then there is a constant $c' = c'(c) > 0$ such that for any fixed set of $\{y_1, y_2, \cdots, y_k\}$ of d vectors in $\{y \in \mathbb{R}^n : x \in \mathbb{R}^k, Ux = y\}$,*

$$\Pr\left[\sum_{i=1}^{k} \|Sy_i\|_1 \geq c' \log(tk) \sum_{i=1}^{k} \|y_i\|_1\right] \leq \frac{1}{1000}.$$

Using Lemma 17.5.12 and the definition of an (α, β) well-conditioned basis, we can show the following corollary.

Corollary 17.5.13. *Suppose we are given an (α, β) ℓ_1 well-conditioned basis $U \in \mathbb{R}^{n \times k}$. Choose S to be an i.i.d. Cauchy matrix with $t = O(k \log k)$ rows, and rescale each entry by $\Theta(1/t)$. Then with probability 99/100, for all vectors $x \in \mathbb{R}^k$,*

$$\|SUx\|_1 \leq O(\alpha\beta \log(k)) \cdot \|Ux\|_1,$$

Proof. Define event E to be the situation when

$$\sum_{i=1}^{k} \|SU_i\|_1 < c' \log(tk) \sum_{i=1}^{k} \|U_i\|_1$$

holds, and U is a well-conditioned basis. Using Lemma 17.5.12, we can show that event E holds with probability 999/1000. We condition on Event E holding. Then for any $y = Ux$ for an $x \in \mathbb{R}^k$, we have

$$\begin{aligned}
\|Sy\|_1 &= \|SUx\|_1 \\
&\leq \sum_{j=1}^{k} \|SU_j x_j\|_1 && \text{by triangle inequality} \\
&= \sum_{j=1}^{k} |x_j| \cdot \|SU_j\|_1 \\
&\leq \|x\|_\infty c' \log(tk) \sum_{j=1}^{k} \|U_j\|_1 && \text{by Lemma 17.5.12} \\
&= \|x\|_\infty c' \log(tk)\alpha && \text{by } \|U\|_1 = \sum_{j=1}^{k} \|U_j\|_1 \leq \alpha \\
&\leq \beta \|Ux\|_1 c' \log(tk)\alpha && \text{by } \|x\|_\infty \leq \beta \|Ux\|_1 \\
&\leq \beta \|y\|_1 c' \log(tk)\alpha && \text{by } Ux = y.
\end{aligned}$$

This completes the proof. □

Lemma 17.5.14. *Given an (α, β) ℓ_1 well-conditioned basis, condition on the following two events,*

1. *For all $x \in \mathcal{N}$, $\|SUx\|_1 \geq \|Ux\|_1$. (Lemma 17.5.10)*
2. *For all $x \in \mathbb{R}^k$, $\|SUx\|_1 \leq O(\alpha\beta \log k)\|Ux\|_1$. (Corollary 17.5.13)*

Then, for all $w \in \mathbb{R}^k$, $\|SUw\|_1 \gtrsim \|Uw\|_1$.

Proof. For any $w \in \mathbb{R}^k$ we can write it as $w = \ell \cdot z$ where ℓ is some scalar and z has $\|z\|_1 = 1$. Define $y = \arg\min_{y' \in \mathcal{N}} \|y' - z\|_1$.

We first show that if U is an (α, β) well-conditioned basis for ℓ_1, then $\|U(y-z)\|_1 \leq \alpha\beta k\epsilon\|Uy\|_1$,

$$\begin{aligned}
&\|U(y-z)\|_1 && \\
&\leq \alpha\|y-z\|_1 && \text{by } \|U(y-z)\|_1 \leq \alpha\|y-z\|_1 \\
&\leq \alpha\epsilon && \text{by } \|y-z\|_1 \leq \epsilon \\
&= \alpha\epsilon\|y\|_1 && \text{by } \|y\|_1 = 1 \\
&\leq \alpha\epsilon\|Uy\|_1\beta k && \text{by } \|Uy\|_1 \geq \frac{1}{\beta k}\|y\|_1.
\end{aligned}$$

Because $\epsilon < 1/(\alpha\beta k^{c+1})$, we have

$$\|U(y-z)\|_1 \leq \frac{1}{k^c}\|Uy\|_1. \tag{17.18}$$

Using the triangle inequality, we can lower bound $\|Uy\|_1$ by $\|Uz\|_1$ up to some constant,

$$\|Uy\|_1 \geq \|Uz\|_1 - \|U(y-z)\|_1 \geq \|Uz\|_1 - \frac{1}{k^c}\|Uy\|_1, \tag{17.19}$$

which implies

$$\|Uy\|_1 \geq .99\|Uz\|_1. \tag{17.20}$$

Thus,

$$\begin{aligned}
&\|SUz\|_1 \\
&\geq \|SUy\|_1 - \|SU(z-y)\|_1 && \text{by triangle inequality} \\
&\geq \|Uy\|_1 - \|SU(z-y)\|_1 && \text{by Lemma 17.5.10} \\
&\geq \|Uy\|_1 - \alpha\beta\log(k)\cdot\|U(z-y)\|_1 && \text{by Corollary 17.5.13} \\
&\geq \|Uy\|_1 - \alpha\beta\log(k)\cdot\frac{1}{k^c}\|Uy\|_1 && \text{by Equation (17.18)} \\
&\gtrsim \|Uy\|_1 && \text{by } k^c \gtrsim \alpha\beta\log(k) \\
&\gtrsim \|Uz\|_1, && \text{by Equation (17.20)}
\end{aligned}$$

by rescaling z to w, we complete the proof. □

Lemma 17.5.15. *Given matrix $U \in \mathbb{R}^{n\times k}$, let $t = O(k\log k)$, and let $S \in \mathbb{R}^{t\times n}$ be a random matrix with entries drawn i.i.d. from a standard Cauchy distribution, where each entry is rescaled by $\Theta(1/t)$. With probability .99,*

$$\forall x \in \mathbb{R}^k, \|SUx\|_1 \gtrsim \|Ux\|_1.$$

Proof. We can compute a well-conditioned basis for U, and denote it U'. Then, $\forall x \in \mathbb{R}^k$, there exists $y \in \mathbb{R}^k$ such that $Ux = U'y$. Due to Lemma 17.5.14, with probability .99, we have

$$\forall y \in \mathbb{R}^k, \|SU'y\|_1 \gtrsim \|U'y\|_1.$$

□

17.5.6 Sparse Cauchy transform

This section presents the proof of two lemmas related to the sparse Cauchy transform. We first prove the no dilation result in Lemma 17.5.16. Then we show how to get the no contraction result in Lemma 17.5.18.

