# Acknowledgments

First of all, I would like to express great gratitude to Dr. Bennighof for guiding me to the academic and professional achievements of the great level. I have benefited greatly from Dr. Bennighof's expertise, passion, inspiration and encouragement. Also, I would like to thank him for always providing constant support and numerous suggestions and careful reading of this dissertation.

I would like to express my gratitude to my other four committee members. It has been great honor for me to work with Dr. Craig, Dr. Stearmann, Dr. Demkowicz, and Dr. Dhillon. I would like to thank Dr. Dhillon for providing his expertise on dense eigenvalue problem and supporting his new tridiagonal eigensolver routine. I would like to thank Matthew Kaplan for giving me an insight to initiate this research. I am very grateful to Mark Muller, who always helps me to continuously develop my programming skill in such a high level. Also, I am very grateful to Chang-Wan Kim, Eric Swenson, Garrett Moran, Jeremiah Palmer, Tim Allison, and Frederic Jottras in my office for providing me with numerous discussions and suggestions. I am very grateful to Korean colleagues in Aerospace Engineering and Engineering Mechanics, Soojae Park, Ungdai Ko, Sehyuk Im, Jaeyoung Lim, Kilho Eom, Ike Lee, and other friends for their close support and encouragement. I am very grateful to all my church friends who has been prayed for me. Without their continuous support and prayers, I could not have achieved the goal of this research.

This research has been supported by Ford Motor Company, CDH GmbH,

IBM, Cray, SGI, Sun Microsystems, Hewlett-Packard. I would like to express special thank to Mladen Chargin in CDH GmbH for his support on this research. I would like to thank Osni Marques, Doug Petesch, David Whitaker, Cheng Liao, and Mark Kelly for sharing their knowledge.

Finally, I would like to praise and thank the LORD God for allowing me to study and continuously guiding me to this level. I humbly confess that I would not have been here without His great help and guidance. Whenever I get frustrated, these words from the LORD God gives me a hope to recover.

Delight yourself in the LORD

and he will give you the desires of your heart.

Commit your way to the LORD;

trust in him and he will do this:

He will make your righteousness shine like the dawn,

the justice of your cause like the noonday sun.

Psalms 37:4-6

Supervisor: Jeffrey K. Bennighof

The automated multilevel substructuring (AMLS) method, which was originally designed for efficient frequency response analysis, has emerged as an alternative to the shift-invert block Lanczos method [23] for very large finite element (FE) model eigenproblems. In AMLS, a FE model of a structure, typically having a ten million degrees of freedom, is automatically and recursively divided into more than ten thousand substructures on dozens of levels. This FE model is projected onto the substructure eigenvector subspace which typically has a dimension of 100,000. Solving the reduced eigenproblem on the substructure eigenvector subspace, however, is unmanageable for modally dense models which typically contain more than 10,000 eigenpairs. In this dissertation, a new eigensolution algorithm for the reduced eigenproblem produced by the AMLS transformation is presented for large structural systems with many eigenpairs. The new eigensolver in combination with AMLS is advantageous for solving the eigenproblems for huge FE models with many eigenpairs because it takes much less computer time and resource than any other existing eigensolvers while maintaining acceptable eigensolution accuracy. Therefore, the

new eigensolution algorithm not only makes high frequency analysis possible with acceptable accuracy, but also extends the capability of solving large scale eigenvalue problems requiring many eigenpairs.

A reduced eigenvalue problem produced by the AMLS transformation for a large finite element model is defined on the substructure eigenvector subspace. A new distilled subspace is obtained by defining subtrees in the substructure tree, solving subtree eigenproblems, and truncating subtree and branch substructure eigenspaces. Then the reduced eigenvalue problem on the substructure eigenvector subspace is projected onto the smaller distilled subspace, utilizing the sparsity of the stiffness and mass matrices. Using a good guess of a starting subspace on the distilled subspace, which is represented by a sparse matrix, one subspace iteration recovers as much accuracy as needed. Hence, the size of the eigenvalue problem for Rayleigh-Ritz analysis can be greatly minimized. Approximate global eigenvalues are obtained by solving the Rayleigh-Ritz eigenproblem on the refined subspace, computed by one subspace iteration, and the corresponding eigenvectors are recovered by simple matrix-matrix multiplications.

For robustness of the implementation of the new eigensolution algorithm, the remedies for a nearly singular stiffness matrix and an indefinite mass matrix are presented. Also, the new eigensolution algorithm is very parallelizable. The parallel implementation of this new eigensolution algorithm for shared memory multiprocessor machines is done by using *OpenMP* Application Program Interface (API) for performance improvement. Timing and eigensolution accuracy of the implementation of the new eigensolution algorithm are presented, compared with the results from the block Lanczos eigensolver in the commercial software *MSC.Nastran*. In addition to the new eigensolution algorithm, a new method for an augmented eigenproblem for residual flexibility is developed to mitigate loss of accuracy by paying little computational cost in modal frequency response analysis.

# Chapter 1

## Introduction

One of the main goals in structural dynamic analysis is to calculate the natural frequencies and the corresponding natural modes of vibration of a structural system. This leads to a generalized eigenvalue problem for the structure of the form

$$K\phi = \omega^2 M\phi \tag{1.1}$$

where  $K$  and  $M$  are  $n \times n$  stiffness and mass matrices, respectively,  $\omega$  is a natural frequency and  $\phi$  represents the corresponding natural mode of vibration for the structure.

Aircraft, submarines, automobiles, complex machine components, and framed structures are examples of structures that require efficient eigensolution techniques for their dynamic analysis. Many of these structures are represented by finite element (FE) models having millions of degrees of freedom. Engineers, especially in the automotive industry, need to perform dynamic analysis to higher frequencies with good accuracy and less computer time. This means that a more refined mesh is required in a finite element model for accuracy especially at higher frequencies, and the computational cost of the eigensolution has to decrease to make the dynamic analysis feasible. These requirements are beyond the capabilities of conventional

eigensolution methods.

A classical approach for approximating the partial solution of large eigenproblems consists of projecting the eigenproblem onto an approximating subspace to reduce the computational cost of the eigensolution [56, 57, 58, 59, 60, 61]. The automated multilevel substructuring (AMLS) method is an efficient dimensional reduction tool that has recently been developed and is now widely used in the automotive industry [3, 4, 5, 6, 7].

In the AMLS method, a finite element model of a structure is automatically and recursively divided into thousands of substructures on numerous levels. The eigenspace of each substructure is truncated for dimensional reduction, and the eigenvectors associated with these substructures are used to approximate the partial eigensolution of the FE model. The global eigenvalue problem in the FE space is projected onto the substructure eigenvector subspace. The size of the eigenproblem after reduction, however, is still unmanageable for very large structural models excited over a broad frequency range, and large computational resources are required for even the reduced eigenvalue problem. Typically industrial models have millions of degrees of freedom, and the reduced models produced by AMLS can have about one hundred thousand degrees of freedom. For the reduced eigenvalue problem, the required number of eigenpairs might be over ten thousand.

The goal of this dissertation is to develop an efficient eigensolution technique for the reduced problem encountered in AMLS that improves performance in terms of execution time, accuracy, storage requirements and robustness. A computer implementation for a new algorithm must be efficient, so that not only is performance improved but the capability of solving larger eigenvalue problems is extended by minimizing the usage of computer resources.

## 1.1 Challenges and Motivations

In the modal dynamic analysis of complex structures, such as modal frequency response analysis and modal transient response analysis, the main computational cost is for calculating the required natural frequencies and natural modes of the structure. Much attention has been directed toward effective eigensolution techniques for large eigenproblems. Since solving for the required natural frequencies and natural modes can be prohibitively expensive with conventional techniques when the order of the structural system is large, approximate solution techniques have been developed for finding the lowest eigenpairs.

There have been several competitors in approximate eigensolution techniques for large scale structural systems, including the “shifted-invert” block Lanczos method [23, 24], component mode synthesis methods [57, 58, 59, 60, 61], and the automated multilevel substructuring method [1, 8]. Over the past 15 years or so, the block Lanczos method has been dominant in the scientific and engineering areas as a partial eigensolution method for large sparse eigenproblems, in conjunction with a sparse direct (out-of-core) solver. However, the block Lanczos method has several drawbacks in terms of computational performance [6]:

### Requirement of High Memory Bandwidth

To get the high performance on the machines that has hierarchical memory system, like most of microprocessor-based systems, it is important to reuse data at the top of the memory hierarchy (vector register and cache memory) and minimize the data movements. One way of measuring this data management is the ratio of arithmetic operations to memory references [55, 71, 72]. The block Lanczos algorithm has a very low ratio of arithmetic operations to memory references, so that it requires a computer that has a high memory bandwidth to keep processors supplied with data. As a result, vector supercomputers have proven to be much faster for this algorithm than microprocessor-based

systems.

#### Significant I/O Requirement for Models with High Modal Density

Large amounts of data must be read from or written to disk, and this causes problems if the CPU(s) must wait for the data transfer to finish. Since the block Lanczos method is highly dependent upon large amounts of I/O for models with high modal density (many closely spaced eigenvalues), the I/O can result in a performance bottleneck.

#### Difficulty in Parallelization

Parallelization of the block Lanczos method has not been very successful for FE models of very large size. To overcome this defect, one parallel Lanczos scheme divides the frequency range among processors so the number of frequencies in each segment is about equal. The Lanczos eigensolver then solves the eigenproblem within each subrange of the frequency range on each processor. However, this parallel scheme requires each processor to work on the same full model and so memory and disk requirements for parallel run increase as a multiple of the number of processors used. Therefore, the parallel Lanczos eigensolver cannot complete the analysis due to the lack of computational resources when FE models are very large and have high modal density.

