## **La Quinta Channel Environmental Monitoring Project - Benthic Diversity**

### **ABSTRACT**

Analysis of benthic invertebrate communities have been widely used in pollution detection and monitoring studies. The environment of concern is the La Quinta Channel, which is located in Corpus Christi Bay. La Quinta Channel serves several industrial plants and a naval station. Three stations were chosen in La Quinta Channel and three reference stations were chosen in Corpus Christi Bay. Benthic animals were collected, identified, enumerated, weighed to assess if La Quinta Channel was different from Corpus Christi Bay. The indicators were similar among all study sites, thus indicating a healthy environment in La Quinta Channel.

## INTRODUCTION

### Background

Man has had a negative effect on estuaries in a variety of ways. The obvious of which is chemical pollutants. The reduced current flow rates in estuaries causes settlement of sediments. Many chemical toxins and suspended wastes settle along with natural sedimentation. Accumulation of these toxins can have a devastating effect that can reach all the way up the food chain to man (Osborne and Grace, 1981).

The Coastal Bend Bays Foundation (CBBF) is a non-profit organization dedicated to the conservation and wise use of our natural resources, especially the bays and estuaries. The CBBF, in a cooperative effort with Occidental Chemical Co. and the Texas Natural Resource Conservation Commission (TNRCC), has initiated a project to perform an environmental assessment of the La Quinta Channel in Corpus Christi Bay, Texas.

There is a need to determine the health of this body of water and to determine the baseline data for an on-going monitoring program. This project could also serve as a model for future expansion of the program to include as many as 20 or more additional sites in future years.

### Use of Benthic Biodiversity in Applied Studies

Analysis of benthic (i.e., bottom dwelling) invertebrate communities may be used for many different purposes. One such purpose is the detection of pollution and another is the estimation of overall anthropogenic effects on the environment (Oglesby, 1967). We expect indicator organisms to do for us today what canaries did for miners in the 18th and 19th centuries. Indicator organisms should have characteristics that make them useful in applied research (Soule, 1988). 1) They should direct our attention to qualities of the environment. 2) They should give us a sign that some characteristic is present. 3) They should express a generalization about the environment. 4) They should suggest a cause, outcome or remedy. 5) Finally, they should show a need for action.

Benthic species and communities, rather than fish or planktonic fauna, have often been regarded as being the best indicators of organic pollution (Wass, 1967; Flint, Kalke, and Rabalais, 1981). There are several reasons why these organisms are good indicators of environmental stress. 1) Because of gravity, everything ends up in bottom sediments. Even pollutants in freshwater will be transported to the coastal sea bottoms. 2) Everything dies and ends up in the detrital food chain, which is utilized by the benthos. Pollutants are usually tightly coupled to organic matrices, therefore benthos have great exposure through their niche (food) and habitat (living spaces) to pollutants. 3) Benthos are relatively long-lived and sessile, so they integrate pollutant effects of over long temporal and spatial scales. 4) Benthic invertebrates are sensitive to pollutants. 5) Bioturbation and irrigation of sediments by benthos effect the

mobilization and burial of xenobiotic materials. Because of these characteristics, benthos have been used widely in applied research.

There are also ecological models that provide a scientific basis for interpreting the data generated in benthic monitoring and detection studies. These approaches utilize many single species, community studies, and statistical models. One of the most important concepts is the succession model proposed by Rhoads *et al.* (1978). They applied scientific theories of ecological succession and its relation to productivity to suggest ways that dredge-spoil could be managed to enhance productivity. One important aspect of this theory is that normal sediments will have a diverse assemblage and deeper dwelling organisms than a polluted or disturbed environment. Thus, we have a scientific justification for biological diversity studies. Since this classic study, numerous other studies have demonstrated that benthic biological diversity is an excellent indicator of environmental health. The goal of the present study was to obtain data on benthic abundance, biomass, and community diversity to assist in assessing the environmental condition of the La Quinta Channel. The assessment is based on the applications of ecological principles.

## METHODS

### Sampling Design and Study Sites

The environment of concern is the La Quinta Channel, which is located in Corpus Christi Bay, Texas. The La Quinta Channel is a spur of the main Corpus Christi Ship Channel, which serves the Port of Corpus Christi. La Quinta Channel serves several industrial plants, including Dupont Chemical, Reynolds Aluminum, and Occidental Chemical Company. Three stations were located in the Channel. Three reference stations were located in Corpus Christi Bay away from any obvious anthropogenic influence. Benthic samples were taken October 1992, January 1993, April 1993, and July 1993. Using three stations in each environment allows us to test for differences between the La Quinta Channel and Corpus Christi Bay.

In the Corpus Christi Bay, the study sites have the designation of NCC, NCD, and NCE (Fig. 1). NCC is located 3,000 m southeast of the Nueces Bay Causeway at a depth of 3.4 m. NCD is located 3,000 m northeast of the mouth of Fish Pass on the bay side of Mustang Island and is 2.7 m deep. NCE, which is 3.4 m deep, is 3,600 m south southwest of Point Mustang. The prefix NC- is used to conform with nomenclature used in other studies (Montagna and Kalke, 1992). NC stands for the Nueces-Corpus Christi Bay system.

The study sites located in La Quinta (LQ) Channel have been designated LQA, LQB, and LQC (Fig. 2). Station LQA is located behind Occidental Chemical Co., Inc. on the south side of the channel; the collections were taken at a depth of 2.5 m. LQB is in Ingleside Cove, about midway through the channel, and is at a depth of 1.8 m. LQC, with a depth of 2.5 m, is about 225 m ESE of Naval Station Ingleside.

Fig. 1. Map of Corpus Christi Bay. Reference site NCC is located near the mouth of Nueces Bay, NCD is located north of the Laguna Madre, and NCE is just south of Point Mustang. All stations are located away from any obvious anthropogenic influences.