Lemma 17.5.16. *Given matrix $A \in \mathbb{R}^{n \times d}$, let U^*, V^* be the optimal solutions of $\min_{U,V} \|UV - A\|_1$. Let $\Pi = \sigma \cdot SC \in \mathbb{R}^{m \times n}$, where $S \in \mathbb{R}^{m \times n}$ has each column vector chosen independently and uniformly from the m standard basis vectors of $\mathbb{R}^m$, where C is a diagonal matrix with diagonals chosen independently from the standard Cauchy distribution, and σ is a scalar. Then*

$$\|\Pi U^* V^* - \Pi A\|_1 \lesssim \sigma \cdot \log(md) \cdot \|U^* V^* - A\|_1$$

holds with probability at least .999.

Proof. We define $\Pi = \sigma \cdot SC \in \mathbb{R}^{m \times n}$, as in the statement of the lemma. Then,

$$
\begin{aligned}
& \|\Pi(U^*V^* - A)\|_1 \\
= & \sum_{i=1}^{d} \|SD(U^*V_i^* - A_i)\|_1 \\
= & \sum_{i=1}^{d} \left\| \begin{bmatrix} S_{11} & S_{12} & \cdots & S_{1n} \\ S_{21} & S_{22} & \cdots & S_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ S_{m1} & S_{m2} & \cdots & S_{mn} \end{bmatrix} \cdot \begin{bmatrix} c_1 & 0 & 0 & 0 \\ 0 & c_2 & 0 & 0 \\ 0 & 0 & \cdots & 0 \\ 0 & 0 & 0 & c_n \end{bmatrix} \cdot (U^*V_i^* - A_i) \right\|_1 \\
= & \sum_{i=1}^{d} \left\| \begin{bmatrix} c_1S_{11} & c_2S_{12} & \cdots & c_nS_{1n} \\ c_1S_{21} & c_2S_{22} & \cdots & c_nS_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ c_1S_{m1} & c_2S_{m2} & \cdots & c_nS_{mn} \end{bmatrix} \cdot (U^*V_i^* - A_i) \right\|_1 \\
= & \sum_{i=1}^{d} \left\| \sum_{l=1}^{n} c_l S_{1l} \cdot (U^*V_i^* - A_i)_l, \sum_{l=1}^{n} c_l S_{2l} \cdot (U^*V_i^* - A_i)_l, \cdots, \sum_{l=1}^{n} c_l S_{ml} \cdot (U^*V_i^* - A_i)_l \right\|_1 \\
= & \sum_{i=1}^{d} \sum_{j=1}^{m} |\sum_{l=1}^{n} c_l S_{jl} \cdot (U^*V_i^* - A_i)_l| \\
= & \sum_{i=1}^{d} \sum_{j=1}^{m} |\widetilde{w}_{ij} \cdot \sum_{l=1}^{n} |S_{jl}(U^*V_i^* - A_i)_l|| \text{ where } \widetilde{w}_{ij} \sim C(0,1) \\
= & \sum_{i=1}^{d} \sum_{j=1}^{m} \sum_{l=1}^{n} |S_{jl}(U^*V_i^* - A_i)_l| \cdot |\widetilde{w}_{ij}| \\
= & \sum_{i=1}^{d} \sum_{j=1}^{m} \sum_{l=1}^{n} |S_{jl}(U^*V_i^* - A_i)_l| \cdot w_{i+(j-1)d} \text{ where } w_{i+(j-1)d} \sim |C(0,1)|,
\end{aligned}
$$

where the last step follows since each w_i can be thought of as a clipped half-Cauchy random variable. Define $d' = md$. Define event ξ_i to be the situation when $w_i < D$ (we will decide upon D later). Define event $\xi = \xi_1 \cap \xi_2 \cap \cdots \cap \xi_{d'}$. By choosing $D = \Theta(d')$, we can conclude

that,

$$\begin{aligned}\mathbb{E}[\|\Pi U^*V^* - \Pi A\|_1|\xi] &= \sum_{i=1}^{d}\sum_{j=1}^{m}\sum_{l=1}^{n}|S_{jl}(U^*V_i^* - A_i)_l| \cdot \mathbb{E}[w_{i+(j-1)d}|\xi] \\ &\lesssim \sum_{i=1}^{d}\sum_{j=1}^{m}\sum_{l=1}^{n}|S_{jl}(U^*V_i^* - A_i)_l| \cdot \log(d') \\ &= \sum_{i=1}^{d}\sum_{l=1}^{n}|(U^*V_i^* - A_i)_l|_1 \cdot \log(d') \\ &= \log(d') \cdot \|U^*V^* - A\|_1.\end{aligned}$$

where the third step follows from $\sum_{j=1}^{m}|S_{jl}| = 1, \forall l \in [n]$.

Thus, we can show that

$$\Pr[\|\Pi U^*V^* - \Pi A\|_1 \lesssim \log(d')\|U^*V^* - A\|_1] \geq 0.999.$$

□

Lemma 17.5.17. *Given any matrix $M \in \mathbb{R}^{n\times d}$. Let $\Pi = \sigma \cdot SC \in \mathbb{R}^{m\times n}$, where $S \in \mathbb{R}^{m\times n}$ has each column vector chosen independently and uniformly from the m standard basis vectors of $\mathbb{R}^m$, where C is a diagonal matrix with diagonals chosen independently from the standard Cauchy distribution, and σ is a scalar. Then*

$$\|\Pi M\|_1 \lesssim \sigma \cdot \log(md) \cdot \|M\|_1$$

holds with probability at least .999.