The automated multilevel substructuring (AMLS) method, which was originally designed for efficient frequency response analysis, has emerged as an alternative to the block Lanczos method for very large FE model eigenproblems. The AMLS method requires far less memory bandwidth and fewer floating point operations than the block Lanczos method [1, 6], because all the necessary computations are done on the smaller substructure eigenvector subspace than large FE degrees of freedom, and also only one numerical pass through  $K$  and  $M$  data, rather than many factorizations and out of core solves, and multiplications. The AMLS method has much less data transfer than the block Lanczos method, because in the block

Lanczos method, tens of thousands of eigenvectors and iteration vectors, expressed in all of the FE degrees of freedom, must be read from or written out to disk for iterations. In contrast, in AMLS it is not necessary to produce eigenvectors in all FE degrees of freedom. As a result, large FE models can be analyzed with much less data transfer, rather than tens of terabytes of data transfer required in the block Lanczos method. The AMLS method is also inherently more parallelizable than the block Lanczos algorithm. Different substructures can be processed simultaneously and independently. Also, as transformation of the FE model to the substructure eigenvector representation progresses toward the root of the substructure tree, there is more opportunity for parallelizing the computation associated with each individual substructure [2, 6]. Therefore, the AMLS method has better capabilities than the block Lanczos method for very large FE models.

However, the AMLS method has a significant bottleneck for modally dense models in solving the reduced eigenproblem encountered in the AMLS method, as mentioned by Kaplan [1]. For a trim body model from industry, as an example, he showed that the overall performance of AMLS was governed by the performance of the eigensolution process on the substructure eigenvector subspace. More specifically, the executable in the AMLS software that computes the eigensolution for the reduced eigenproblem took about 75 % of the total elapsed time of AMLS, and this executable determined the maximum memory usage and the maximum disk usage for AMLS. The above challenges have served as the motivations for this dissertation. Therefore, we want to develop an efficient and parallelizable algorithm and its implementation for the reduced eigenproblem encountered in AMLS.

## 1.2 Overview of AMLS Software

The AMLS software for solving large sparse algebraic eigenproblems consists of four separate programs [1]. Each program is responsible for one phase of the process. We

will denote the programs as *Phase2*, *Phase3*, *Phase4*, and *Phase5*. For convenience, we refer to any FE software that generates FE matrices for AMLS as *Phase1*. There is another phase for solving frequency response problems, which is called *Phase6*, but this phase is not related to the scope of this dissertation. The flow of AMLS software is outlined in Figure 1.1.

*Phase1* generates FE model data, which include stiffness and mass matrices, by some finite element software. In this dissertation, *MSC.Nastran* is the finite element software package used to generate the finite element data. *Phase2* reads through the matrix data and automatically divides the FE model into thousands of substructures on dozens of levels based on the sparsity structure of system matrices. *Phase3* computes hundred thousands of substructure eigenvectors whose eigenvalues are below a specified cutoff value, which is much higher than the square of the highest excitation frequency of interest, and projects the stiffness and mass matrices onto the substructure eigenvector subspace. In *Phase4*, which contains new eigensolution algorithm which is the focus of this dissertation, the global eigensolution is approximated. *Phase5* computes the approximate eigenvectors on the FE discretization subspace. This dissertation is focused on the new eigensolution algorithm in *Phase4* for the reduced eigenproblem on the substructure eigenvector subspace and its implementation.

### 1.3 Outline of Dissertation

In this dissertation, we present an efficient numerical method for solving the symmetric semi-definite generalized eigenvalue problem for large structural systems. The following summarizes the outline of this dissertation.

In Chapter 2, the global eigenvalue problem is defined in the FE discretization subspace. Since AMLS is used for model reduction, the AMLS transformation process is explained briefly using a simple plate example. The reduced eigenvalue

Figure 1.1: Flowchart of the AMLS software

problem generated by the AMLS transformation is defined. This reduced eigenvalue problem is the one that we want to solve very efficiently using a new eigensolution algorithm.

In Chapter 3, we discuss the existing algorithms available for solving the reduced eigenproblem, which is rather large and sparse. Since an eigensolver for dense matrices is needed for Rayleigh-Ritz analysis for a new eigensolution algorithm, we also discuss the stable and fast dense eigensolver for the standard eigenproblem, which is obtained from the generalized eigenproblem by using a Cholesky factorization of one of the matrices.

In Chapter 4, we describe the characteristics of the reduced eigenvalue problem in detail and the motivations for developing a new eigensolution algorithm. Then, the new eigensolution algorithm for the reduced eigenproblem is explained in detail. Two significant difficulties in implementing the new algorithm are discussed with their remedies.

In Chapter 5, parallelization issues for the new algorithm are discussed for shared memory multiprocessor machines.

In Chapter 6, numerical results are shown for three industrial models to show the efficiency and accuracy of the new eigensolution algorithm.

In Chapter 7, we finish by summing up the conclusions of this dissertation and highlighting areas of potential future work.

In addition to the above chapters, the augmented eigenvalue problem is discussed in Appendix A, to obtain the residual flexibility vectors for mitigating loss of accuracy in frequency response analysis. A very cost efficient algorithm for the large augmented eigenproblem for residual flexibility is described.

## Chapter 2

# Reduced Eigenproblem by the AMLS Transformation

In this chapter, we will start from the generalized eigenvalue problem for a FE model and proceed to define the reduced eigenproblem produced by the AMLS transformation, giving a typical size of the problem. To help readers interested in the AMLS transformation process, an overview of the AMLS transformation will be presented with a simple plate example.

### 2.1 Reduced Eigenvalue Problem

The eigenvalue problem for the finite element model of a large scale structural system is represented by the equation

$$K \Phi = M \Phi \Lambda \tag{2.1}$$

where  $K \in \mathbb{R}^{n_F \times n_F}$  and  $M \in \mathbb{R}^{n_F \times n_F}$  are finite element stiffness and mass matrices which are real, symmetric, and positive semi-definite, and  $n_F$  is the number of degrees of freedom in the finite element model, which defines the dimension of the

problem. The matrix  $\Lambda \in \mathbb{R}^{n_E \times n_E}$  is a diagonal matrix of the eigenvalues less than a global cutoff value  $\omega_G^2$ , where  $n_E$  is the number of global eigenpairs computed and  $\omega_G$  is the global radian cutoff frequency for this eigenproblem, which is typically 50% higher than the highest excitation frequency. The matrix  $\Phi \in \mathbb{R}^{n_F \times n_E}$  contains the corresponding eigenvectors. We will assume that the eigenvalues are in increasing order and the eigenvectors are normalized with respect to the mass matrix so that  $\Phi^T M \Phi = I$ , where  $I$  is an identity matrix.

The natural frequencies and modes of vibration of the structure can be approximated by solving this very large algebraic eigenproblem. The eigenvalues are squares of natural frequencies and the eigenvectors represent natural modes of vibration. The system matrices,  $K$  and  $M$ , are sparsely populated and their dimension is in the millions, so conventional eigensolution techniques are very costly.

To reduce the computational cost of the eigensolution, this global eigenproblem can be projected onto an approximating subspace, which has a much smaller dimension. With AMLS, the eigensolution is approximated using a subspace of substructure eigenvectors [1, 11, 10] which can be produced very efficiently. By forming the triple products,

$$K_A = T_A^T K T_A \quad M_A = T_A^T M T_A, \quad (2.2)$$

where  $T_A \in \mathbb{R}^{n_F \times n_A}$  is an AMLS transformation matrix containing substructure eigenvectors and  $n_A$  is the total number of substructure eigenvectors computed, the global eigenproblem is transformed to the form

$$K_A \Phi_A = M_A \Phi_A \Lambda_A \quad (2.3)$$

where  $\Phi_A \in \mathbb{R}^{n_A \times n_E}$  is a matrix of eigenvectors and  $\Lambda_A \in \mathbb{R}^{n_E \times n_E}$  is a diagonal matrix containing eigenvalues for the reduced eigenproblem. The approximation of the global eigensolution is given by  $\Phi \approx T_A \Phi_A$  and  $\Lambda \approx \Lambda_A$ .

The reduced eigenvalue problem is still not feasible to solve within a suitable job turn-around time on workstations using available eigensolution methods because its dimension is typically on the order of one hundred thousand and the required number of eigenpairs can be over ten thousand. This eigenvalue problem is too large for a conventional eigensolver suited for dense problems, which typically uses Householder reduction to tridiagonalize the matrix, solves the tridiagonal eigenproblem and backtransforms the solution of the tridiagonal eigenproblem to the original space. In addition, the Lanczos method, which is ideal for finding a few extreme eigenpairs for a sparse problem, does not perform well when so many eigenpairs must be found.

The generalized eigenvalue problem in Equation (2.3) is the eigenproblem that we are aiming to solve for the smallest  $n_E$  (perhaps 10,000) eigenvalues and the corresponding eigenvectors. The new eigensolution approximation scheme for this problem will be discussed in Chapter 4. In the next section, the AMLS transformation is discussed in detail.

## 2.2 An Overview of the AMLS Transformation

In the AMLS method, a FE model of a structure is automatically divided into two substructures, and then each of these is subdivided into its own substructures. Here, a substructure is defined as a set of degrees of freedom in a finite element model, which are typically associated with a group of contiguous finite elements. This subdivision process is repeated recursively until substructures reach a specified target size, so that typically ten thousands of substructures are defined on dozens of levels.

For a simple illustrative example, consider a finite element model of a square plate. Figure 2.1(a) shows a possible partitioning of this model into substructures. Substructure 1 consists of interior degrees of freedom inside the upper left quarter of

Figure 2.1: (a) A square plate recursively partitioned to two levels. (b) Substructure tree associated with the two level partitioning.

the plate. At the next level, substructure 3 consists of degrees of freedom between substructures 1 and 2. The highest level substructure, substructure 7, consists of the interface degrees of freedom at the interface which separates substructures 1, 2, and 3 from substructures 4, 5, and 6. This partitioning into substructures can be arranged in a tree topology, as shown in Figure 2.1(b). In order to help readers understand the AMLS transformation, the transformation process for one substructure will be discussed followed by that for multiple levels of substructures.