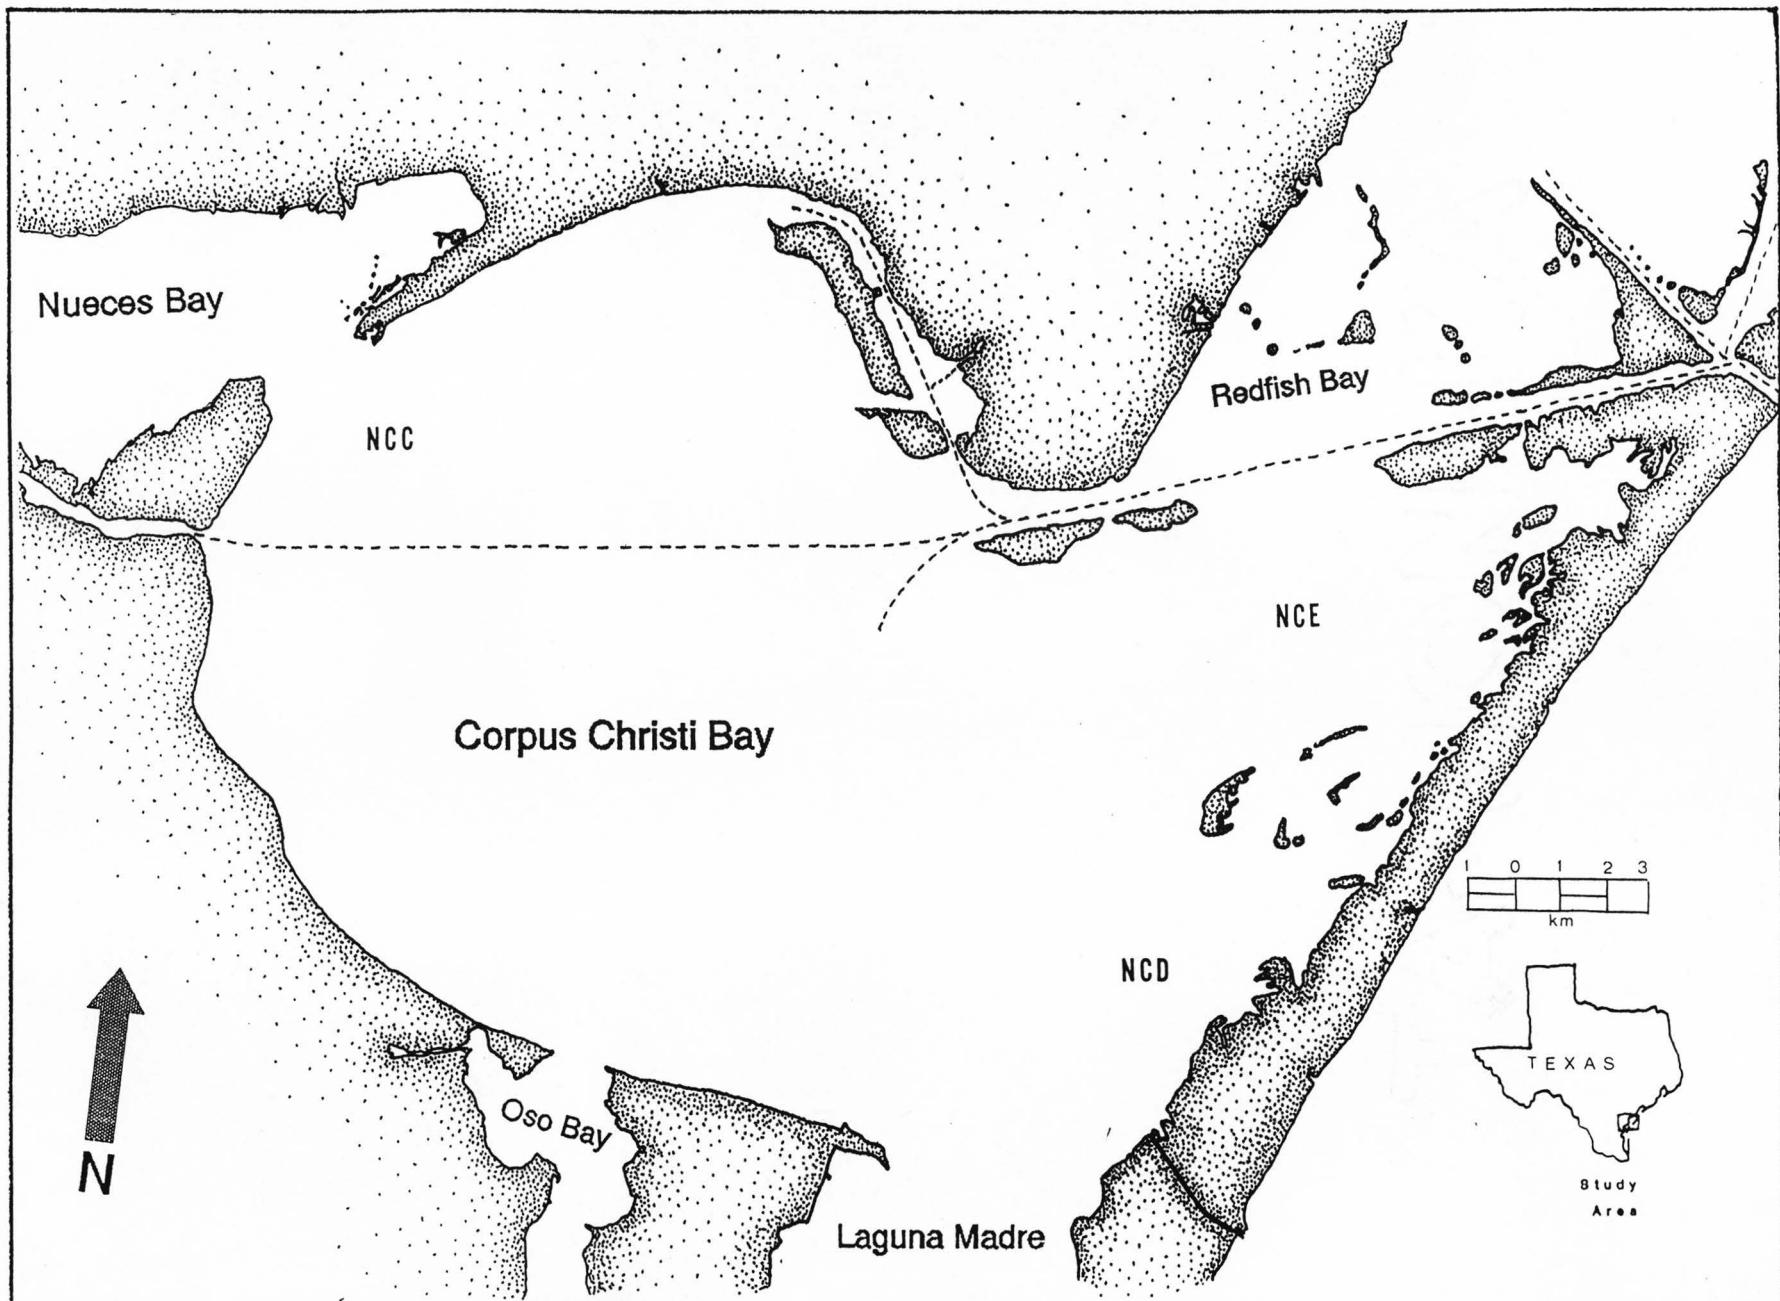

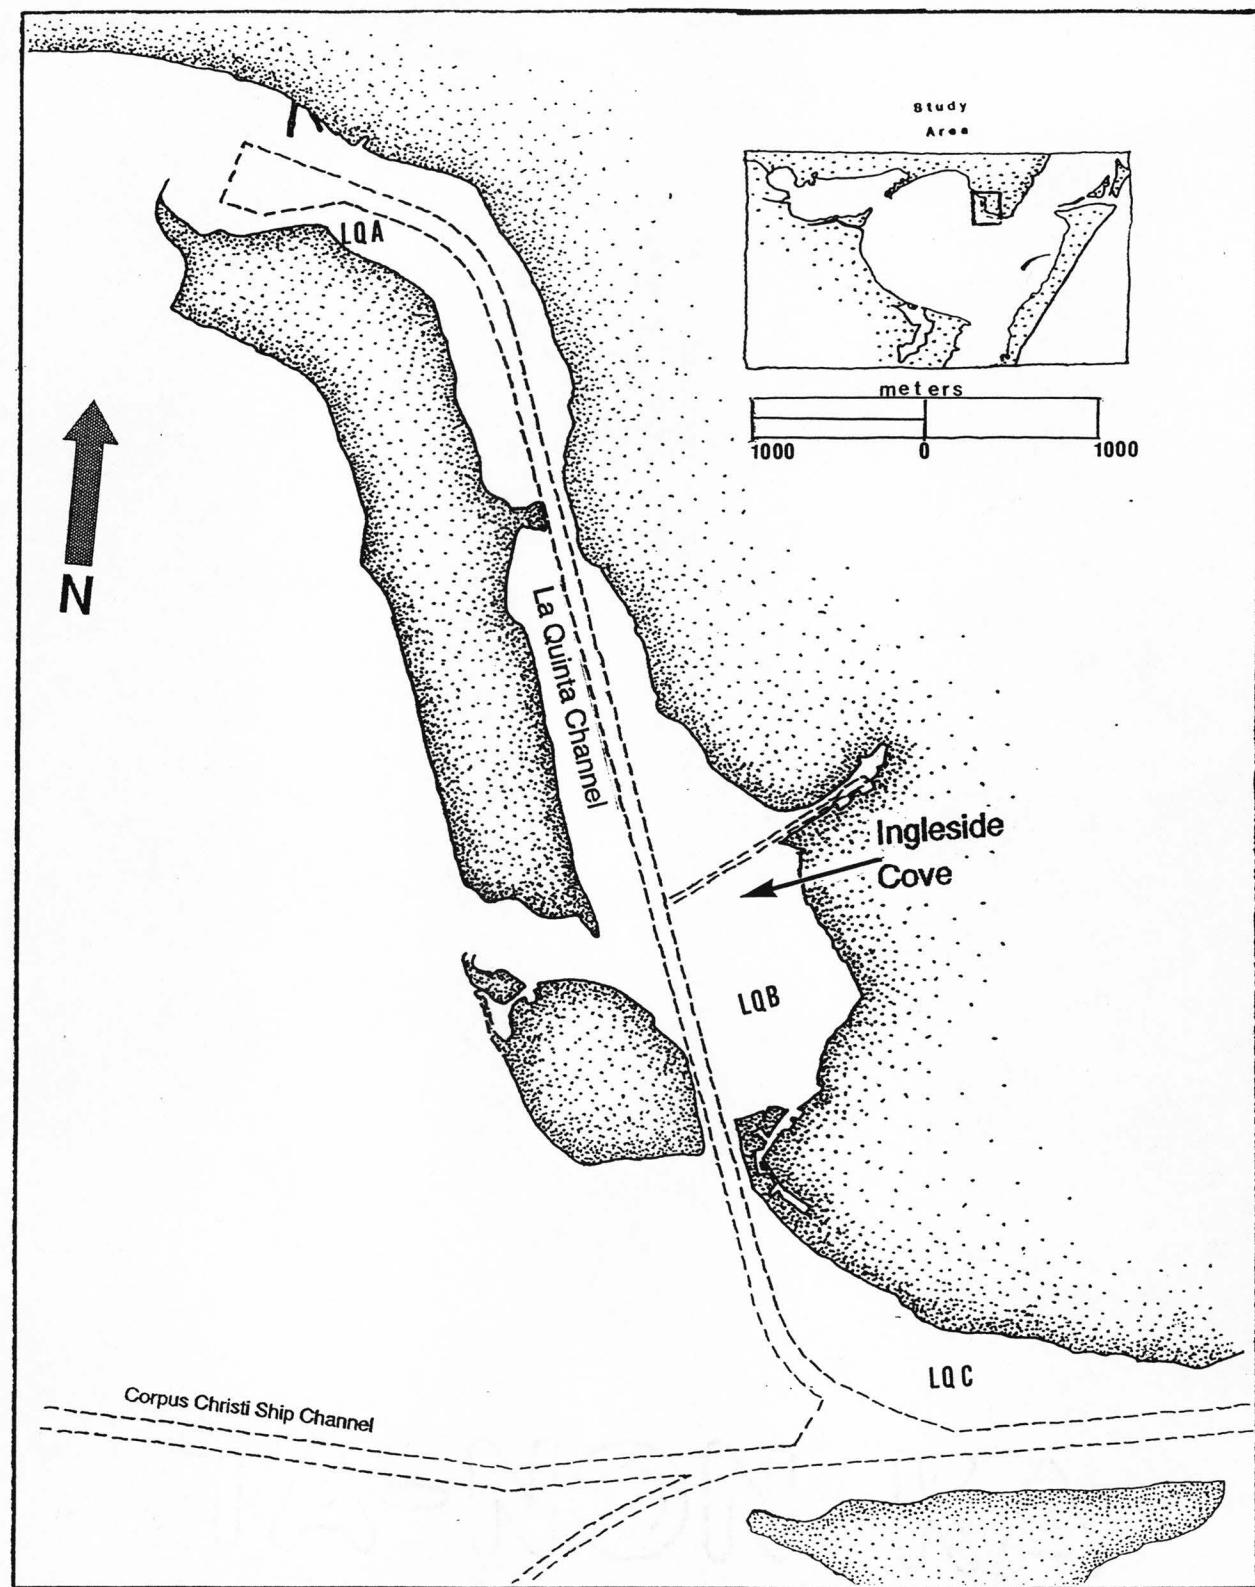

Fig. 2. Map of La Quinta Channel. Station LQA is on the north end of the Channel, LQB is located in Ingleside Cove, and LQC is near the juncture of the La Quinta Ship Channel from the Corpus Christi Ship Channel.

## Hydrography

During each collection period hydrographic measurements were taken at each station using a Hydrolab Surveyor II. These measurements were taken just below the water surface and at the bottom of the water column. The information taken consisted of the following parameters (units and accuracy): depth ( $\pm 1$  m), water temperature ( $\pm 0.15$  °C), pH ( $\pm 0.1$  units), dissolved oxygen ( $\pm 0.2$  mg/l), specific conductivity ( $\pm 0.015$  - $1.5$  mmhos/cm depending on range), redox potential ( $\pm 0.05$  mV), and salinity (ppt). Salinity is automatically corrected to 25 °C. A visual estimate of weather conditions such as wind speed, wind direction, cloud cover, and wave height was also recorded.

## Sediment

Using techniques described by Folk (1964) we determined the percent of sand, silt, and clay present at each station from sediment samples taken during the first collection period. These samples were placed in a jar and filled with distilled water and hydrogen peroxide and were allowed to sit for one week to digest organic material in the sample. The samples were then wet filtered through a  $62.5\text{ }\mu\text{m}$  Millipore Hydrosol SST filter using a vacuum pump to separate sand and shell hash from the silt and clay. Sediment that was left on the  $62.5\text{ }\mu\text{m}$  filter was placed in a 50 ml beaker that was previously weighed. That sediment was then dried at 80 °C for 24 h and then weighed. The sediment fraction that flowed through the  $62.5\text{ }\mu\text{m}$  filter was placed in a 1,000 ml graduated cylinder. The temperature of the water in the cylinders was measured to determine how long to let the sediment settle between subsamples. Each graduated cylinder had its contents well mixed and a 20 ml subsample was placed in a preweighed 50 ml beaker. After settling, another 20 ml subsample was taken and placed in a preweighed 50 ml beaker. These fractions were all dried at 80 °C and then the total dry weight of the sediment was calculated.