Proof. Just replace the matrix $U^*V^* - A$ in the proof of Lemma 17.5.16 with M. Then we can get the result directly. □

We already provided the proof of Lemma 17.5.16. It remains to prove Lemma 17.5.18.

Lemma 17.5.18. *Given matrix $A \in \mathbb{R}^{n\times d}$, let U^*, V^* be the optimal solution of $\min_{U,V} \|UV - A\|_1$. Let $\Pi = \sigma \cdot SC \in \mathbb{R}^{m\times n}$, where $S \in \mathbb{R}^{m\times n}$ has each column vector chosen independently and uniformly from the m standard basis vectors of $\mathbb{R}^m$, and where C is a diagonal matrix with diagonals chosen independently from the standard Cauchy distribution. Then with probability at least .999, for all $V \in \mathbb{R}^{k\times d}$,*

$$\|\Pi U^* V - \Pi A\|_1 \geq \|U^* V - A\|_1 - O(\sigma \cdot \log(md))\|U^* V^* - A\|_1.$$

Notice that $m = O(k^5 \log^5 k)$ and $\sigma = O(k^2 \log^2 k)$ according to Theorem 2 in [MM13].

We start by using Theorem 2 in [MM13] to generate the following Corollary.

Corollary 17.5.19. *Given $U \in \mathbb{R}^{n\times k}$ with full column rank, let $\Pi = \sigma \cdot SC \in \mathbb{R}^{m\times n}$ where $S \in \mathbb{R}^{m\times n}$ has each column chosen independently and uniformly from the m standard basis vectors of $\mathbb{R}^m$, and where $C \in \mathbb{R}^{n\times n}$ is a diagonal matrix with diagonals chosen independently from the standard Cauchy distribution. Then with probability .999, for all $x \in \mathbb{R}^k$, we have*

$$\|\Pi U x\|_1 \geq \|U x\|_1.$$

Notice that $m = O(k^5 \log^5 k)$ and $\sigma = O(k^2 \log^2 k)$ according to Theorem 2 in [MM13].

We give the proof of Lemma 17.5.18.

Proof. Follows by Corollary 17.5.19, Lemma 17.5.16, Lemma 17.5.1. □

17.5.7 ℓ_1-Lewis weights

In this section we show how to use Lewis weights to get a better dilation bound. The goal of this section is to prove Lemma 17.5.24 and Lemma 17.5.23. Notice that our algorithms in Section 17.4 use Lewis weights in several different ways. The first way is using Lewis weights to show an existence result, which means we only need an existential result for Lewis weights. The second way is only guessing the nonzero locations on the diagonal of a sampling and rescaling matrix according to the Lewis weights. The third way is guessing the values on the diagonal of a sampling and rescaling matrix according to the Lewis weights. The fourth way is computing the Lewis weights for a known low dimensional matrix($n \times \mathrm{poly}(k)$ or $\mathrm{poly}(k) \times d$). We usually do not need to optimize the running time of computing Lewis weights for a low-rank matrix to have input-sparsity time.

Claim 17.5.20. *Given matrix $A \in \mathbb{R}^{n \times d}$, let $B = U^* V^* - A$. For any distribution $p = (p_1, p_2, \ldots, p_n)$ define random variable X such that $X = \|B_i\|_1 / p_i$ with probability p_i. Then take any m independent samples $X^1, X^2, \ldots, X^m$, let $Y = \frac{1}{m} \sum_{j=1}^m X^j$. We have*

$$\Pr[Y \leq 1000 \|B\|_1] \geq .999$$

Proof. We can compute the expectation of X^j, for any $j \in [m]$

$$\mathbb{E}[X^j] = \sum_{i=1}^n \frac{\|B_i\|_1}{p_i} \cdot p_i = \|B\|_1.$$

Then, $\mathbb{E}[Y] = \frac{1}{m} \sum_{j=1}^m \mathbb{E}[X^j] = \|B\|_1$. Using Markov's inequality, we have

$$\Pr[Y \geq 1000 \|B\|_1] \leq .001$$

□

Lemma 17.5.21. *Given matrix $M \in \mathbb{R}^{n\times d}$, let $S \in \mathbb{R}^{n\times n}$ be any sampling and rescaling diagonal matrix. Then with probability at least .999,*

$$\|SM\|_1 \lesssim \|M\|_1.$$

Proof. Just replace the matrix B in the proof of Claim 17.5.20 with M. Then we can get the result directly. □

Using Theorem 1.1 of [CP15], we have the following result,

Claim 17.5.22. *Given matrix $A \in \mathbb{R}^{n\times d}$, for any fixed $U^* \in \mathbb{R}^{n\times k}$ and $V^* \in \mathbb{R}^{k\times d}$, choose $D \in \mathbb{R}^{n\times n}$ to be the sampling and rescaling diagonal matrix with $m = O(k \log k)$ nonzeros according to the Lewis weights of U^*. Then with probability .999, for all V,*

$$\|U^*V^* - U^*V\|_1 \leq \|DU^*V^* - DU^*V\|_1 \lesssim \|U^*V^* - U^*V\|_1.$$

Lemma 17.5.23. *Given matrix $A \in \mathbb{R}^{n\times d}, U^* \in \mathbb{R}^{n\times k}$, define $V^* \in \mathbb{R}^{k\times d}$ to be the optimal solution of $\min_{V\in\mathbb{R}^{k\times d}} \|U^*V - A\|_1$. Choose a sampling and rescaling diagonal matrix $D \in \mathbb{R}^{n\times n}$ with $m = O(k \log k)$ non-zero entries according to the Lewis weights of U^*. Then with probability at least .99, we have: for all $V \in \mathbb{R}^{k\times d}$,*

$$\|DU^*V - DA\|_1 \lesssim \|U^*V^* - U^*V\|_1 + O(1)\|U^*V^* - A\|_1 \lesssim \|U^*V - A\|_1,$$

holds with probability at least .99.