There are two sets of degrees of freedom in a substructure on the lowest level. One is called “shared” degrees of freedom, which consists of both interface and, if they exist, forced degrees of freedom. The other is called “local” degrees of freedom which are not excited directly but only through coupling with the “shared” degrees of freedom through the system matrices. The local degrees of freedom are represented in terms of quasi-static dependence on shared degrees of freedom obtained by considering only the stiffness matrix, and dynamic response in substructure modes. Hence, the substructure response on the lowest level is represented in Craig-Bampton

form [57] as

$$\mathbf{u} = \begin{Bmatrix} \mathbf{u}_L \\ \mathbf{u}_S \end{Bmatrix} = \begin{bmatrix} \Phi_L & \Psi_L \\ 0 & I \end{bmatrix} \begin{Bmatrix} \boldsymbol{\eta}_L \\ \mathbf{u}_S \end{Bmatrix} = T \begin{Bmatrix} \boldsymbol{\eta}_L \\ \mathbf{u}_S \end{Bmatrix} \quad (2.4)$$

where  $\Phi_L$  satisfies the algebraic eigenvalue problem

$$K_{LL}\Phi_L = M_{LL}\Phi_L\Lambda_L \quad (2.5)$$

where the eigenpairs are truncated according to some cutoff value, which is based on the frequency range of interest and the desired accuracy. Here, the stiffness and mass matrices  $K$  and  $M$  are partitioned as  $\mathbf{u}$  is partitioned, and  $\Lambda_L$  is a diagonal matrix of the substructure's eigenvalues. The right-hand partition of  $T$ ,  $[\Psi_L^T \ I]^T$ , is the matrix of “constraint modes”, which are defined as static responses of the substructure with unit displacements in one “shared” degree of freedom and zero displacements in all others [57], where  $I$  represents an identity submatrix. The submatrix of constraint modes  $\Psi_L$  is given by  $\Psi_L = -K_{LL}^{-1}K_{LS}$ , and  $\boldsymbol{\eta}_L$  is a vector of substructure modal coordinates.

As a consequence of this transformation, the stiffness matrix becomes, assuming that substructure eigenvectors are mass-normalized,

$$\begin{aligned} \tilde{K} &= T^T \begin{bmatrix} K_{LL} & K_{LS} \\ K_{SL} & K_{SS} \end{bmatrix} T \\ &= \begin{bmatrix} \Lambda_L & 0 \\ 0 & K_{LS}^T \Psi_L + K_{SS} \end{bmatrix} \end{aligned} \quad (2.6)$$

where off-diagonal submatrices are null due to the definition of  $\Psi_L$ . The mass matrix is transformed to

$$\begin{aligned} \tilde{M} &= T^T \begin{bmatrix} M_{LL} & M_{LS} \\ M_{SL} & M_{SS} \end{bmatrix} T \\ &= \begin{bmatrix} I & \Phi_L^T (M_{LL} \Psi_L + M_{LS}) \\ (sym.) & \Psi_L^T (M_{LL} \Psi_L + M_{LS}) + M_{LS}^T \Psi_L + M_{SS} \end{bmatrix} \end{aligned} \quad (2.7)$$

where  $I$  represents an identity submatrix. Therefore, the AMLS transformation process for one substructure consists of forming  $\Phi_L$  and  $\Psi_L$ , and transforming  $K$  and  $M$  according to the formulations above.

This transformation process for substructures on a single level can be extended to multiple levels. First, the partitioning of the system matrices based on the substructure tree in Figure 2.1(b) yields stiffness and mass matrices of the form

$$K = \begin{bmatrix} K_{1,1} & 0 & K_{1,3} & 0 & 0 & 0 & K_{1,7} \\ & K_{2,2} & K_{2,3} & 0 & 0 & 0 & K_{2,7} \\ & & K_{3,3} & 0 & 0 & 0 & K_{3,7} \\ & & & K_{4,4} & 0 & K_{4,6} & K_{4,7} \\ & & & & K_{5,5} & K_{5,6} & K_{5,7} \\ (sym.) & & & & & K_{6,6} & K_{6,7} \\ & & & & & & K_{7,7} \end{bmatrix} \quad (2.8)$$

$$M = \begin{bmatrix} M_{1,1} & 0 & M_{1,3} & 0 & 0 & 0 & M_{1,7} \\ & M_{2,2} & M_{2,3} & 0 & 0 & 0 & M_{2,7} \\ & & M_{3,3} & 0 & 0 & 0 & M_{3,7} \\ & & & M_{4,4} & 0 & M_{4,6} & M_{4,7} \\ & & & & M_{5,5} & M_{5,6} & M_{5,7} \\ (sym.) & & & & & M_{6,6} & M_{6,7} \\ & & & & & & M_{7,7} \end{bmatrix} \quad (2.9)$$

We assume that the matrices are transformed in order, with the transformation proceeding down the diagonal of the matrices from upper left to lower right.

We transform the first substructure, whose shared degrees of freedom are in

substructures 3 and 7, by using the transformation matrix

$$T^{(1)} = \begin{bmatrix} \Phi_1 & 0 & \Psi_{1,3} & 0 & 0 & 0 & \Psi_{1,7} \\ 0 & I_2 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & I_3 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & I_4 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & I_5 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & I_6 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & I_7 \end{bmatrix} \quad (2.10)$$

Because substructure 1's shared degrees of freedom are associated with substructures 3 and 7, substructure 1's constraint modes are partitioned into two sets.  $\Psi_{1,3}$  represents the quasi-static dependence of  $\mathbf{u}_1$  on  $\mathbf{u}_3$ , and  $\Psi_{1,7}$  the quasi-static dependence on  $\mathbf{u}_7$ .  $\Phi_1$  contains fixed interface eigenvectors for substructure 1 whose eigenvalues are smaller than some cutoff value  $\omega_A^2$ , where  $\omega_A$  is a cutoff frequency for substructures used in the AMLS transformation.  $\Psi_{1,j}$  and  $\Phi_1$  are defined by

$$\begin{aligned} \Psi_{1,j} &= -K_{1,1}^{-1} K_{1,j}, & j = 3, 7 \\ K_{1,1} \Phi_1 &= M_{1,1} \Phi_1 \Lambda_1 \end{aligned} \quad (2.11)$$

Upon transforming substructure 1, the stiffness and mass matrices become

$$K^{(1)} = T^{(1)T} K T^{(1)} = \begin{bmatrix} \Lambda_1 & 0 & \kappa_{1,3}^{(1)} & 0 & 0 & 0 & \kappa_{1,7}^{(1)} \\ & K_{2,2} & K_{2,3} & 0 & 0 & 0 & K_{2,7} \\ & & K_{3,3}^{(1)} & 0 & 0 & 0 & K_{3,7}^{(1)} \\ & & & K_{4,4} & 0 & K_{4,6} & K_{4,7} \\ & & & & K_{5,5} & K_{5,6} & K_{5,7} \\ & (sym.) & & & & K_{6,6} & K_{6,7} \\ & & & & & & K_{7,7}^{(1)} \end{bmatrix} \quad (2.12)$$

$$M^{(1)} = T^{(1)T} M T^{(1)} = \begin{bmatrix} I_1 & 0 & \mu_{1,3}^{(1)} & 0 & 0 & 0 & \mu_{1,7}^{(1)} \\ & M_{2,2} & M_{2,3} & 0 & 0 & 0 & M_{2,7} \\ & & M_{3,3}^{(1)} & 0 & 0 & 0 & M_{3,7}^{(1)} \\ & & & M_{4,4} & 0 & M_{4,6} & M_{4,7} \\ & & & & M_{5,5} & M_{5,6} & M_{5,7} \\ & (sym.) & & & & M_{6,6} & M_{6,7} \\ & & & & & & M_{7,7}^{(1)} \end{bmatrix} \quad (2.13)$$

Note that only those substructures that are “ancestors” of substructure 1 in the substructure tree are affected by this transformation. Thus, the submatrices associated with substructures 2, 4, 5, and 6 are unchanged by this transformation. The components  $\kappa_{1,j}^{(1)}$  are given by

$$\kappa_{1,j}^{(1)} = \Phi_1 (K_{1,1} \Psi_{1,j} + K_{1,j}), \quad j = 3, 7 \quad (2.14)$$

The definition of  $\Psi_{1,j}$  causes  $K_{1,1} \Psi_{1,j}$  to cancel out  $K_{1,j}$ , leaving  $\kappa_{1,j} = 0$ . Similarly, cancellation gives the simplified expression for  $K_{i,j}^{(1)}$  as

$$K_{i,j}^{(1)} = K_{i,j} + K_{1,i}^T \Psi_{1,j}, \quad i, j = 3, 7. \quad (2.15)$$

For the mass matrix, however, this cancellation does not apply. Its components are given by

$$\mu_{1,j}^{(1)} = \Phi_1^T (M_{1,1} \Psi_{1,j} + M_{1,j}), \quad j = 3, 7 \quad (2.16)$$

$$M_{i,j}^{(1)} = \Psi_{1,i}^T (M_{1,1} \Psi_{1,j} + M_{1,j}) + M_{1,i}^T \Psi_{1,j} + M_{i,j}, \quad i, j = 3, 7 \quad (2.17)$$

The transformation of the second substructure is similar to that of the first, yielding

$$K^{(2)} = T^{(2)T} K^{(1)} T^{(2)} \quad \text{and} \quad M^{(2)} = T^{(2)T} M^{(1)} T^{(2)}. \quad (2.18)$$

After the second substructure is transformed, the transformation matrix  $T^{(3)}$  may be applied to transform the third substructure.  $T^{(3)}$  is given by

$$T^{(3)} = \begin{bmatrix} I_1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & I_2 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \Phi_3 & 0 & 0 & 0 & \Psi_{3,7} \\ 0 & 0 & 0 & I_4 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & I_5 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & I_6 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & I_7 \end{bmatrix} \quad (2.19)$$

where  $\Psi_{3,7}$  and  $\Phi_3$  satisfy

$$\Psi_{3,7} = -K_{3,3}^{(2)-1} K_{3,7}^{(2)}, \quad K_{3,3}^{(2)} \Phi_3 = M_{3,3}^{(2)} \Phi_3 \Lambda_3. \quad (2.20)$$