## Benthic Abundance

Benthic abundance and community structure was measured using the standard techniques that Montagna and Kalke (1992) have been using since 1984. The samples were collected using core tubes rather than grabs, because most grabs take a semi-circular "bite" out of the sediment and cause redistribution of the benthic community (Holme and McIntyre, 1971). The core tubes were 6.715 cm in diameter and were taken from the surface of the sediment (0 cm) to a depth of 10 cm, yielding a sample area of  $35.4\text{ cm}^2$ .

Two types of coring methods were used for collecting: a simple corer and the Kalke corer. The simple coring required a diver to insert the coring tube, which was open on both ends, into the sediment. A rubber stopper was placed on the top end, which then acted as a suction device to hold the sample in place as the tube was pulled out and then capped on the bottom end. The Kalke corer used the same basic technique as the simple corer, but does not require a dive. A long pole was used to push the tube into the sediment from the side of a boat. To load the device the tube was clamped onto the end of the pole and then lightly capped by a rubber stopper so

that air could escape but was able to stopper completely when the tube was pulled out of the sediment. The tube was then quickly brought to the surface so that the bottom of the tube could be capped, thus not allowing any of the sample to escape. This technique could not be performed in areas with high sand or shell content.

These cores were then sectioned to depths of 0-3 cm and 3-10 cm to examine the vertical distribution of macrofauna. After sectioning, each individual sediment section was stored in a container filled with 10% formalin and 90% seawater to fix and preserve the live animals. The samples then remained in the formalin mixture until they were ready to be analyzed.

Before analyzing a sample, the contents of the container were swirled and allowed to settle for a few seconds and then slowly poured through a 500  $\mu\text{m}$  sieve. The container was then filled half full with fresh water, swirled, allowed to settle for a few seconds, and then slowly poured through the sieve again. The swirling allowed the finer sediment and the lighter animals to rise to the top so that they could be decanted. The heavier sediment and shells precipitated out and stayed on the bottom. This process was repeated until the majority of "lighter" things had been decanted and all that remained was the shell hash and the larger clay clumps. The sediment that had been decanted was fine enough to flow through the sieve while the animals remained, thus allowing one to carefully rinse the contents of the sieve into a beaker, fill it partially with fresh water and set it aside. The contents remaining in the container were then poured through two sieves (2 mm and 500  $\mu\text{m}$ ) that were placed one on top of the other with the 2 mm sieve on top. The clumps of sediment that did not flow through the top sieve was rinsed through with fresh water at low pressure. The remains of the top sieve (usually consisting of worm tubes and shells) were then sorted under a magnifying lens and the preserved animals were picked out and placed in a second beaker, which was set aside with the first beaker. The contents that flowed onto the 500  $\mu\text{m}$  sieve were rinsed with fresh water at low pressure, to wash the remaining sediment through, and then those contents were carefully rinsed into a third beaker. Each beaker was then subsampled into a petri dish for easier study under a dissecting scope where the animals were picked out, identified into their lowest possible taxon (i.e. species), and enumerated. The animals that were identified were cross-referenced with a reference collection that is available for Corpus Christi Bay. The debris that was not picked out of the samples was discarded.

### Benthic Biomass

After the species have been identified and enumerated, biomass was determined. Benthic biomass was measured using the standard techniques used by Montagna and Kalke (1992). Mollusk shells were removed by an acidic vaporization technique (Hedges and Stern, 1984). The animals were separated into their major groups: polychaetes, crustaceans, mollusks, rhyncocoels, ophiuroids, sipunculids, and others. Small aluminum pans were then weighed out and each group was placed on its own pan; the purpose for this was to get a dry biomass weight. These pans were then placed into an oven and dried at 50 °C for a minimum of 48 hours, after which another weight was obtained for the pan and animals together. A weight on the animals was calculated by subtracting the pan weight from the pan/animal weight.

These numbers were then logged into a SAS data base, which cross-checked the data to make sure that the number of animals on the identification sheet matched the number of animals on the biomass sheet.

### Statistical Analyses

Statistical analyses to reveal differences among sampling periods, stations and sediment depths was performed using general linear model procedures (SAS, 1985). Three-way analysis of variance (ANOVA) models were used where sampling dates, stations, and sediment sections were the three main effects. Two-way ANOVA models will be used where sampling dates and stations were the two main effects. Analyses were run on raw and log-transformed data. The distribution of the residual error terms from the ANOVA models were tested for conformance to normality. Orthogonal linear contrasts were used to test for the specific null hypothesis that La Quinta Channel was different from Corpus Christi Bay. Tukey multiple comparison procedures were used to find *a posteriori* differences among sample means (Kirk, 1982).

Factor analysis with rotated and unrotated factors were used to determine if communities were similar on different sampling dates or stations. Cluster analysis was used to find similar species composition among stations.

### Diversity Analyses

Diversity was calculated using Hill's diversity number one (N1) (Hill, 1973). It is a measure of the effective number of species in a sample, and indicates the number of abundant species. It is calculated as the exponentiated form of the Shannon diversity index:

$$N1 = e^{H'} \quad (1)$$

As diversity decreases N1 will tend toward 1. The Shannon index is the average uncertainty per species in an infinite community made up of species with known proportional abundances (Shannon and Weaver, 1971). The Shannon index is calculated by:

$$H' = -\sum_{i=1}^s \left[ \left( \frac{n_i}{n} \right) \ln \left( \frac{n_i}{n} \right) \right] \quad (2)$$

Where  $n_i$  is the number of individuals belonging to the  $i$ th of  $S$  species in the sample and  $n$  is the total number of individuals in the sample.

Richness is an index of the number of species present. The obvious richness index is simply the total number of all species found in a sample regardless of their abundances. Hill (1973) named this index N0. Another well known index of species richness is the Margalef (1958) index (R1). R1 is based on the relationship between the number of species ( $S$ ) and the total number of individuals ( $n$ ) observed:

$$R1 = \frac{S-1}{\ln(n)} \quad (3)$$

Although common, this relationship presupposes that there is a functional relationship between  $S$  and  $n$ . This assumption may not be justified in all cases.

Evenness is an index that expresses that all species in a sample are equally abundant. Evenness is a component of diversity. Two evenness indices, E1 and E5, have been calculated. E1 is probably the most common, it is the familiar  $J'$  of Pielou (1975). It expresses  $H'$  relative to the maximum value of  $H'$ :

$$E1 = \frac{H'}{\ln(S)} = \frac{\ln(N1)}{\ln(N0)} \quad (4)$$

E1 is sensitive to species richness. E5 is an index that is not sensitive to species richness. E5 is a modified Hill's ratio (Alatalo, 1981):

$$E5 = \frac{(1/\lambda) - 1}{N1 - 1} \quad (5)$$

where,  $\lambda = \sum_{i=1}^s \frac{n_i(n_i-1)}{n(n-1)}$

$\lambda$  is the Simpson (1949) diversity index. E5 approaches zero as a single species becomes more and more dominant.

## RESULTS

### Hydrography

Hydrographic measurements were taken at all stations during each collection (Appendix I). Refractometer readings dropped from a mean of 30.5 ppt to 23.5 ppt in La Quinta Channel from October, 1992 to July, 1993 due to the amounts of rainfall that occurred during the year, especially in May, 1993. The trend was similar in Corpus Christi Bay, although the salinity was slightly lower. There was a large seasonal drop in temperature, from 24 °C to 13 °C, between October and January, but the temperature went back to 40 °C by July. The pH remained constant and was similar among each of the six stations all year. The dissolved oxygen (DO) concentration in the water had a mean of 7.0 mg/l for all stations except NCC and NCD, which were lower (5.5-6.5 mg/l), during October. In January and April the DO was higher (8.5-9.5 mg/l) for all stations. By July it decreased to 5.0-6.5 mg/l and was similar at all stations except for the bottom of NCD, where the DO was only 1.7 mg/l. The oxidation-redox potential remained constant during the entire year at all stations. Overall, the measurements recorded at each of the stations were very similar to one another.