Proof. Using the above two claims, we have with probability at least .99, for all $V \in \mathbb{R}^{k\times d}$,

$$\begin{aligned}
\|DU^*V - DA\|_1 \leq & \|DU^*V - DU^*V^*\|_1 + \|DU^*V^* - DA\|_1 \\
\lesssim & \|DU^*V - DU^*V^*\|_1 + O(1)\|U^*V^* - A\|_1 \\
\lesssim & \|U^*V - U^*V^*\|_1 + O(1)\|U^*V^* - A\|_1 \\
\leq & \|U^*V - A\|_1 + \|U^*V^* - A\|_1 + O(1)\|U^*V^* - A\|_1 \\
\lesssim & \|U^*V - A\|_1,
\end{aligned}$$

where the first step follows from triangle inequality, the second step follows from Claim 17.5.20, the third step follows from Claim 17.5.22, the forth step follows from triangle inequality. □

Lemma 17.5.24. *Given matrix $A \in \mathbb{R}^{n\times d}$, define $U^* \in \mathbb{R}^{n\times k}, V^* \in \mathbb{R}^{k\times d}$ to be the optimal solution of $\min_{U\in\mathbb{R}^{n\times k}, V\in\mathbb{R}^{k\times d}} \|UV - A\|_1$. Choose a sampling and rescaling diagonal matrix $D \in \mathbb{R}^{n\times n}$ with $m = O(k \log k)$ non-zero entries according to the Lewis weights of U^*. For all $V \in \mathbb{R}^{k\times d}$ we have*

$$\|U^*V - A\|_1 \lesssim \|DU^*V - DA\|_1 + O(1)\|U^*V^* - A\|_1,$$

holds with probability at least .99.

Proof. Follows by Claim 17.5.20, Lemma 17.5.23, Lemma 17.5.1.

17.6 Hardness Results for Cauchy Matrices, Row Subset Selection, OSE

Section 17.6.1 presents some inapproximability results by using random Cauchy matrices. Section 17.6.2 is a warmup for inapproximability results for row subset selection problems. Section 17.6.3 shows the inapproximability results by using any linear oblivious subspace embedding(OSE), and also shows inapproximability results for row subset selection.

17.6.1 Hard instance for Cauchy matrices

The goal of this section is to prove Theorem 17.6.2. Before stating the result, we first introduce some useful tools in our analysis.

Lemma 17.6.1 (Cauchy Upper Tail Inequality, Lemma 3 of [CDMI+13]). *For $i \in [m]$, let C_i be m random Cauchy variables from $C(0,1)$ (not necessarily independent), and $\gamma_i > 0$ with $\gamma = \sum_{i\in[m]} \gamma_i$. Let $X = \sum_{i\in[m]} \gamma_i |C_i|$. Then, for any $t \geq 1$,*

$$\Pr[X > \gamma t] \leq O(\log(mt)/t).$$

Theorem 17.6.2. *Let $k \geq 1$. There exist matrices $A \in \mathbb{R}^{d\times d}$ such that for any $o(\log d) \geq t \geq 1$, where c can be any constant smaller than $1/3$, for random Cauchy matrices $S \in \mathbb{R}^{t\times d}$ where each entry is sampled from an i.i.d. Cauchy distribution $C(0,\gamma)$ where γ is an arbitrary real number, with probability .99 we have*

$$\min_{U\in\mathbb{R}^{d\times t}} \|USA - A\|_1 \geq \Omega(\log d/(t\log t)) \min_{\text{rank}-k\ A'} \|A' - A\|_1.$$

Proof. We define matrix $A \in \mathbb{R}^{d\times d}$

$$A = B + I = \alpha \cdot \begin{bmatrix} 1 & 1 & 1 & \cdots & 1 \\ 0 & 0 & 0 & \cdots & 0 \\ 0 & 0 & 0 & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & 0 & \cdots & 0 \end{bmatrix} + \begin{bmatrix} 1 & 0 & 0 & \cdots & 0 \\ 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & 0 & \cdots & 1 \end{bmatrix},$$

where $\alpha = \Theta(\log d)$.So, if we only fit the first row of A, we can get approximation cost at most $O(d)$.

For $t > 0$, let $S \in \mathbb{R}^{t\times d}$ denote a random Cauchy matrix where $S_{i,j}$ denotes the entry

in the ith row and jth column. Then SA is

$$SA = SB + SI = \alpha \cdot \begin{bmatrix} S_{1,1} & S_{1,1} & S_{1,1} & \cdots & S_{1,1} \\ S_{2,1} & S_{2,1} & S_{2,1} & \cdots & S_{2,1} \\ S_{3,1} & S_{3,1} & S_{3,1} & \cdots & S_{3,1} \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ S_{t,1} & S_{t,1} & S_{t,1} & \cdots & S_{t,1} \end{bmatrix} + \begin{bmatrix} S_{1,1} & S_{1,2} & S_{1,3} & \cdots & S_{1,d} \\ S_{2,1} & S_{2,2} & S_{2,3} & \cdots & S_{2,d} \\ S_{3,1} & S_{3,2} & S_{3,3} & \cdots & S_{3,d} \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ S_{t,1} & S_{t,2} & S_{t,3} & \cdots & S_{t,d} \end{bmatrix}.$$

Since $\forall \gamma$,

$$\min_{U \in \mathbb{R}^{d \times t}} \|USA - A\|_1 = \min_{U \in \mathbb{R}^{d \times t}} \|\gamma USA - A\|_1,$$

without loss of generality, we can let $S_{i,j} \sim C(0,1)$. Then we want to argue that, if we want to use SA to fit the first row of A, with high probability, the cost will be $\Omega(d \log d)$.