Applying this transformation matrix  $T^{(3)}$  to  $K^{(2)}$  and  $M^{(2)}$  and taking into account the cancellation that occurs in  $K$  results in

$$K^{(3)} = T^{(3)T} K^{(2)} T^{(3)} = \begin{bmatrix} \Lambda_1 & 0 & 0 & 0 & 0 & 0 & 0 \\ & \Lambda_2 & 0 & 0 & 0 & 0 & 0 \\ & & \Lambda_3 & 0 & 0 & 0 & 0 \\ & & & K_{4,4} & 0 & K_{4,6} & K_{4,7} \\ & & & & K_{5,5} & K_{5,6} & K_{5,7} \\ (sym.) & & & & & K_{6,6} & K_{6,7} \\ & & & & & & K_{7,7}^{(3)} \end{bmatrix} \quad (2.21)$$

and

$$M^{(3)} = T^{(3)T} M^{(2)} T^{(3)} = \begin{bmatrix} I_1 & 0 & (M_A)_{1,3} & 0 & 0 & 0 & \mu_{1,7}^{(3)} \\ & I_2 & (M_A)_{2,3} & 0 & 0 & 0 & \mu_{2,7}^{(3)} \\ & & I_3 & 0 & 0 & 0 & \mu_{3,7}^{(3)} \\ & & & M_{4,4} & 0 & M_{4,6} & M_{4,7} \\ & & & & M_{5,5} & M_{5,6} & M_{5,7} \\ & & (sym.) & & & M_{6,6} & M_{6,7} \\ & & & & & & M_{7,7}^{(3)} \end{bmatrix} \quad (2.22)$$

The changed components of  $K^{(3)}$  and  $M^{(3)}$  are given by

$$\begin{aligned} K_{7,7}^{(3)} &= K_{7,7}^{(2)} + K_{3,7}^{(2)T} \Psi_{3,7} \\ M_{7,7}^{(3)} &= \Psi_{3,7}^T (M_{3,3}^{(2)} \Psi_{3,7} + M_{3,7}^{(2)}) + M_{3,7}^{(2)T} \Psi_{3,7} + M_{7,7}^{(2)} \\ \mu_{3,7}^{(3)} &= \Phi_3^T (M_{3,3}^{(2)} \Psi_{3,7} + M_{3,7}^{(2)}) \\ (M_A)_{i,3} &= \mu_{i,3}^{(i)} \Phi_3 \quad i = 1, 2 \\ \mu_{i,7}^{(3)} &= \mu_{i,7}^{(i)} + \mu_{i,3}^{(i)} \Psi_{3,7} \quad i = 1, 2 \end{aligned} \quad (2.23)$$

The submatrices  $(M_A)_{1,3}$  and  $(M_A)_{2,3}$  are fully transformed and they will not be altered by the remainder of the transformation procedure.

The transformations for substructure 4 and substructure 5 are similar to that of substructure 1. Substructure 6's transformation is similar to substructure 3's. Skipping these for brevity leaves only the final substructure. Its transformation

matrix is given by

$$T^{(7)} = \begin{bmatrix} I_1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & I_2 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & I_3 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & I_4 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & I_5 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & I_6 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & \Phi_7 \end{bmatrix} \quad (2.24)$$

Applying  $T^{(7)}$  to  $K^{(6)}$  and  $M^{(6)}$  yields the fully transformed stiffness and mass matrices, denoted as  $K_A$  and  $M_A$  which are given by

$$K_A = \begin{bmatrix} \Lambda_1 & 0 & 0 & 0 & 0 & 0 & 0 \\ & \Lambda_2 & 0 & 0 & 0 & 0 & 0 \\ & & \Lambda_3 & 0 & 0 & 0 & 0 \\ & & & \Lambda_4 & 0 & 0 & 0 \\ & & & & \Lambda_5 & 0 & 0 \\ (sym.) & & & & & \Lambda_6 & 0 \\ & & & & & & \Lambda_7 \end{bmatrix} \quad (2.25)$$

and

$$M_A = \begin{bmatrix} I_1 & 0 & (M_A)_{1,3} & 0 & 0 & 0 & (M_A)_{1,7} \\ & I_2 & (M_A)_{2,3} & 0 & 0 & 0 & (M_A)_{2,7} \\ & & I_3 & 0 & 0 & 0 & (M_A)_{3,7} \\ & & & I_4 & 0 & (M_A)_{4,6} & (M_A)_{4,7} \\ & & & & I_5 & (M_A)_{5,6} & (M_A)_{5,7} \\ (sym.) & & & & & I_6 & (M_A)_{6,7} \\ & & & & & & I_7 \end{bmatrix} \quad (2.26)$$

where the fully transformed mass submatrices  $(M_A)_{i,7}$  may be expressed as

$$(M_A)_{i,7} = \mu_{i,7}^{(6)} \Phi_7, \quad i = 1, 2, \dots, 6. \quad (2.27)$$

The transformed mass and stiffness matrices may also be expressed as

$$\begin{aligned} K_A &= T_A^T K T_A \\ M_A &= T_A^T M T_A \end{aligned} \quad (2.28)$$

where  $T_A$  is the overall transformation matrix.  $T_A$  is also needed for transforming load vectors from the finite element subspace to the substructure eigenvector subspace and for transforming solutions of the reduced model back to the FE subspace.  $T_A$  in Equation (2.28) can be expressed as

$$T_A = T^{(1)} T^{(2)} T^{(3)} \dots T^{(7)}. \quad (2.29)$$

After the complete transformation of system matrices, the transformed stiffness matrix becomes completely diagonal, containing substructure eigenvalues. Also, the transformed mass matrix has unity on the diagonal entries due to mass normalization in substructure eigensolutions and off-diagonal elements in dense rectangular blocks that represent coupling between substructures and their “ancestors” or “descendants” in the substructure tree as shown in Equation (2.26). The complete transformation matrix becomes

$$T_A = \begin{bmatrix} \Phi_1 & 0 & \hat{\Psi}_{1,3}\Phi_3 & 0 & 0 & 0 & \hat{\Psi}_{1,7}\Phi_7 \\ 0 & \Phi_2 & \hat{\Psi}_{2,3}\Phi_3 & 0 & 0 & 0 & \hat{\Psi}_{2,7}\Phi_7 \\ 0 & 0 & \Phi_3 & 0 & 0 & 0 & \hat{\Psi}_{3,7}\Phi_7 \\ 0 & 0 & 0 & \Phi_4 & 0 & \hat{\Psi}_{4,6}\Phi_6 & \hat{\Psi}_{4,7}\Phi_7 \\ 0 & 0 & 0 & 0 & \Phi_5 & \hat{\Psi}_{5,6}\Phi_6 & \hat{\Psi}_{5,7}\Phi_7 \\ 0 & 0 & 0 & 0 & 0 & \Phi_6 & \hat{\Psi}_{6,7}\Phi_7 \\ 0 & 0 & 0 & 0 & 0 & 0 & \Phi_7 \end{bmatrix} \quad (2.30)$$

where  $\hat{\Psi}_{i,j}$  may be expressed as

$$\hat{\Psi}_{i,j} = \Psi_{i,j} + \sum_{k \in S_{i,j}} \Psi_{i,k} \hat{\Psi}_{k,j} \quad (2.31)$$

where  $S_{i,j}$  is the set of indices for ancestors of substructure  $i$  that are descendants of substructure  $j$ . Note that this is a recursive relation, so each  $\hat{\Psi}_{k,j}$  in Equation (2.31) must be calculated before  $\hat{\Psi}_{i,j}$ . Substituting this for individual entries in  $T_A$  yields the recursive relation

$$(T_A)_{i,j} = \begin{cases} \Phi_j & \text{if } i = j , \\ \hat{\Psi}_{i,j}\Phi_j & \text{if } i \in \mathcal{R}_j , \\ 0 & \text{otherwise.} \end{cases} \quad (2.32)$$

where  $\mathcal{R}_j$  is the set of indices for descendants of substructure  $j$ .

Since we are interested in only a partial eigensolution for the global eigenproblem for a FE model, the cutoff frequency  $\omega_A$  for substructures is selected based on the frequency range of interest, so substructure eigenpairs with natural frequencies above  $\omega_A$  are not included. As a result, the dimension of the substructure eigenvector subspace is typically reduced by orders of magnitude compared to the dimension of the original FE model. In the next chapter, we survey the eigensolution methods suitable for the reduced eigenvalue problem produced by the AMLS transformation.

# Chapter 3

## Survey of Eigensolution Methods

In Chapter 2, we defined the symmetric generalized eigenvalue problem in the substructure eigenvector subspace in Equation (2.3). For the purpose of surveying eigensolution methods, we can restate this eigenproblem for a single eigenpair as follows.

$$K_A \phi = \lambda M_A \phi \quad (3.1)$$

where  $K_A \in \mathbb{R}^{n_A \times n_A}$  is diagonal and positive semi-definite, and  $M_A \in \mathbb{R}^{n_A \times n_A}$  is block-sparse and positive definite in general. As mentioned in Chapter 2, the mass matrix in the FE discretization subspace,  $M$ , is positive semi-definite in general because the mass matrix may be positive definite for a consistent mass formulation or positive semi-definite for a lumped mass formulation. But, the AMLS transformed mass matrix  $M_A$  is positive definite because the zero mass degrees of freedom, which are associated with infinite eigenvalues, are eliminated by substructure eigenspace truncation in the AMLS transformation. For this eigenproblem, we are to find  $n_E$

mutually  $M_A$ -orthogonal eigenvectors  $\phi_i$ , ( $i = 1, 2, \dots, n_E$ ), such that

$$\Phi_A^T K_A \Phi_A = \Lambda_A, \quad \Phi_A^T M_A \Phi_A = I, \quad (3.2)$$

where  $\Lambda_A \in \mathbb{R}^{n_E \times n_E} = \text{diag}(\lambda_i)$ ,  $\Phi_A \in \mathbb{R}^{n_A \times n_E} = [\phi_1, \phi_2, \dots, \phi_{n_E}]$ , and  $n_A \gg n_E$ . Note that the eigenvalues are ordered such that

$$\lambda_1 \leq \lambda_2 \leq \dots \leq \lambda_{n_E}. \quad (3.3)$$

In the following sections, several eigensolution methods are discussed for our reduced eigenproblem in Equation (3.1). Single vector iteration methods, subspace iteration methods, Lanczos methods, and similarity transformation methods are discussed in this chapter. The comparison between subspace iteration methods and Lanczos methods for our reduced eigenproblem will be given in detail in Chapter 4, so we discuss general concepts of both methods in this chapter instead of details of applying the eigensolution methods to our reduced eigenproblem. Similarity transformation methods are discussed because the new eigensolution algorithm in Chapter 4 requires a robust and fast dense eigensolver. Note that we drop the subscript  $A$  from the system matrices ( $K_A$  and  $M_A$ ) and the matrices representing the eigensolution for the reduced eigenproblem ( $\Lambda_A$  and  $\Phi_A$ ) for convenience and brevity in the following sections.