### Sediment

Sand was predominant at most stations (Fig. 3) The sand content was usually greater in the top 3 cm of the samples (Appendix II). This measurement was taken only once in October, 1992 (NCD was taken October, 1991). All of the La Quinta Channel stations had sand making up more than 75% of the sediment. Both layers at NCC consisted mostly of silt and clay, making up 79.7% in the upper section and 89.2% in the lower section, while there was more sand in NCD (82.4%) and NCE (56.7%). Sand made up the largest percentage dry weight for all stations, except for NCC.

### Benthic Abundance

There were more individuals in the top 3 cm during each study period, except for July, 1993 (Fig. 4, Appendix III). Polychaetes made up the majority of individuals in the top and bottom sections of all stations sampled (Table 1, Appendix III). Polychaetes made up 77% of the mean total abundance found in the top 3 cm and 90% for the bottom 7 cm of La Quinta Channel and 84% of the total species in the upper section and 90% in the bottom section of Corpus Christi Bay. The percent difference between the polychaetes in the top section and those in the bottom section in La Quinta Channel was lower than that of Corpus Christi Bay. La Quinta Channel had an average percent difference of 4%, in favor of the top section, while in Corpus Christi Bay it was 32%, again in favor of the top 3 cm. There were significant interactions between the sections, dates, and stations for the density ( $n \cdot m^{-2}$ ) as well. The average number of species found in the top section for all stations was  $13,024 \cdot m^{-2}$ , which is 61% of the total average of both sections. The average of  $12,126 \cdot m^{-2}$  individuals in the top section of LQA, however, was lower than that of bottom section ( $13,307 \cdot m^{-2}$ ).

Also, October, 1992, and January and April, 1993 had an average mean of 67% density in the upper layer while there was only 41% density in the upper layer for July, 1993. An examination of the residuals was done for density. Here the residuals did conform to a normal distribution. The bell-shaped curve had a coefficient of skewness of only 0.24 and the coefficient of kurtosis was 1.4. The skewness, being so small, had no affect on the boxplot, the median and mode overlapped. The normal probability plot had the raw data converging on the straight line, thus repeating that the distribution was normal.

The mean density of macrofauna taxa at all stations combined to a depth of 10 cm was dominated by polychaetes with a mean of  $17,980 \cdot m^{-2}$  or 84% of the total taxa (Table 2). For the individual stations polychaetes still dominated each station (Table 3). Polychaetes were most abundant at LQA with a mean of  $22,691 \cdot m^{-2}$ . The fewest number of polychaetes occurred at NCE with  $15,955 \cdot m^{-2}$ . There were significant interactions between the dates and stations for the mean density to 10 cm (Fig. 5). Stations LQA and NCC are significantly different from one another, as seen in the Tukey test for mean density ( $n \cdot m^{-2}$ ) to 10 cm:

25,433	21,722	21,060	20,895	20,351	18,295
LQA	NCD	LQB	LQC	NCE	NCC

The residuals of macrofauna taxa density at all stations combined to a depth of 10 cm conformed to a normal distribution. The coefficient of skewness that occurred to the bell-shaped curve had no affect on the overlapping of the median and the mode. The normal probability plot had the raw data converging on the straight line. According to the orthogonal linear contrast, La Quinta Channel was not significantly different ( $P=0.0873$ ) from Corpus Christi Bay. La Quinta Channel had an average of  $25,796 \cdot m^{-2}$  and Corpus Christi Bay had  $20,123 \cdot m^{-2}$ . The three stations in La Quinta Channel and NCE in Corpus Christi Bay were similar in the number of species throughout the study periods, while NCD was consistently lower (Fig. 6). The highest number of species, however, was found to be in LQC.

### Benthic Biomass

La Quinta Channel and Corpus Christi Bay both had a greater biomass ( $g \cdot m^{-2}$ ) in the bottom (3-10 cm) sediment section (Fig. 7). La Quinta Channel had an average of 72% and Corpus Christi Bay averaged 69% of the biomass in the bottom sections. Polychaetes made up the greatest biomass at all stations and sections ranging from 0.8 to  $9.3 g \cdot m^{-2}$  (Table 1). The biomass of all of the taxa, except polychaetes, was greater in the top 3 cm than in the bottom 7 cm (Appendix III). The polychaete biomass in the bottom section made the overall average biomass of the bottom section greater than that of the top section. There were significant interactions between the sections, dates, and stations for the biomass. Overall, the percent of biomass found in the top 3 cm was 29%, but composition was different among stations. LQA had 17% in the top section, LQB had 35%, there was 39% at LQC, NCC had 23%, NCD was found to

contain 50%, and NCE had 33% (Table 1). The high percentage of biomass at NCD occurred in January and April, 1993, when NCD had 64% of the biomass in the top 3 cm while the other 2 sampling periods had less than 40% each in the top 3 cm at NCD. After examining the residuals (errors) of the biomass to determine if they conformed to a normal distribution it was determined that they did not. Although they are not normal, they still present a bell-shaped curve. The problem with the bell curve is that it has a small coefficient of skewness (1.1). This skewness was not enough, however, to affect the boxplot where the median and the mode still overlapped. The coefficient of kurtosis is 4.1 and the bell curve was very narrow. Another way to determine how far the bell curve is from normal is to construct a normal probability plot, which draws a straight line and then plots the raw data around it. Although the raw data did not fit the straight line exactly, it never veered far from that line demonstrating that, although the residuals were not normal, they were not bad enough to warrant transformation.

The mean biomass of macrofauna taxa to a depth of 10 cm at all stations was dominated by polychaetes with a mean of  $9.9 \text{ g}\cdot\text{m}^{-2}$  or 83% of the total taxa (Table 4). Polychaete biomass to 10 cm was dominant at each station (Table 5). Other than at NCC and NCD, there were no stations that had a taxa that came close to polychaetes in the amount of biomass present. The polychaetes at NCC weighed  $6.42 \text{ g}\cdot\text{m}^{-2}$ , ophiuroids were next with  $4.27 \text{ g}\cdot\text{m}^{-2}$ , the mollusks were the third highest but weighed much less with only  $0.7 \text{ g}\cdot\text{m}^{-2}$ . At NCD, the polychaetes weighed very little, only  $1.76 \text{ g}\cdot\text{m}^{-2}$ , and the rest of the taxa were between  $0.01$  and  $0.27 \text{ g}\cdot\text{m}^{-2}$ . In La Quinta Channel, the polychaete biomass was never less than 83%. For Corpus Christi Bay, the polychaetes were 55%, 72%, and 89% for stations NCC, NCD, and NCE, respectively. There were significant interactions between the dates and stations for the mean biomass to 10 cm (Fig. 8). While station NCE is not significantly different from most of the stations, NCD is significantly different from all of the other stations, a fact that can be seen in the following Tukey test for mean biomass ( $\text{g}\cdot\text{m}^{-2}$ ) to 10 cm at each station:

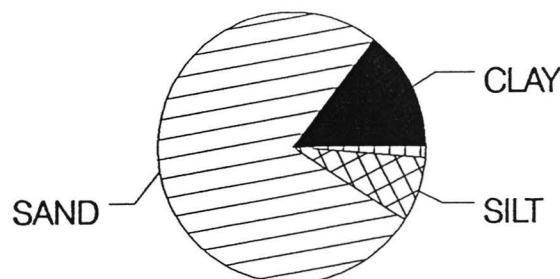

20.1 <u>LQA</u>	15.7 <u>NCE</u>	11.8 <u>NCC</u>	10.9 <u>LQB</u>	10.3 <u>LQC</u>	2.4 <u>NCD</u>
--------------------	--------------------	--------------------	--------------------	--------------------	-------------------

The residuals for the mean biomass to 10 cm did not conform to a normal distribution. There was still a bell-shaped curve that showed a small coefficient of skewness, but did not cause the overlapping of the median and the mode not to occur. The coefficient of kurtosis was also close to normal distribution. All of this was confirmed with the normal probability curve because the raw data veered only slightly from the normality line, but not enough to warrant transformation. Orthogonal linear contrasts that tested for the specific null hypothesis that La Quinta Channel was different from Corpus Christi Bay showed that there was a significant difference ( $P=0.0112$ ) between the two. La Quinta Channel had an average of  $13.8 \text{ g}\cdot\text{m}^{-2}$  and Corpus Christi Bay had an average of only  $10.0 \text{ g}\cdot\text{m}^{-2}$ . Without station NCD being figured into the Corpus Christi Bay average, the average went up to  $13.8 \text{ g}\cdot\text{m}^{-2}$ .

## Benthic Diversity

Using R1 to indicate species richness, there is not a significant interaction between date and station. There were differences among the stations ( $P=0.0001$ ) and the dates ( $P=0.0001$ ). There was a significant difference between the stations in La Quinta Channel and in Corpus Christi Bay. The La Quinta Channel stations had an average of 4.6 compared to 3.5 found among Corpus Christi stations (Table 6). The overall mean for R1 is 4.0. The Tukey test for the mean of R1 at each stations is:

5.4 <u>LQC</u>	5.0 <u>NCE</u>	4.7 <u>LQA</u>	3.6 <u>LQB</u>	3.2 <u>NCC</u>	2.3 <u>NCD</u>
-------------------	-------------------	-------------------	-------------------	-------------------	-------------------

Species diversity was calculated with Hill's N0 and N1 (Table 6). N0 simply measures the total number of species in a sample. In this study, the mean N0 for all stations combined was 17.9. There was no significant interaction between dates and stations for N0. There were significant differences among the stations ( $P=0.0001$ ) and the dates ( $P=0.0001$ ). There were significant differences between the mean number of species in La Quinta Channel (20.9) and Corpus Christi Bay (14.9). The Tukey test for mean number of species (N0) at each station for the entire year appeared as follows:

24.2 <u>LQC</u>	22.2 <u>NCE</u>	22.0 <u>LQA</u>	16.7 <u>LQB</u>	13.1 <u>NCC</u>	9.3 <u>NCD</u>
--------------------	--------------------	--------------------	--------------------	--------------------	-------------------

Hill's N1 is an indicator of the number of dominant species in a sample. The mean number of species for N1 was slightly lower with 10.7, because it takes into account only the abundant species. Even though there were no significant differences between the stations and dates for N1, there were significant differences among the dates ( $P=0.0001$ ) and stations ( $P=0.0001$ ) (Fig. 8). There was a significant difference between the two systems; La Quinta Channel had an average mean of 12.4 species and Corpus Christi Bay had an average mean of 9.0 species. The Tukey test that follows is of the mean number of abundant species (N1) at each station:

14.5 <u>LQC</u>	14.4 <u>NCE</u>	12.9 <u>LQA</u>	9.9 <u>LQB</u>	8.2 <u>NCC</u>	4.5 <u>NCD</u>
--------------------	--------------------	--------------------	-------------------	-------------------	-------------------

The variable E1 was chosen to indicate evenness because it is calculated with N0 and N1. When E1 is equal to 1.0 then there is complete evenness. The mean of E1 for all stations combined throughout the year was 0.78, which means that there was a high level of evenness. There were significant interactions between dates and stations ( $P=0.0001$ ). Station NCD had the 2 lowest evenness indices and it was the lowest in evenness 3 out of 4 times (Table 6). During April, however, it had the highest degree of evenness, which was the second highest evenness value overall.

Plotting the Dominance-diversity curves (Fig. 9) presented a graphic illustration that NCD had the least evenness and had a very different curve from all of the other stations. The curves of the other stations were not significantly different from each other and showed a good evenness. Station NCC, which had a curve that was similar to NCD though not as drastic, was not significantly different from the other stations, but did not have a very good evenness. The Tukey test for the mean of E1 for each station has NCD being the only station that is significantly different from the rest and NCE is the station with the most species evenness overall:

0.855	0.822	0.819	0.808	0.795	0.606
NCE	LQA	LQC	LQB	NCC	NCD

Factor analysis indicated that stations LQA, LQB, LQC, and NCE were most similar, while stations NCC and NCD were similar to each other, but different from the rest (Fig. 10, Table 7, Table 8, Appendix IV). Factor 1 analysis explained 81% of the variance, and Factor 2 analysis explained only 19% of the variance. Station NCD separated on the first factor and NCC and NCD separated on the second factor because there were different polychaetes present. A cluster analysis (Fig. 11) demonstrated that NCC and NCE were most alike in species composition. It also demonstrated that station LQC was most like the Corpus Christi Bay stations, while it considered station LQA to be the most unique station.

Polychaetes were the dominant form of benthos at all stations during the entire study period. The most dominant and ubiquitous species throughout entire study was Mediomastus ambiseta, with a combined average of 25,906 individuals·m<sup>-2</sup> from all stations. This subsurface deposit-feeding species was most abundant at NCC (6,264 individuals·m<sup>-2</sup>) (Table 7). All stations, except for NCD, had Mediomastus ambiseta as the dominant polychaete.

## DISTANCES

## DISCUSSION

The objective of this study was to determine if La Quinta Channel, an area that has anthropogenic disturbances, has suffered any environmental decline relative to other areas of Corpus Christi Bay that have not had as much anthropogenic influence. The approach was to take sediment samples and analyze benthic community structure and diversity. Benthic organisms can be affected by other influences as well as anthropogenic disturbances. We must examine all the factors that explain or influence the benthos to assess a relative role to anthropogenic disturbance.

Sediment was most similar between stations LQA, LQB, LQC, and NCD, which are all stations in bay margin areas. Shideler (1980) and Flint and Younk (1983) noted that the marginal areas of Corpus Christi Bay were made up of muddy and shelly sand. Sand made up greater than 75% of the total sediment composition at these stations. The sand was fine and muddy enough to allow Mediomastus ambiseta to live in these areas. Previous studies performed near the location of LQC show that the sediment is made up primarily of fine sand with small amounts of shell (Flint *et al.*, 1980; Flint and Kalke, 1986). The stations that were located more towards the middle of the bay, NCC and NCE, were mainly muddy, which is also noted in the study done by Shideler (1980). In a previous study (Montagna and Kalke, 1992) NCC had an average of 7.9% sand and NCD had an average of 74.5% sand, which was comparable to the 10.5% and 82.4% found in this study. In general, the sediment characteristics were similar at all stations, except NCD, indicating that differences among stations were probably not due to differences in sediment texture.