Let $b \in \mathbb{R}^d$ denote the first row of A. Then, we want to use SA to fit the first row of A, which is a d-dimensional vector that has entry $\Theta(\log d)$ on each position. The problem is equivalent to

$$\min_{x \in \mathbb{R}^t} \|(SA)^\top x - b\|_1.$$

First, we want to show that for any x in $\mathbb{R}^t$, if $x^\top SA$ fits the first row of A very well, then the ℓ_1 and ℓ_2 norm of vector x must have reasonable size.

Claim 17.6.3. *Define A^1 to be the first row of matrix A. With probability .999, for any column vector $x \in \mathbb{R}^{t \times 1}$, if $\|x^\top SA - A^1\|_1 \leq o(d \log d)$, then*

Property (I) : $\|x\|_2 \geq \Omega(1/t \log t)$;

Property (II) : $\|x\|_1 \leq O(\log d)$.

Proof. Consider the absolute value of the i-th coordinate of $x^\top SA$. We can rewrite $|\langle (SA)_i, x\rangle|$ in the following sense,

$$\begin{aligned} |\langle (SA)_i, x\rangle| &= |\langle (SB)_i, x\rangle + \langle (SI)_i, x\rangle| \\ &= |\langle (SB)_1, x\rangle + \langle (SI)_i, x\rangle| \\ &= |\langle (SB)_1, x\rangle + \langle S_i, x\rangle|, \end{aligned} \tag{17.21}$$

where the second step follows because $(SB)_i = (SB)_1, \forall i \in [n]$, and the last step follows because $(SI)_i = S_i, \forall i \in [n]$.

We start by proving Property I. Using the triangle inequality and Equation (17.21),

$$\begin{aligned} & |\langle (SA)_i, x\rangle| \\ \leq\ & |\langle (SB)_1, x\rangle| + |\langle S_i, x\rangle| \\ \leq\ & \|(SB)_1\|_2 \|x\|_2 + \|S_i\|_2 \|x\|_2 && \text{by Cauchy-Schwarz inequality} \\ \leq\ & \|(SB)_1\|_1 \|x\|_2 + \|S_i\|_1 \|x\|_2. && \text{by } \|\cdot\|_2 \leq \|\cdot\|_1 \end{aligned}$$

Then, according to Lemma 17.6.1, with probability .99999, we have $\|(SB)_1\|_1 \leq O(t \log t \log d)$ and for a fixed $i \in [d]$, $\|S_i\|_1 \leq O(t \log t)$. Applying the Chernoff bound, with probability $1 - 2^{-\Omega(d)}$, there are a constant fraction of i such that $\|S_i\|_1 = O(t \log t)$. Taking the union bound, with probability .9999, there exists a constant fraction of i such that $|\langle (SA)_i, x\rangle| \leq O(t \log t \log d)\|x\|_2$. Because $A_{1,i} \geq \alpha$, $\forall i \in [d]$ where $\alpha = \Theta(\log d)$, we need $\|x\|_2 \geq \Omega(1/t \log t)$. Otherwise, the total cost on this constant fraction of coordinates will be at least $\Omega(d \log d)$.

For Property II, for a fixed $x \in \mathbb{R}^t$, we have

$$\begin{aligned}
&|\langle (SA)_i, x\rangle| \\
=&|\langle (SB)_1, x\rangle + \langle S_i, x\rangle| && \text{by Equation (17.21)} \\
=&\left|\Theta(\log d)\|x\|_1 w_1'(x) + \|x\|_1 w_i'(x)\right|.
\end{aligned}$$

where $w_i'(x) \sim C(0,1)$, and for different x, $w_i'(x)$ are different. Then for a fixed $x \in \mathbb{R}^t$ with probability at least 0.9, $|w_i'(x)| = \Omega(1)$, and with probability 0.5, $w_1'(x)$ and $w_i'(x)$ have the same sign. Since these two events are independent, with probability at least 0.45, we have

$$|\langle (SA)_i, x\rangle| \geq \|x\|_1 \cdot \Omega(1).$$

Applying the Chernoff bound, with probability at least $1 - 2^{\Theta(d)}$, there exists a 3/10 fraction of i such that $|\langle (SA)_i, x\rangle| \geq \|x\|_1 \Omega(1)$.

We build an ϵ-net $\mathcal{N}$ for $x \in \mathbb{R}^t$ on an ℓ_1-norm unit ball, where $\epsilon = 1/(t^2 \log^2 d)$. Thus the size of the net is $|\mathcal{N}| = 2^{\widetilde{\Theta}(t)}$. Consider y to be an arbitrary vector, let $y/\|y\|_1 = x + \delta$, where x is the closest point to $y/\|y\|_1$ and $x \in \mathcal{N}$. For any $\delta \in \mathbb{R}^t$,

$$\begin{aligned}
|\langle (SA)_i, \delta\rangle| &= |\langle (SB)_1, \delta\rangle + \langle (SI)_i, \delta\rangle| \\
&\leq |\langle (SB)_1, \delta\rangle| + |\langle (SI)_i, \delta\rangle| && \text{by triangle inequality} \\
&\leq \|(SB)_1\|_2 \|\delta\|_2 + \|S_i\|_2 \|\delta\|_2 && \text{by Cauchy-Schwarz inequality} \\
&\leq \|(SB)_1\|_2 \|\delta\|_1 + \|S_i\|_2 \|\delta\|_1. && \text{by } \|\cdot\|_2 \leq \|\cdot\|_1
\end{aligned}$$

As we argued before, With probability .99999, we have

$$\|(SB)_1\|_2 \leq \|(SB)_1\|_1 \leq O(t \log t \log d), \tag{17.22}$$

and with probability $1-2^{-\Theta(d)}$, there is a $9/10$ fraction of $i \in [d]$, $\|S_i\|_2 \leq \|S_i\|_1 = O(t \log t)$. Therefore, with probability .999, for any $\delta \in \mathbb{R}^t$, there exists a $9/10$ fraction of i such that $|\langle (SA)_i, \delta \rangle| \leq \Theta(t \log t \log d)\|\delta\|_1$.