### 3.1 Single Vector Iteration Methods

One of the oldest methods for solving eigenvalue problems is the power method. Stodola used this method to compute the fundamental frequency of turbine shafts of variable cross section in the early 1900s [44]. So this method is also called the Stodola method.

The inverse iteration method is one example of the power/Stodola method. The basic algorithm of inverse iteration is shown in Figure 3.1. Assuming  $K$  is

```

begin
  initial guess  $x_0$ 
  for  $k = 1, 2, \dots$  do
1     $\bar{x}_k = K^{-1}Mx_{k-1}$ 
2     $x_k = \bar{x}_k / \|\bar{x}_k\|_M^1$ 
3     $\mu_k = x_k^T K x_k$ 
4    if converged then
       $\lambda = \mu_k, \phi = x_k$  and stop
    end
  end

```

---

<sup>1</sup> $\|x\|_M = (x^T M x)^{1/2}$ .

Figure 3.1: Basic algorithm for inverse iteration method

positive definite, a new iteration vector is generated by multiplying a previous iteration vector by  $K^{-1}M$  in step 1, and normalized with respect to the mass matrix  $M$  in step 2 as shown in Figure 3.1. As the iteration number  $k$  increases,  $\mu_k$  and  $x_k$  converge to the smallest eigenvalue  $\lambda$  and the corresponding eigenvector  $\phi$  of Equation (3.1).

For multiple eigenpairs, the deflation technique, or Gram-Schmidt orthogonalization can be adopted [38, 41]. For Gram-Schmidt orthogonalization, one step is added inside of the loop over  $k$ :

$$\bar{x}_k = \bar{x}_k - \sum_{i=1}^{n_c} (\bar{x}_k^T M \phi_i) \phi_i \quad (3.4)$$

where  $n_c$  is the number of previously converged eigenvectors. This step removes the  $\phi_i$  component in every iteration step by orthogonalizing an iteration vector  $\bar{x}_k$  against  $\phi_i$  with respect to  $M$ .

The convergence rate for the  $r$ th eigenvalue is  $|\lambda_r/\lambda_{r+1}|$ . This implies that convergence strongly depends on the separation of the eigenvalues. The convergence rate can be improved greatly by shifting [38, 45]. For this acceleration, step 1 can be replaced in the iteration with:

$$\bar{x}_k = (K - \sigma M)^{-1} M x_{k-1} = K_\sigma^{-1} M x_{k-1} \quad (3.5)$$

where  $\sigma$  is a shift corresponding to  $x_{k-1}$ . Due to shifting, the convergence rate is changed to  $|(\lambda_r - \sigma)/(\lambda_{r+1} - \sigma)|$  and the eigenvalue becomes  $\lambda = \mu_k + \sigma$ .

In practice, it is difficult to choose an appropriate shift in the iteration process. One possibility is to use as a shift value the Rayleigh quotient [38, 39, 46]. This method is called Rayleigh quotient iteration. If  $x_k$  is reasonably close to the eigenvector of interest, then convergence of Rayleigh quotient iteration is cubic [38]. Even though Rayleigh quotient iteration accelerates the convergence, it is more expensive per iteration than plain inverse iteration, requiring a factorization of  $(K - \sigma_k M)$  at every iteration if  $\sigma_k$  changes with each iteration. Inverse iteration is one of the most widely used methods to compute an eigenvector for a tridiagonal matrix [63] because factoring tridiagonal matrix is extremely inexpensive, but it is not appropriate for solving very large generalized eigenproblems for multiple eigenpairs.

### 3.2 Subspace Iteration Methods

The subspace iteration method was originally introduced by Bauer in 1957 [15, 21]. Later it was developed and named by Bathe and Wilson [17] in the early 1970s. The similar simultaneous iteration method was proposed by Clint and Jennings [20] in 1970. This method can be thought of as inverse iteration on a set of vectors combined with the Rayleigh-Ritz procedure [13].

Subspace iteration is defined by the equation

$$\bar{X}_k = K^{-1} M X_{k-1} \quad (3.6)$$

where  $X_{k-1}$  is an  $n \times q$  matrix of  $M$ -orthonormalized vectors and  $k$  is an iteration number. Note that the bar indicates that the vectors in  $\bar{X}_k$  are not yet mass orthonormalized. A Rayleigh-Ritz analysis accomplishes this, and it begins by pro-

jecting the stiffness and mass matrices onto the subspace created in the  $k$ th iteration:

$$K_k = \bar{X}_k^T K \bar{X}_k \quad (3.7)$$

$$M_k = \bar{X}_k^T M \bar{X}_k \quad (3.8)$$

where  $K_k$  and  $M_k$  are the projections of the system matrices onto the subspace represented by the matrix  $\bar{X}_k$ . The eigensolution can be obtained by solving the following projected eigenvalue problem:

$$K_k Q_k = M_k Q_k \Lambda_k \quad (3.9)$$

where  $Q_k \in \mathbb{R}^{q \times n_c}$  is a matrix containing eigenvectors,  $\Lambda_k \in \mathbb{R}^{n_c \times n_c}$  is a diagonal matrix containing eigenvalues,  $q$  is the number of iteration vectors, and  $n_c$  is the number of converged eigenpairs. Finally, new  $M$ -orthonormalized Ritz vectors represented by  $X_k$  are generated by

$$X_k = \bar{X}_k Q_k \quad (3.10)$$

The basic algorithm of the subspace iteration method is summarized in Figure 3.2.

The convergence rate of the  $i$ th eigenvalue when  $q$  iteration vectors are used is  $|\lambda_i/\lambda_{q+1}|$ . To obtain a higher convergence rate, one can use more iteration vectors. Bathe suggested that the number of iteration vectors for computing  $r$  eigenpairs should be

$$q = \min(r + 8, 2r). \quad (3.11)$$

The number of subspace iterations required depends on the  $q/r$  ratio. For large  $q/r$  ratios, the number of subspace iterations required will be less whereas the solution time required for each iteration will be large. On the other hand, for small  $q/r$  ratios, a large number of subspace iterations may be required, although the solution time for each iteration will be small. The optimal value of  $q$  for a given problem is not known in advance.

```

begin
  start with  $M$ -orthonormalized initial matrix,  $X_0$ 
  for  $k = 1, 2, \dots$  do
     $Y_{k-1} = M X_{k-1}$ 
     $\bar{X}_k = K^{-1} Y_{k-1}$ 
    Rayleigh-Ritz analysis
     $K_k = \bar{X}_k^T Y_{k-1}$ ,  $M_k = \bar{X}_k^T M \bar{X}_k$ 
    solve the projected eigenproblem:  $K_k Q_k = M_k Q_k \Lambda_k$ 
     $X_k = \bar{X}_k Q_k$ 
  end
  if converged then exit
end
   $\Lambda = \Lambda_k$ ,  $\Phi = X_k$ 
end

```

Figure 3.2: Basic subspace iteration method for generalized eigenproblem

Due to the expense of the Rayleigh-Ritz procedure when many eigenpairs are needed, the efficiency of subspace iteration is limited. To solve for a large number of eigenpairs, some acceleration techniques have been developed [9, 13, 12, 14]. In order to accelerate the iteration itself, several techniques, such as over-relaxation, shifting, and the use of Chebyshev polynomials [9, 14, 15], have been used.

The number of iterations required for convergence also depends on how close the starting subspace is to the eigenspace of interest. Frequently, a set of unit vectors with unity at the degree of freedom with the smallest ratio ( $K_{i,i}/M_{i,i}$ ) is used [38]. Improved starting vectors obtained by dynamic condensation have also been used for forming a better starting subspace [11, 10]. Several methods for finding good starting vectors have been developed for subspace iteration in order to have the iteration converge in fewer steps. Cheu *et al.* [11] investigated the effects of selecting initial vectors on computational efficiency for a subspace iteration method. Kaplan [1] showed that his accelerated subspace iteration method obtained least-dominant eigenpairs within a couple of steps in substructure eigenvector subspace due to the good quality of the starting subspace.

The subspace iteration method is one candidate for solving our reduced eigenproblem, but it is very inefficient to apply our case because the Rayleigh-Ritz procedure in the subspace iteration method is very expensive due to the large dimension of a starting subspace for adequate accuracy.

### 3.3 Lanczos Methods

The Lanczos algorithm was first proposed in 1950 by C. Lanczos for reducing a symmetric matrix to tridiagonal form. After Paige's pioneering work in 1971 [40], the Lanczos algorithm has been developed continuously as a powerful tool for extracting some of the extreme eigenvalues of a real symmetric matrix. It is natural to see this algorithm as the Rayleigh-Ritz procedure on a Krylov subspace [40]. Compared with the subspace iteration method, it is relatively inexpensive to use to compute a large number of eigenpairs of very large sparse matrices [16].