Odum (1969) proposed a conceptual model for succession based on terrestrial observations. This succession model has been used in marine ecosystems in later studies (Rhoads *et al.*, 1978; Flint *et al.*, 1980; Flint and Younk, 1983; Kennish, 1986; Gray *et al.*, 1988). Odum's model suggests that in the early stages of succession (the time following a recent disturbance) a pioneering species is the first to inhabit the area. These organisms are small and *r*-selected (i.e. they have short life cycles and high rates of reproduction). In the benthos these are suspension feeders or surface deposit-feeders (Rhoads *et al.*, 1978; Flint *et al.*, 1980; Kennish, 1986; Gray *et al.*, 1988). With time, the disturbed area matures and the organisms that move in are larger and *k*-selected (i.e. have longer life cycles and lower rates of reproduction). These are subsurface deposit-feeders in the benthos (Rhoads *et al.*, 1978; Kennish, 1986; Gray *et al.*, 1988). Not only are the organisms of the mature stage larger, they are also found deeper in the sediment (Rhoads *et al.*, 1978; Flint *et al.*, 1980; Kennish, 1986; Gray *et al.*, 1988). This means that the subsurface sediments would have a greater abundance and biomass than the surface sediments in mature sediments. This model gives us a method to interpret benthic community structure data.

Abundance and biomass in the bottom sediment section (3-10 cm) of this study was usually as great or greater than that of the top 3 cm of sediment. This finding is consistent with the succession model. It indicates that there was no disturbance during our study of the La Quinta Channel.

Mediomastus ambiseta is a non-selective subsurface-deposit feeder (Fauchald and Jumars, 1979; Flint et al., 1980; Flint and Kalke, 1986). It is not considered a pioneering species (Fauchald, 1977). It is a *k*-selected species and usually follows a pioneering species that oxygenates the deeper sediment strata by building tubes; M. ambiseta is then able to inhabit the deeper sediments (Flint et al., 1980). Mediomastus ambiseta was the most abundant and ubiquitous species throughout this study. It was the most dominant species at each station during each sampling period, with the exceptions of NCC and NCD in October, 1992 and NCD in April, 1993. This polychaete was compared to the one identified earlier as M. californiensis in previous studies (Holland et al., 1973; Holland et al., 1974; Holland et al., 1975; Flint et al., 1980; Flint et al., 1981; Flint and Younk, 1983; Flint et al., 1983; Flint and Kalke, 1986; Montagna and Kalke, 1992) and was determined to be the same species, but had been misidentified until a couple of years ago (Rick Kalke, personal communication). No recent disturbance was visible during any of the sampling periods as indicated by the overall dominance of M. ambiseta.

Pioneering species are those benthic organisms that are *r*-selected and are the first group to colonize an area of recent disturbance, either natural or anthropogenic in nature. Pioneering species were found in small numbers at all stations and have been reported in past studies. Pioneering species that occurred in this study and previous studies (Flint et al., 1980; Flint and Younk, 1983; Flint and Kalke, 1986; Montagna and Kalke, 1992) include: Streblospio benedicti, Paraprionospio pinnata, Apoprionospio pygmeae, Minuspio cirrifera, Onuphis eremita oculata, Owenia fusiformis, Mulinia lateralis, and Abra aequalis. There was a possible disturbance at stations NCC and NCD in October, 1992 and with station NCD in April, 1993. High numbers of pioneering species were found at these stations and they may be a possible example of an early succession communities. In October, 1992, there were high numbers of S. benedicti in the surface sediment ( $5,000 \cdot m^{-2}$  at NCC and  $11,500 \cdot m^{-2}$  at NCD) (Fig. 6), but there was very little biomass ( $3.46 g \cdot m^{-2}$  at NCC and  $1.15 g \cdot m^{-2}$  at NCD) (Fig. 4). Station NCD had another case of a large number of *r*-selected species in April, 1993 when oligochaetes numbered  $4,000 \cdot m^{-2}$ , but this time there was no M. ambiseta found in the samples. There are three possibilities for these observations. 1) There may have been a species recruitment in those areas, 2) there may have been a local disturbance (e.g., that caused by a shrimp trawl), or 3) perhaps sampling error (i.e., S. benedicti may be there constantly, but only in a localized area that was never sampled again). Streblospio benedicti was an abundant polychaete on occasion at some of the stations in past studies (Flint et al., 1980; Flint et al., 1983). Since large numbers of any of these pioneering species were not consistently encountered there is no evidence that a recent disturbance took place.

The dominance of deeper-dwelling organisms, M. ambiseta, and the low numbers of pioneering species indicates that Corpus Christi Bay and La Quinta Channel were not disturbed in the short time before each sampling period. However, it would be incorrect to state that there never was a disturbance in these areas. Firstly, the sampling frequency was low (sites were sampled only once every 4 months). Sampling only covered six stations; these stations are then supposed to representative

of the entire bay. Each sampling area was only 2 m<sup>2</sup>. The sampling in Corpus Christi Bay, which was the control area, took place in areas with little or no anthropogenic influences (i.e. trawling, dumping, or sewage release). No visible anthropogenic influences, such as trawling or boating, were witnessed in the shoal areas of the La Quinta Channel, either, but they could have occurred. The sampling period took place during a wet year. According to Kalke and Montagna (1991), benthos do better during wet years. Lastly, no dredging occurred in the La Quinta Channel during the study period (the last dredging occurred during early- to mid-1991). However, the study done by Flint and Younk (1983) had six stations at the junction of the La Quinta Channel and the Corpus Christi Ship Channel. These stations were sampled every month. Mediomastus ambiseta was one of the dominant species and occurred in every sample, but so was the pioneering species Parapriionospio pinnata. With these caveats in mind, the present data suggests a lack of disturbance.

When a disturbance has not occurred recently then the benthic diversity will be high, however, if an area was disturbed recently then the diversity will be low. Diversity was even at every station except for station NCD. Using H', the mean overall diversity at the La Quinta Channel stations was 2.45 and the Corpus Christi Bay stations had 1.99. The Bay stations without NCD had a diversity index of 2.32. Measures of species diversity (H') in previous studies of the La Quinta Channel averaged 1.74 (Holland *et al.*, 1974), 1.83 (Holland *et al.*, 1975), 3.76 (Flint *et al.*, 1980; Flint and Younk, 1986), and 3.49 (Flint *et al.*, 1983). Corpus Christi Bay averaged 2.89 (Holland *et al.*, 1974), 3.26 (Holland *et al.*, 1975), 1.63 (Flint *et al.*, 1983), and 2.41 (Montagna and Kalke, 1992). The diversity indices of this study were within the range of past studies of the study areas, again supporting the conclusion that La Quinta Channel was not recently disturbed.