Therefore, with probability .99, $\forall y \in \mathbb{R}^t$, due to the pigeonhole principle, there is a $3/10 + 9/10 - 1 = 1/5$ fraction of i such that

$$
\begin{aligned}
& |\langle (SA)_i, y \rangle| \\
= & \|y\|_1 \cdot |\langle (SA)_i, y/\|y\|_1 \rangle| \\
= & \|y\|_1 \cdot |\langle (SA)_i, x + \delta \rangle| && \text{by } y/\|y\|_1 = x + \delta \\
\geq & \|y\|_1 \cdot \big(|\langle (SB)_i, x \rangle + \langle (SI)_i, x \rangle| - |\langle (SB)_1, \delta \rangle + \langle (SI)_i, \delta \rangle| \big) && \text{by triangle inequality} \\
\geq & \|y\|_1 \big(\Omega(1) - \epsilon O(t \log t \log d) \big) \\
\geq & \|y\|_1 \Omega(1).
\end{aligned}
$$

So $\|y\|_1$ should be $O(\log d)$. Otherwise, the total cost on this $1/5$ fraction of coordinates is at least $\Omega(d \log d)$.

Combining Property (I) and (II) completes the proof. □

Next, we need to show the following claim is true,

Claim 17.6.4. *For any d independent Cauchy random variables $x_1, x_2, \cdots, x_d$ from $C(0,1)$, with probability $1 - 1/\operatorname{poly}(t \log d)$, for any $j \in [1, 2, \cdots, \log d - \Theta(\log \log(t \log d))]$, there are $\Omega(d/2^j)$ variables belonging to $(2^j, 2^{j+1}]$.*

Proof. For each Cauchy random variable x_i, we have for any $j \in [1, 2, \cdots, \Theta(\log d)]$,

$$
\Pr\Big[|x_i| \in (2^j, 2^{j+1}] \Big] = \Theta(1/2^j).
$$

We define the indicator random variable $z_{i,j}$

$$z_{i,j} = \begin{cases} 1 & \text{if } |x_i| \in (2^j, 2^{j+1}], \\ 0 & \text{otherwise.} \end{cases}$$

We define $z_j = \sum_{i=1}^{d} z_{i,j}$. It is clear that $\mathbb{E}[z_{i,j}] = \Theta(1/2^j)$. We use a Chernoff bound,

$$\Pr[X < (1-\delta)\mu] < \left(\frac{e^{-\delta}}{(1-\delta)^{1-\delta}} \right)^{\mu},$$

and set $X = z_j$, $\delta = 1/2$, $\mu = \mathbb{E}[z_j]$. Then, this probability is at most $2^{-\Omega(\mu)} = 2^{-\Omega(\mathbb{E}[z_j])}$. For any $j \in [1, \log d - \Theta(\log\log(t \log d))]$, we have $\mathbb{E}[z_j] = d\,\mathbb{E}[z_{ij}] = \Omega(d/2^j) = \Omega(\log(t \log d))$. Thus, this probability is at most $1/\operatorname{poly}(t \log d)$. Overall, we have

$$\Pr\left[z_j \gtrsim d/2^j \right] \geq 1 - 1/\operatorname{poly}(t \log d).$$

Taking a union bound over $\Theta(\log d)$ such j, we complete the proof.

□

Claim 17.6.5. *Let $1 > c_1 > c_2 > 1/3 > 0$ be three arbitrary constants. We fix the first column of $(SI)^\top \in \mathbb{R}^{d \times t}$. All the rows are grouped together according to the value in the first column. Let R_j be the set of rows for which the entry in the first column is $\in (2^j, 2^{j+1}]$. With probability at least $1 - O(1/\operatorname{poly}(t \log(d)))$, for any $j \in [c_2 \log d, c_1 \log d]$, the following event holds. There exist $\Omega(d/2^j)$ rows such that the first coordinate $\in (2^j, 2^{j+1}]$ and all the other coordinates are at most $O(d^{1/3})$.*

Proof. Let R_j be a subset of rows of $S^\top$, such that for any row in R_j, the first coordinate is $\in (2^j, 2^{j+1}]$. By Claim 17.6.4, we have that with probability $1 - 1/\operatorname{poly}(t \log d)$, for any $j \in [c_2 \log d, c_1 \log d]$, $|R_j| \geq \Omega(d/2^j)$. We want to show that for any $j \in [c_2 \log d, c_1 \log d]$,

there exists a constant fraction of rows in R_j such that, the remaining coordinates are at most $O(d^{1/3})$.

For a fixed row in R_j and a fixed coordinate in that row, the probability that the absolute value of this entry is at least $\Omega(d^{1/3})$ is at most $O(1/d^{1/3})$. By taking a union bound, with probability at least $1 - O(t/d^{1/3})$, the row has every coordinate of absolute value at most $O(d^{1/3})$.

By applying a Chernoff bound, for a fixed subset R_j of rows, the probability that there is a constant fraction of these rows for which every coordinate except the first one in absolute value is at most $O(d^{1/3})$, is at least $1 - 2^{-\Theta(|R_j|)} \geq 1 - 2^{-\Theta(d^{1-c_1})} \geq 1 - O(1/\operatorname{poly}(t \log(d)))$.