The Lanczos algorithm constructs an orthonormal basis for the *Krylov subspace*

$$\begin{aligned}\mathcal{K}_m &= \text{span} \{ \mathbf{q}_1, (K^{-1}M)\mathbf{q}_1, \dots, (K^{-1}M)^{m-1}\mathbf{q}_1 \} \\ &= \text{span} \{ \mathbf{q}_1, \mathbf{q}_2, \dots, \mathbf{q}_m \}\end{aligned}\tag{3.12}$$

where  $\mathbf{q}_1$  is an arbitrary starting vector,  $\mathbf{q}_j$  is a Lanczos vector orthonormal to the previous  $j - 1$  Lanczos vectors with respect to  $M$ , and  $m$  is the dimension of the Krylov subspace. The Lanczos algorithm involves the transformation of a generalized eigenproblem into a standard form with a tridiagonal matrix with smaller dimension  $m$ , which is much less than the size of the eigenproblem. The tridiagonal matrix and the orthogonal Lanczos vectors are computed by a three-term recurrence relationship as follows [26]:

$$\beta_j \mathbf{q}_{j+1} = (K^{-1}M)\mathbf{q}_j - \alpha_j \mathbf{q}_j - \beta_{j-1} \mathbf{q}_{j-1}, \quad j = 1, 2, \dots, m \tag{3.13}$$

In the recurrence equation,  $\alpha_j$  and  $\beta_j$  are defined as

$$\alpha_j = \langle K^{-1}M\mathbf{q}_j, \mathbf{q}_j \rangle_M \quad (3.14)$$

$$\beta_j = \|(K^{-1}M)\mathbf{q}_j - \alpha_j\mathbf{q}_j - \beta_{j-1}\mathbf{q}_{j-1}\|_M \quad (3.15)$$

where  $\langle \cdot, \cdot \rangle_M$  denotes an inner product with respect to  $M$ , such that  $\langle \mathbf{x}, \mathbf{y} \rangle_M = \mathbf{x}^T M \mathbf{y}$ , and  $\|\cdot\|_M$  is defined as  $\|\mathbf{x}\|_M = \sqrt{\langle \mathbf{x}^T, \mathbf{x} \rangle_M}$ . As a result, the tridiagonal matrix becomes

$$T_m = \begin{bmatrix} \alpha_1 & \beta_2 & & & 0 \\ \beta_2 & \alpha_2 & \beta_3 & & \\ & \beta_3 & \ddots & \ddots & \\ & & \ddots & \ddots & \beta_m \\ 0 & & & \beta_m & \alpha_m \end{bmatrix} \quad (3.16)$$

The tridiagonalization process terminates at a value much smaller than  $n$ , which is the dimension of the matrix, and eigenpairs are computed from solving the standard tridiagonal eigenvalue problem

$$T_m \mathbf{s} = \frac{1}{\lambda} \mathbf{s}. \quad (3.17)$$

The eigenvector corresponding to  $\lambda_k$  is computed by

$$\phi_k = Q_m \mathbf{s}_k, \quad k = 1, 2, \dots, n_c \quad (3.18)$$

where  $Q_m = [\mathbf{q}_1, \mathbf{q}_2, \dots, \mathbf{q}_m]$  and  $n_c$  is the number of converged eigenvalues. The basic Lanczos algorithm for a generalized symmetric eigenproblem is summarized in Figure 3.3.

The tridiagonalization procedure, which is in step 1 to step 5 in the algorithm, does not produce  $M$ -orthonormal vectors as desired in practice due to round-off errors. This makes the Lanczos method less efficient especially for problems with closely spaced eigenvalues. To remedy this problem, Gram-Schmidt orthogonaliza-

```

begin
  set a starting vector  $\mathbf{q}$ 
   $\mathbf{q}_1 = \mathbf{q} / \|\mathbf{q}\|_M$ 
  set  $\beta_0 = 0$ 
  Lanczos Loop:
  for  $j = 1, 2, \dots, m$  do
1     $\mathbf{p}_j = K^{-1}(M\mathbf{q}_j)$ 
2     $\alpha_j = \mathbf{p}_j^T(M\mathbf{q}_j)$ 
3     $\mathbf{r}_j = \mathbf{p}_j - \alpha_j\mathbf{q}_j - \beta_{j-1}\mathbf{q}_{j-1}$ 
4     $\beta_j = \|\mathbf{r}_j\|_M$ 
5     $\mathbf{q}_{j+1} = \mathbf{r}_j / \beta_j$ 
6    solve the eigenproblem  $T_m \mathbf{s} = \theta \mathbf{s}$  as needed
    if converged then exit
  end
  compute the eigenpair approximations:
   $\phi_k = Q_m \mathbf{s}_k, \quad \lambda_k = 1/\theta_k \quad \text{where } k = 1, \dots, n_c$ 
end

```

Figure 3.3: Basic Lanczos algorithm for generalized symmetric eigenproblem

tion can be used, right after step 3 as follows.

$$\mathbf{r}_j = \mathbf{r}_j - \sum_{k=1}^j (\mathbf{r}_j^T M \mathbf{q}_k) \mathbf{q}_k - \sum_{k=1}^{n_{so}} (\mathbf{r}_j^T M \phi_k) \phi_k, \quad (3.19)$$

where  $n_{so}$  is the number of selected Ritz vectors for selective orthogonalization. There are several techniques to avoid loss of orthogonality in Lanczos vectors. The second term on the right-hand side in Equation (3.19) represents a full reorthogonalization against previous Lanczos vectors and the third term represents a selective orthogonalization against selected converged Ritz vectors [23, 24, 38]. Also, a partial reorthogonalization against previous Lanczos vectors when loss of orthogonality is detected, was proposed by Simon [28].

A spectral transformation or shifting strategy is useful when many eigenvalues are required and the eigenvalue distribution is clustered. By the spectral transformation, the relative separation of eigenvalues is affected dramatically even though their absolute separation is decreased [23]. This spread of the eigenvalues

```

Lanczos Loop:
for  $j = 1, 2, \dots$  do
1    $P_j = (K - \sigma M)^{-1}(MQ_j) - Q_{j-1}B_j^T$ 
2    $A_j = P_j^T(MQ_j)$ 
3    $R_{j+1} = P_j - Q_jA_j$ 
4   Compute the orthogonal factorization of  $R_{j+1}$ :
       $Q_{j+1}B_{j+1} = R_{j+1}$ ,
      where  $B_{j+1}$  is upper triangular and  $Q_{j+1}^T(MQ_{j+1}) = I$ .
5   Solve the eigenproblem  $T_j s_k = s_k \theta_k$  as needed,
      where  $k = 1, 2, \dots, (blocksize \times j)$ 
      if converged then exit
end

```

Figure 3.4: Lanczos Loop for the block Lanczos algorithm

ensures fast convergence to the eigenvalues near  $\sigma$ . Step 1 can be modified with shifted  $K_\sigma = (K - \sigma M)$  such that

$$\mathbf{p}_j = (K - \sigma M)^{-1} M \mathbf{q}_j, \quad (3.20)$$

and  $\lambda_k = \sigma + 1/\theta_k$ . The major cost for this fast convergence is the cost of a symmetric factorization  $(K - \sigma M) = LDL^T$ , where  $L$  is a unit lower triangular matrix and  $D$  is a diagonal matrix. Since the inertias of  $(K - \sigma M)$  and  $D$  are the same by Sylvester's Inertia Theorem [40, 45], we can compute the number of eigenvalues in the interval  $[\sigma_1, \sigma_2]$  within the spectrum by using two factorizations of  $(K - \sigma_1 M)$  and  $(K - \sigma_2 M)$ . Thus we can confirm the number of computed eigenvalues by comparing the number of eigenvalues in the interval  $[\sigma_1, \sigma_2]$  from the matrix inertias of  $(K - \sigma_1 M)$  and  $(K - \sigma_2 M)$ , which provides robustness of implementation. The strategy for choosing shifts should be carefully chosen so that the total cost, including the cost of the factorizations and the costs of Lanczos iterations, is minimized. Some heuristics are used for selecting an optimal sequence of shifts in some implementations [23, 24].

The block strategy, in addition to the shifting strategy, is preferable for better convergence when there are multiple eigenvalues and for better data management

on some computer architectures, particularly if  $(K - \sigma M)$  factors are out of core. As we notice in the basic Lanczos algorithm as shown in Figure 3.3 all the floating point operations performed are matrix-vector or vector-vector operations, which are very inefficient in terms of operation-to-memory-reference rate (or computational intensity) for sparse matrices. To achieve high performance, those operations are modified to matrix-matrix operations by the block strategy. One of the most robust implementations of the block Lanczos algorithm was produced by Grimes, Lewis, and Simon [23, 25] along with a sparse linear solver package. This is an implementation of a block Lanczos technique with a dynamic shift-invert scheme. The block version of the Lanczos loop in the Lanczos algorithm is summarized in Figure 3.4. In the figure,  $Q_j$  is a block of Lanczos vectors, and  $A_j$  and  $B_j$  for the block tridiagonal matrix  $T_j$  are analogous to the scalars  $\alpha_j$  and  $\beta_j$  for the tridiagonal matrix  $T_m$  in the basic Lanczos algorithm. In general, it is best to choose a blocksize as large as the largest expected multiplicity of eigenvalues. A blocksize of 6 or 7 works well on all systems [23], not only due to the multiplicity of eigenvalues but also due to the I/O expense. In a system in which I/O is less costly, a blocksize of 3 is more effective [24].

The factorizations typically represent the largest single cost in shift-invert block Lanczos eigenanalysis. There is a large constant cost per a block Lanczos iteration, comprising the matrix-block solve, matrix-block multiplication,  $QR$  factorization of  $R_{j+1}$  and reorthogonalizations as shown in Figure 3.4. Even though the block version of Lanczos algorithm improves the computational intensity, the block Lanczos algorithm has some significant performance bottlenecks for a huge size of eigenproblem requiring many eigenpairs because of the limitation on blocksize and the I/O cost relating to the Lanczos vectors for reorthogonalizations and the matrix factors for matrix-block solve.

### 3.4 Similarity Transformation Methods

Two matrices  $A, B \in \mathbb{R}^{n \times n}$  are said to be *similar* if there exists a nonsingular  $Q \in \mathbb{R}^{n \times n}$  such that

$$B = Q^{-1}AQ. \quad (3.21)$$

Equation (3.21) is called a *similarity transformation*. If  $Q$  is an orthogonal matrix, i.e.,  $Q^T Q = I$  [46], then by an orthogonal similarity transformation the standard eigenproblem,  $A\mathbf{x} = \lambda\mathbf{x}$ , becomes

$$(Q^T A Q)\mathbf{y} = \lambda\mathbf{y}, \quad (3.22)$$

where  $\mathbf{y} = Q^T \mathbf{x}$ . It is evident that if  $(\mathbf{x}, \lambda)$  is an eigenpair of  $A$ , then  $(Q^T \mathbf{x}, \lambda)$  is an eigenpair of  $(Q^T A Q)$ . With a suitable choice of an orthogonal matrix, the similarity transformation technique can be used to reduce  $A$  to a simpler form.