The average abundance and biomass to a depth of 10 cm during this study period are analogous to those of previous studies. There was an average of 22,470 individuals·m<sup>-2</sup> and 13.8 g·m<sup>-2</sup> in the La Quinta Channel stations and 20,128 individuals·m<sup>-2</sup> and 9.8 g·m<sup>-2</sup> for Corpus Christi Bay (Table 2, Table 3, Table 7, Table 8). The numbers of individuals found in La Quinta Channel in previous studies (Flint *et al.*, 1980; Flint *et al.*, 1983; Flint and Younk, 1983) were much lower, averaging 9,000 individuals·m<sup>-2</sup>. The likely reason our numbers were higher is that we used a core to sample, rather than a Peterson grab. Their biomass was figured as wet weight and cannot be compared. The numbers of individuals found in Corpus Christi Bay by Montagna and Kalke (1992) averaged 20,000 individuals·m<sup>-2</sup> and only 4.4 g·m<sup>-2</sup>. Even though the numbers of individuals·m<sup>-2</sup> was the same between the two studies, our biomass was higher because NCC had ophiuroids throughout the sampling period which added 4 g·m<sup>-2</sup> to our total. No ophiuroids were reported by Montagna and Kalke (1992). When the techniques employed for collecting and measuring benthos in this study are similar to those of previous studies, the abundance and biomass are comparable.

The large amounts of individuals and biomass indicates that the sediment was not highly contaminated with pollutants. Sediment was analyzed for trace metals,

volatile organics, and extractable organics by AnalySys, Inc. (1993). They sampled stations 1A, 1B, 2A, 2B, 3A, and 3B. The A stations were in the Channel, while the B stations were located in shoals. AnalySys stations 1B, 2B, and 3B were the same as LQA, LQB, and LQC reported in the present study. The concentrations of all of the volatile organics were below detection limits. Most of the extractable organics concentrations were also below detection limits, except for dibutyl phthalate (*n*-Butyl Phthalate), which has a lower testing limit of 200  $\mu\text{g}/\text{Kg}$ . Dibutylphthalate, which is used as an insect repellent for the impregnation of clothing and is soluble in 2500 parts water (Budavari, 1989), was present at levels of 650  $\mu\text{g}/\text{Kg}$ , 1700  $\mu\text{g}/\text{Kg}$ , and 3900  $\mu\text{g}/\text{Kg}$  at stations 1B, 2B, and 3B, respectively. There were several trace metals that were detectable, but not by much (Table 9). After comparing the levels of trace metals with a report written by Long and Morgan (1991), all of the trace metals were considered to be in the "no effect" range. Other studies in Ingleside Cove (Fig. 2) examined concentrations of pollutants in the oyster *Crassostrea virginica* (Presley *et al.*, 1990; Sericano *et al.*, 1990; Sericano *et al.*, 1992; Garcia-Romero *et al.*, 1993). Pesticides, including DDT and non-DDT, PCB's, and chlordane-related pesticides, were at or below the average found along the Texas coast. The pesticide DDT was found at levels of less than 1  $\text{ng}\cdot\text{g}^{-1}$  dry weight, the non-DDT pesticides were found at levels of 1  $\text{ng}\cdot\text{g}^{-1}$  dry weight, and PCB's were measured to be less than 10  $\text{ng}\cdot\text{g}^{-1}$  dry weight (Sericano *et al.*, 1990). The chlordane-related pesticides averaged 8.89  $\text{ng}\cdot\text{g}^{-1}$  dry weight (Sericano *et al.*, 1992). Garcia-Romero *et al.* (1993) determined that an anti-fouling paint (Tributyltin) and its degradants were above the average for the Texas coast with 200  $\text{ng Sn}\cdot\text{g}^{-1}$  for tributyltin, 75  $\text{ng Sn}\cdot\text{g}^{-1}$  for dibutyltin, and 30  $\text{ng Sn}\cdot\text{g}^{-1}$  for monobutyltin. A study by Presley *et al.* (1990) calculated that oysters accumulated 100 ppb of mercury in the Ingleside Cove area, which was lower than average amounts found along the Texas coast. La Quinta Channel, which has some pollution in it, appears to be as clean or cleaner than most bays along the Texas coast.

There was dredging in Corpus Christi Bay from the junction of the La Quinta Channel and the Corpus Christi Ship Channel to Beacon 82 (1 mile south of Harbor Bridge), but there has been no dredging in the La Quinta Channel since July, 1991 (Robert Beggs at Corps of Engineers, Corpus Christi, personal communication). There were 1,011 ships that went through the Inner Channel (part of the Corpus Christi Ship Channel) and 179 that went through the La Quinta Channel in 1992; 1,124 ships went through the Inner Channel and 124 went through the La Quinta Channel in 1993 (Port of Corpus Christi, personal communication). The ship traffic of concern were ships with drafts of over 10 meters. While shrimper traffic has been witnessed during each of the sampling periods, we have no information about how heavy the traffic was during the study year or which specific areas were trawled. Heavy storms, such as hurricanes or tropical storms, did not come through the Corpus Christi Bay system during the sampling period either. Considering the above, apparently no true disturbances took place in the Corpus Christi Bay system during this study.

Throughout the study period, both the La Quinta Channel stations and the Corpus Christi Bay stations had similar benthic diversity, abundance and biomass and community structure. During the study, there was little evidence that disturbances

occurred, except for the simple occasions at NCC and NCD. Based on an analysis of the data from the present study and a comparison with data from previous studies, there is no evidence that the stations sampled in La Quinta Channel are less healthy or undisturbed than the stations sampled in Corpus Christi Bay.

## ACKNOWLEDGEMENTS

This project was initiated by the Coastal Bend Bays Foundation, local industries, the Texas Water Commission, and other environmental groups to perform an environmental assessment of the La Quinta Channel in Corpus Christi Bay. This project was partially supported by a grant from the Coastal Bend Bays Foundation to Dr. Paul Montagna, research scientist at UTMSI. Partial support was also provided by the University of Texas Marine Science Institute, the Texas Water Development Board under grant numbers 93-483-352 and 94-483-003, and Texas A&M University, Sea Grant College Program, project number R/ES-57.

Richard D. Kalke, a research associate at UTMSI was instrumental in the collection of the samples and in aiding with the identification and techniques. Antonio Mannino, a M.S. candidate at UT Austin, and Robert Burgess and Robert Rewolinski, research scientist assistants at UTMSI, helped in the collection of the samples. Carroll Simanek aided with the computer work and data management.

Table 9. Concentrations of trace metals in the sediment that were measured for in the La Quinta Channel. Stations 1B, 2B, and 3B are identical to stations LQA, LQB, and LQC. This data is summarized from a report to the Coastal Bend Bays Foundation (AnalySys, Inc., 1993).

Parameter	Station 1B	Station 2B	Station 3B	Units
Antimony	<60.00	<60.00	<60.00	µg/Kg
Arsenic	1,300.00	1,200.00	690.00	µg/Kg
Beryllium	0.21	0.14	<0.10	mg/Kg
Cadmium	0.33	0.29	<0.20	mg/Kg
Chromium	6.70	2.20	4.00	mg/Kg
Copper	4.00	4.00	1.50	mg/Kg
Lead	10.00	8.80	3.20	mg/Kg
Mercury	22.00	26.00	18.00	µg/Kg
Nickel	5.40	2.80	2.40	mg/Kg
Selenium	67.00	<40.00	<40.00	µg/Kg
Silver	<4.00	<4.00	<4.00	µg/Kg
Thallium	<20.00	<20.00	<20.00	µg/Kg
Zinc	22.00	14.00	12.00	mg/Kg
Cyanide	<0.02	<0.02	<0.02	mg/Kg