After taking a union over all the j, we complete the proof. □

Claim 17.6.6. *With probability at least $1 - O(1/t)$, the absolute value of any coordinate in column vector $(SB)_1 \in \mathbb{R}^{t \times 1}$ is at most $O(t^2 \log d)$.*

Proof. Because each entry is sampled from a Cauchy distribution $C(0, 1)$ scaled by $O(\log d)$, then with probability at most $O(1/t^2)$, the absolute value of one coordinate is at least $\Omega(t^2 \log d)$. Taking a union over all the coordinates, we complete the proof. □

Because $\|x\|_1 \leq O(\log d), \|x\|_2 \geq \Omega(1/t \log t)$, there exists one coordinate i such that the absolute value of it is at least $\Omega(1/t \log t)$ and all the other coordinates are most $O(\log d)$. We can assume that $i = 1$ for now. (To remove this assumption, we can take a union bound over all the possibilities for $i \in [t]$.) According to Claim 17.6.5 and 17.6.6, let $\widehat{R}_j$ denote a subset of R_j, which is a "good" constant fraction of R_j. Considering the ℓ_1-norm of all

coordinates $l \in \widehat{R}_j \subset R_j \subset [d]$, we have

$$\begin{aligned}
&\sum_{l\in\widehat{R}_j} |((SA)^\top x)_l - O(\log d)| \\
\geq &\sum_{l\in\widehat{R}_j} |\langle (SA)_l, x\rangle - O(\log d)| \\
\geq &\sum_{l\in\widehat{R}_j} \Big(|(SI)_{1,l}\cdot x_1| - \sum_{j=2}^{t} |(SI)_{j,l}\cdot x_j| - |\langle (SB)_l, x\rangle| - O(\log d) \Big) \\
\geq &\sum_{l\in\widehat{R}_j} \Big(\Omega(\frac{2^j}{t\log t}) - O(td^{1/3}\log d) - |\langle (SB)_1, x\rangle| - O(\log d) \Big) \\
\geq &\sum_{l\in\widehat{R}_j} \Big(\Omega(\frac{2^j}{t\log t}) - O(td^{1/3}\log d) - \|(SB)_1\|_1 \|x\|_1 - O(\log d) \Big) \\
\geq &\sum_{l\in\widehat{R}_j} \Big(\Omega(\frac{2^j}{t\log t}) - O(td^{1/3}\log d) - O(t\log t\log^2 d) - O(\log d) \Big) \\
\gtrsim &\sum_{l\in\widehat{R}_j} 2^j/(t\log t) \\
\gtrsim &\, d/2^j \cdot 2^j/(t\log t) \\
\gtrsim &\, d/(t\log t).
\end{aligned}$$

The second inequality follows by the triangle inequality. The third inequality follows by $(SB)_1 = (SB)_l$, $|x_1| = \Omega(1/t\log t), (SI)_{1,l} \in [2^j, 2^{j+1})$, and $\forall j \neq 1, |x_j| < O(\log d), (SI)_{j,l} \leq O(d^{1/3})$. The fourth inequality follows by Cauchy-Schwarz and $\|\cdot\|_2 \leq \|\cdot\|_1$. The fifth inequality follows by Equation (17.22) and Claim 17.6.3. The sixth inequality follows by $t = o(\log d)$ where c is a constant smaller than $1/3$ and $2^j \geq d^{c_2} > \mathrm{poly}(t)$. The seventh inequality follows from $|\widehat{R}_j| \geq \Omega(d/2^j)$.

Since there are $c1 - c2$ different j, the total cost is $\Omega(d\log d/(t\log t))$. The gap then is $\Omega(\log d/(t\log t))$. This completes the proof of Theorem 17.6.2. □

17.6.2 Hard instance for row subset selection

Theorem 17.6.7. *Let $\epsilon \in (0,1)$. There exists a value $k \geq 1$ and matrix $A \in \mathbb{R}^{(d-1)\times d}$ such that, for any subset R of rows of A, letting B be the ℓ_1-projection of each row of A onto R, we have*

$$\|A - B\|_1 > (2-\epsilon) \min_{\text{rank}-k \ A'} \|A' - A\|_1,$$

unless $|R| \gtrsim \epsilon d$.

Proof. We construct the $(d-1) \times d$ matrix A in the following way. The first column is all 1s, and then the remaining $(d-1) \times (d-1)$ matrix is the identity matrix.

$$A = \begin{bmatrix} 1 & 1 & 0 & 0 & \cdots & 0 \\ 1 & 0 & 1 & 0 & \cdots & 0 \\ 1 & 0 & 0 & 1 & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ 1 & 0 & 0 & 0 & \cdots & 1 \end{bmatrix}.$$

Note that $\min_{\text{rank}-1 \ A'} \|A - A'\|_1 = \text{OPT} \leq d-1$, since one could choose A' to have the first column all 1s and remaining entries 0. On the other hand, consider any subset of r rows. We can permute the columns and preserve the entrywise ℓ_1-norm so w.l.o.g., we can take the first r rows for R.

Because we are taking the first r rows, we do not pay any cost on the first rows. To minimize the cost on the i-th row, where $i \in \{r+1, r+2, \ldots, d\}$, let v_i denote the row vector we use for the i-th row. Then v_i can be written as a linear combination of the first r rows $\{A^1, A^2, \ldots, A^r\}$,

$$v_i = \sum_{j=1}^{r} \alpha_{i,j} A^j.$$

Then the cost of using v_i to approximate the i-th row of A is:

$$\begin{aligned}
\|v_i - A^i\|_1 = & \text{ (cost in 1st col) + (cost in 2nd,3rd, } \ldots, r+1\text{th cols) + (cost in } i+1\text{th col)} \\
= & \ |\sum_{j=1}^{r} \alpha_{i,j} - 1| + \sum_{j=1}^{r} |\alpha_{i,j}| + 1 \\
\geq & \ |\sum_{j=1}^{r} \alpha_{i,j} - 1 - \sum_{j=1}^{r} \alpha_{i,j}| + 1 \text{ by triangle inequality} \\
= & \ 2.
\end{aligned}$$

Hence, the cost of using v_i to approximate the i-th row of A is at least 2. So in total, across these $(d-1-r)$ rows, the algorithm pays at least $2(d-1-r)$ cost, which needs to be at most $C(d-1)$, and therefore $r \geq (d-1)(1-C/2) = \Omega(\epsilon d)$. Choosing $C = 2-\epsilon$ completes the proof.