Frequently Householder reflectors are used for solving dense eigenvalue problems, to construct an orthogonal matrix  $Q$  that tridiagonalizes the matrix  $A$ . To use this approach on a generalized eigenvalue problem, it is common and convenient to transform the eigenproblem to standard form first. Using Cholesky factorization of the positive definite mass matrix  $M = U^T U$ , we can transform a generalized eigenvalue problem,  $K\mathbf{x} = \lambda M\mathbf{x}$ , to standard form,  $A\mathbf{y} = \lambda\mathbf{y}$ , while maintaining the symmetry of the original matrices, where  $A = U^{-T} K U^{-1}$ ,  $U$  is upper triangular, and  $\mathbf{x} = U^{-1} \mathbf{y}$ .

After we have a symmetric standard eigenproblem, the most common method to solve this eigenproblem has three phases [47, 68]: (1) **reduction** - reduce the given symmetric matrix  $A$  to tridiagonal form  $T$ , (2) **tridiagonal eigenproblem** - compute all or some of the eigenpairs of  $T$ , (3) **backtransformation** - transform  $T$ 's eigenvectors to  $A$ 's.

The initial reduction of  $A$  to tridiagonal form is made by a sequence of  $(n-2)$  orthogonal Householder reflections. More detailed explanation of this algorithm can

be found in [45]. This algorithm is implemented in the *LAPACK* routine *DSYTRD*.

For the tridiagonal eigenproblem, *Algorithm of Multiple Relatively Robust Representation* [66, 67] can be used to compute a full or partial eigensolution. Previously, there have been several algorithms to compute the eigensolution of the tridiagonal problem, including tridiagonal QR iteration, the divide-and-conquer algorithm, and bisection with inverse iteration. All of these require more than  $\mathcal{O}(n^2)$  operations for a full eigensolution. However, Parlett and Dhillon [63, 66, 67] have proposed a new  $\mathcal{O}(n^2)$  algorithm for computing all eigenvalues and eigenvectors for a symmetric tridiagonal problem. This new algorithm was implemented in the *LAPACK* routine *DSTEGR*. This algorithm is faster than any other existing algorithms and uses the least workspace.

For backtransformation, the eigenvectors can be obtained by simple matrix-matrix multiplication  $QS$ , where  $S$  is a matrix whose columns are eigenvectors of  $T$  and  $Q$  is a matrix representing the orthogonal matrix that was used for tridiagonal reduction. However, since  $Q$  is usually not explicitly computed in the tridiagonal reduction, we can form the product  $QS$  using Householder reflectors without forming  $Q$  explicitly. An efficient block algorithm for this backtransformation is implemented in the *LAPACK* routine *DORMTR*.

## Chapter 4

# A New Eigensolution Algorithm

In this chapter, characteristics of the reduced eigenproblem are carefully examined, and two standard approaches for the reduced eigenproblem are discussed in terms of computational efficiency. Then, a new eigensolution algorithm is introduced to efficiently solve the reduced eigenproblem on the substructure eigenvector subspace. After a brief preliminary overview of the new eigensolution algorithm is given, each piece of the algorithm is explained in detail, using the same example problem used for the AMLS transformation, in the later sections of this chapter. Finally, two practical issues in computer implementation of this new algorithm are discussed, along with proposed remedies for both problems.

### 4.1 Motivation for a New Eigensolution Algorithm

The primary objectives in designing a new eigensolution algorithm for the reduced eigenvalue problem produced by AMLS are to compute a large partial eigensolution, to minimize memory and disk space requirements by exploiting sparsity of matrices, to minimize operation counts and maximize parallel efficiency for fast runtime, and to be reliable. Note that we are looking for typically 10,000 eigenpairs. In order

to develop a new eigensolution algorithm satisfying these requirements, it is necessary to discuss the characteristics of the reduced eigenproblem generated by AMLS first. We will then compare two possible candidate eigensolvers for our reduced eigenproblem considering the characteristics of the problem.

#### 4.1.1 Reduced Eigenproblem Characteristics

After projecting  $K$  and  $M$  onto the substructure eigenvector subspace using AMLS, the transformed (or reduced) eigenproblem has the following characteristics:

1. The stiffness matrix is diagonal and its diagonal entries are substructure eigenvalues.
2. The mass matrix has unity on the diagonal entries and values less than unity on off-diagonal entries. The fact that the values on off-diagonal entries are less than unity can be simply proved by positive definiteness of the mass matrix  $M_A$ .
3. The approximate number of global eigenvalues within the frequency range of interest can be estimated due to the facts above.
4. An off-diagonal block of the mass matrix is nonzero only if its rows and columns correspond to an ancestor-descendant pair in the substructure tree as shown in Equation (2.26). Nonzero off-diagonal blocks of the mass matrix are densely populated.
5. According to Kaplan's experience with his eigensolution method [1], a good initial guess for a subspace containing the global eigenvectors can be obtained easily and economically. This subspace is represented with a very sparse matrix.

6. For practical frequency response analysis of structures, the accuracy of the eigensolution is only required to be consistent with the accuracy available from the FE discretization, rather than on the order of machine precision. Only an approximate partial eigensolution is required.
7. The total number of substructure eigenvectors  $n_A$  ( $\approx 10^5$ ) kept using the AMLS transformation is typically less than  $n_F$  ( $\approx 10^7$ ), the number of degrees of freedom in the FE discretization, by orders of magnitude, but the reduced eigenproblem is still too large to solve with conventional eigensolution algorithms for dense problems.
8. The number of global eigenpairs required,  $n_E$ , is typically about  $10^4$ . For frequency response applications, interest is primarily in the modal subspace from which the frequency response is approximated rather than individual eigenpairs.

Considering the characteristics above, we can consider a couple of existing eigensolution methods for this large sparse problem. As mentioned in the preceding chapter, candidates include the Lanczos method and the subspace iteration method. In the next subsection, we will discuss the advantages and disadvantages of both methods and arrive at a more promising approach for addressing our reduced eigenvalue problem.

#### 4.1.2 Lanczos Method versus Subspace Iteration Method

The block Lanczos method is useful for large, sparse eigenproblems because the operations involving the system matrices can take advantage of their sparsity. These operations include symmetric indefinite factorization of  $(K_A - \sigma M_A)$  with the necessary values of the shift  $\sigma$ , linear equation solution for a block of vectors at each iteration using the factored  $(K_A - \sigma M_A)$  matrix, and matrix-matrix multiplication

Table 4.1: The number of natural frequencies in several frequency ranges for “8.4M DOF” model

| Frequency range | Number of natural frequencies in range |
|-----------------|--|
| 1-100 Hz        | 581                                    |
| 100-200 Hz      | 990                                    |
| 200-300 Hz      | 1302                                   |
| 300-400 Hz      | 1520                                   |
| 400-500 Hz      | 1719                                   |
| 500-600 Hz      | 1852                                   |

with  $M_A$ , as discussed in Chapter 3.

For a large eigenproblem with many modes needed, mass matrix multiplications require not only many floating point operations, but also a very large amount of I/O when the sparse mass matrix is in secondary data storage. For example, if we need 10,000 eigenpairs, 25,000 or 30,000 Lanczos vectors are typically required for convergence, which require more than 2,000 iterations with a rather large blocksize of 12. Such a large number of mass matrix multiplications will be very expensive, especially if  $M_A$  is too large to fit in memory.

Because a large number of eigenpairs are sought, we frequently encounter close spacing of eigenvalues, which causes slow convergence. As an example, Table 4.1 presents the number of natural frequencies in several frequency ranges below 600 Hz for the “8.4M DOF” model, which will be used as a typical model with high modal density in Chapter 6. As a frequency range becomes higher, the number of natural frequencies within 100 Hz interval increases. Thus, the average number of natural frequencies in 1 Hz interval within the frequency range between 500 Hz and 600 Hz becomes about 18, which implies very close spacing of eigenvalues in that frequency range. To accelerate the convergence, a shifting strategy is used. If we expect typically around 200 converged eigenvalues per shift, dozens of shifts and factorizations of the shifted stiffness matrix are required. In addition, although

$K_A$  is diagonal, the shifted stiffness matrix,  $(K_A - \sigma M_A)$ , is not diagonal so its factorizations require many floating point operations.

If there are some clusters of eigenvalues within the spectrum of interest, reorthogonalization must be done very carefully to avoid loss of orthogonality between Lanczos vectors. A lot of costly I/O is required for reading in preceding Lanczos vectors of length 100,000 for reorthogonalization as the iteration proceeds. To overcome this defect, some techniques have been developed: full reorthogonalization against previous Lanczos vectors, selective orthogonalization against converged Ritz vectors, and partial reorthogonalization against Lanczos vectors when loss of orthogonality is detected [23, 24, 27, 28]. However, the reorthogonalization is still costly for Lanczos vectors of length 100,000.

As we have seen in the list of characteristics of our eigenproblem, a good initial subspace for all of the desired global eigenvectors is available. The Lanczos method, however, cannot exploit this initial guess for the entire subspace because the Lanczos method operates with a small block of vectors and converges to only a few eigenvectors at a time. It would be desirable to use an algorithm that can take full advantage of the initial guess for the entire eigenvector subspace for the reduced eigenproblem.

Subspace iteration is not as efficient as the Lanczos method in general [16], but it may be better than the Lanczos method in our case, because a very good starting subspace is represented with a very sparse matrix. Since we have a good guess of the eigenspace<sup>1</sup> for the reduced eigenproblem, convergence can be expected in very few iteration steps. However, the dimension of the substructure eigenvector subspace, typically 100,000, is still too large for inexpensive Rayleigh-Ritz analysis.