□

Theorem 17.6.8. *There exists a value $k \geq 1$ and matrix $A \in \mathbb{R}^{(d-1)\times d}$ such that, there is no algorithm that is able to output a* rank $-k$ *matrix B in the row span of A satisfying*

$$\|A - B\|_1 < 2(1 - \Theta(\frac{1}{d})) \min_{\text{rank}-k \ A'} \|A' - A\|_1.$$

Proof. We use the same matrix A as in the previous theorem.

$$A = \begin{bmatrix} 1 & 1 & 0 & 0 & \cdots & 0 \\ 1 & 0 & 1 & 0 & \cdots & 0 \\ 1 & 0 & 0 & 1 & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ 1 & 0 & 0 & 0 & \cdots & 1 \end{bmatrix}.$$

Let vector v be $(\sum_{i=1}^{d-1} \beta_i, \beta_1, \ldots, \beta_{d-1})$. For the i-th row of A, we use $\alpha_j \cdot v$ to cancel the cost of that row, where α_j is a scalar. Then for any $\beta_1, \ldots, \beta_{d-1}, \alpha_1, \ldots, \alpha_{d-1}$, we can

compute the entire residual cost,

$$f(\alpha,\beta) = \sum_{j=1}^{d-1} \|A^j - v\alpha_j\|_1$$
$$= \sum_{j=1}^{d-1} \left(|1-\alpha_j(\sum_{i=1}^{d-1}\beta_i)| + |1-\alpha_j\beta_j| + \sum_{i\neq j}|\alpha_j\beta_i| \right).$$

In the next few paragraphs, we will show that optimizing $f(\alpha,\beta)$ over some extra constraints for α,β does not change the optimality. Without loss of generality, we can assume that $\sum_{i=1}^{d-1}\beta_i = 1$. If not we can just rescale all the α_i. Consider a fixed index j. All the terms related to α_j and β_j are,

$$\left|1-\alpha_j(\sum_{i=1}^{d-1}\beta_i)\right| + |1-\alpha_j\beta_j| + \sum_{i\neq j}|\alpha_j\beta_i| + |\alpha_i\beta_j|.$$

We first show a simple proof by assuming $\beta_j \geq 0$. Later, we will prove the general version which does not have any assumptions.

Handling a special case We can optimize $f(\alpha,\beta)$ in the following sense,

$$\begin{aligned} &\min\ f(\alpha,\beta) \\ &\text{s.t.}\ \sum_{j=1}^{d-1}\beta_j = 1 \\ &\quad \alpha_j \geq 0, \beta_j \geq 0, \forall j \in [d-1]. \end{aligned}$$

For each j, we consider three cases. Case I, if $\alpha_j \geq \frac{1}{\beta_j}$, then

$$|1-\alpha_j| + |1-\alpha_j\beta_j| + \sum_{i\neq j}\alpha_j\beta_i = \qquad \alpha_j - 1 + \alpha_j\beta_j - 1 + \sum_{i\neq j}\alpha_j\beta_i$$
$$= 2\alpha_j - 2 \geq 2(1/\beta_j - 1) \geq 2(1-\beta_j),$$

where the last step follows by $\beta_j + 1/\beta_j \geq 2$. Case II, if $1 \leq \alpha_j < 1/\beta_j$, then

$$|1-\alpha_j| + |1-\alpha_j\beta_j| + \sum_{i\neq j} \alpha_j\beta_i = \qquad \alpha_j - 1 + 1 - \alpha_j\beta_j + \sum_{i\neq j} \alpha_j\beta_i$$
$$= 2\alpha_j(1-\beta_j) \geq 2(1-\beta_j).$$

Case III, if $\alpha_j < 1$, then

$$|1-\alpha_j| + |1-\alpha_j\beta_j| + \sum_{i\neq j} \alpha_j\beta_i = \qquad 1 - \alpha_j + 1 - \alpha_j\beta_j + \sum_{i\neq j} \alpha_j\beta_i$$
$$= 2(1-\alpha_j\beta_j) \geq 2(1-\beta_j).$$

Putting it all together, we have

$$f(\alpha,\beta) \geq \sum_{j=1}^{d-1} 2(1-\beta_j) = 2(d-1) - 2\sum_{j=1}^{d-1}\beta_j = 2(d-2).$$

To handle the case where β_i can be negative Without loss of generality, we can assume that $\sum_{i=1}^{d-1}\beta_i = 1$. Notice that we can also assume $\beta_i \neq 0$, otherwise it means we do not choose that row. We split all β_i into two disjoint sets S and $\overline{S}$. For any $i \in S$, $\beta_i > 0$ and for any $i \in \overline{S}$, $\beta_i < 0$.

As a first step, we discuss the case when all the j are in set S. Case I, if $1 - \alpha_j\sum_{i=1}^{d-1}\beta_i < 0$ and $1-\alpha_j\beta_j < 0$, then it means $\alpha_j \geq \max(\frac{1}{\sum_{i=1}^{d-1}\beta_i}, \frac{1}{\beta_j})$. The cost of that row is,

$$= \alpha_j \sum_{i=1}^{d-1}\beta_i - 1 + \alpha_j\beta_j - 1 + \sum_{i\neq j}|\alpha_j\beta_i|$$
$$= 2\alpha_j\beta_j + 2\alpha_j \sum_{i\in S\setminus j}\beta_i - 2.$$

If $\beta_j \geq 1$, then $\alpha_j \geq 1$. The cost is at least $2\sum_{i\in S\setminus j}\beta_i$. If $\beta_j < 1$, then $\alpha_j \geq 1/\beta_j$, and the cost is at least $2\frac{1}{\beta_j}\sum_{i\in S\setminus j}\beta_i$. If there are C such j in Case I, then the total cost of Case I is at least 0 if $C = 1$, and $2(C-1)$ if $C \geq 2$.

Case II, if $1 - \alpha_j \sum_{i=1}^{d-1}\beta_i < 0$ and $1 - \alpha_j\beta_j > 0$, then it means $1 < \alpha_j < 1/\beta_j$. The cost of that row is,

$$\begin{aligned}
&= \alpha_j \sum_{i=1}^{d-1}\beta_i - 1 + 1 - \alpha_j\beta_j + |\alpha_j| \sum_{i\neq j}|\beta_j| \\
&= 2\alpha_j \sum_{i\in S\setminus j}\beta_i \\