The above considerations lead us to explore a new eigensolution algorithm that takes the greatest possible advantage of subspace iteration, where the iteration

---

<sup>1</sup>In this dissertation, the term “eigenspace” is defined as a subspace spanned by eigenvectors of the matrix pencil  $(K, M)$ , where  $K$  and  $M$  are stiffness and mass matrices, respectively.

```

begin
1   Form the distilled subspace, represented by  $T_D$ 
2   Project  $K_A$  and  $M_A$  onto the distilled subspace:
       $K_D = T_D^T K_A T_D$  ;  $M_D = T_D^T M_A T_D$ 
3   Set starting subspace :  $V_0$ 
4   One subspace iteration:  $V_1 = [K_D^{-1} M_D] V_0$ 
5   Rayleigh-Ritz analysis
5.1   Project onto the Ritz subspace represented by  $V_1$ :
       $K_V = V_1^T K_D V_1$  ;  $M_V = V_1^T M_D V_1$ 
5.2   Solve the projected eigenproblem:
       $K_V Q_V = M_V Q_V \Lambda_V$ 
5.3   Compute Ritz eigenvectors:
       $\Phi_D \approx V_1 Q_V$ ,  $\Lambda_D \approx \Lambda_V$ 
      end
6   Compute eigenvectors on the substructure eigenvector subspace:
       $\Phi_A \approx T_D \Phi_D$ ,  $\Lambda_A \approx \Lambda_D$ 
end

```

Figure 4.1: New eigensolution algorithm for the reduced eigenproblem produced by the AMLS transformation

is very inexpensive because the subspace is represented with a very sparse matrix. By taking advantage of substructure eigensolution properties to minimize the number of operations required, we can minimize the size of the eigenproblem for Rayleigh-Ritz analysis to save computational costs. In the next section, an overview of a new eigensolution algorithm for our reduced eigenproblem is presented.

## 4.2 Preliminary Eigensolution Algorithm

From the identified characteristics of the reduced eigenproblem in Section 4.1.1 and the survey of eigensolution methods in Section 4.1.2, we learned that subspace iteration has the advantage of being able to exploit the initial guess available for the entire subspace of desired eigenvectors, but has disadvantage of expensive computational cost in the Rayleigh-Ritz analysis due to the large dimension of the substructure eigenvector subspace and possibly the large dimension of a starting subspace.

There is an opportunity for further reduction in order to improve the efficiency of the subspace iteration method, if we can reduce the substructure eigenvector subspace without losing much accuracy. We can call this process “distillation”. Within the “distilled” subspace, we can select a particularly good initial subspace which is represented by a sparse matrix, and we can perform one subspace iteration to refine it. Then we perform Rayleigh-Ritz analysis on the refined subspace to approximate the global eigenpairs, and compute the eigenvectors on the substructure eigenvector subspace and on the FE discretization subspace subsequently. The algorithm for this new eigensolution method is summarized in Figure 4.1.

For better understanding of this new algorithm in terms of subspaces used, the relationships between subspaces in the new eigensolution method are illustrated with their typical dimensions in Figure 4.2. We have the eigenproblem of 10 million degrees of freedom (10M DOF) in the finite element subspace “ $\mathcal{F}$ ”<sup>2</sup>. Using the AMLS transformation, we can project the FE eigenproblem onto the AMLS subspace (“ $\mathcal{A}$ ”) of dimension 100,000 (100K). We distill the AMLS subspace and so obtain new smaller distilled subspace (“ $\mathcal{D}$ ”) of typically dimension 40,000 (40K). Then, we form a truncated subspace “ $\mathcal{V}_0$ ” of dimension 12,000 (12K) in the distilled subspace and do one subspace iteration to obtain the refined subspace “ $\mathcal{V}_1$ ”. The approximate global eigenspace “ $\mathcal{E}$ ” is computed by one Rayleigh-Ritz analysis on the refined subspace  $\mathcal{V}_1$ . Finally, eigenvector computations on the subspace  $\mathcal{A}$  and subsequently on the subspace  $\mathcal{F}$  can be done to obtain the approximate global eigensolution in the original FE discretization subspace. Each of the steps of the new eigensolution algorithm shown in Figure 4.1 is explored individually in the remainder of this chapter.

---

<sup>2</sup>From now on, the subspaces used in the new eigensolution algorithm will be denoted with calligraphic letters.

|                 |   |                   |   |
|-----------------|---|-------------------|---|
| $\mathcal{F}$ : | FE subspace (10M)                         | $\mathcal{V}_0$ : | Truncated subspace of $\mathcal{D}$ (12K) |
| $\mathcal{A}$ : | AMLS subspace (100K)                      | $\mathcal{V}_1$ : | Refined subspace of $\mathcal{D}$ (12K)   |

Figure 4.2: Subspaces of the new eigensolution method

### 4.3 Projection onto a Distilled Subspace

In the process of setting the parameters for the AMLS reduction from the FE subspace ( $\mathcal{F}$ ) to the AMLS subspace ( $\mathcal{A}$ ), we investigated tradeoffs between substructure sizes, substructure eigenvalue cutoff values, global eigensolution accuracy and computer resource usage. We observed that increasing the size of the “leaf” substructure, which is a substructure does not have descendant in the substructure tree, while keeping the same accuracy for the global eigensolution, decreases the number of substructure eigenvectors kept, and allows the eigenvalue cutoff  $\omega_A^2$  for substructure eigenproblems to decrease. However, increasing the leaf substructure size increases the time required for *Phase3*, the program executes the AMLS transformation, because the cost of factoring substructure stiffness matrices and solving substructure eigenvalue problems increases faster than the substructure size. Moreover, the memory usage of *Phase3* increases significantly as the leaf substructure

size increases. This observation indicates that using larger leaf substructures for a FE model results in a more compact substructure eigenvector subspace, but at the cost of a substantial performance penalty in *Phase3*. This means that if the FE model is divided into larger substructures, the substructure eigenvalue cutoff  $\omega_A^2$  can be lowered while achieving the same global eigensolution accuracy as with a smaller leaf substructure size.

Figure 4.3 summarizes the effects of varying the maximum size of leaf substructures, on the number of substructure eigenvectors kept (or the dimension of the subspace  $\mathcal{A}$ ) and the performance of *Phase3* for a “Trim-Body” model, which will be used for numerical results in Chapter 6. The target size of leaf substructures was varied from 700 to 12000. A consistent level of accuracy in the global eigensolution was maintained by adjusting the substructure eigenvalue cutoff  $\omega_A^2$  so that the number of approximate global eigenpairs with natural frequencies below a cutoff frequency of  $\omega_G = 2\pi \cdot 600$  Hz was equal to 4,208 in all cases, according to the inertias of the matrix  $(K_A - \omega_G^2 M_A)$ . Note that the inertia of the matrix  $A$  is defined by the nonnegative number triple  $(\nu(A), \zeta(A), \pi(A))$ , each of which denotes the number of negative, zero, and positive eigenvalues of  $A$ , respectively. From the results in Figure 4.3, we can recognize that as the maximum leaf substructure size increases, a smaller substructure eigenvector subspace ( $\mathcal{A}$ ), which gives the same accuracy in the global eigensolution, can be obtained. The elapsed time and memory usage, however, increase significantly as the maximum substructure size increases.

These results suggest that we can build a reduced subspace of the substructure eigenvector subspace without any performance penalty in *Phase3*. To do this, we can compute and truncate the eigenpairs of a subtree, which is a node in the substructure tree and all of its descendants down to the leaf level. In other words, we can distill the substructure eigenvector subspace by combining together the substructures that constitute a subtree of the substructure tree, and computing eigen-

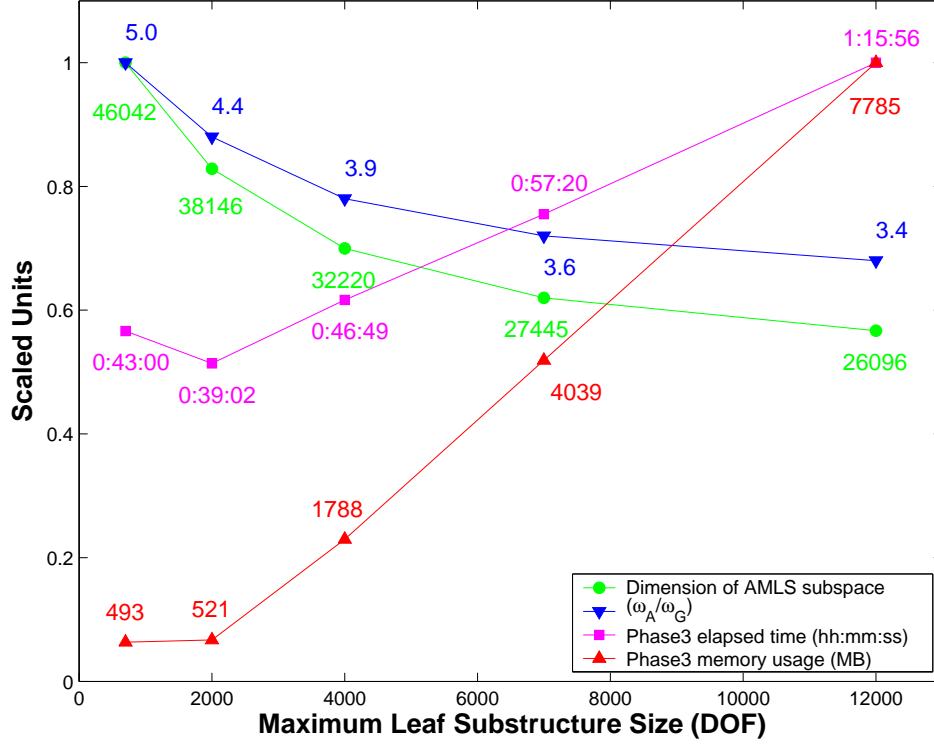

Figure 4.3: Effect of leaf substructure size for “Trim-Body” model

vectors inexpensively for small subtree eigenproblems. Truncation on the subtree level yields a result similar to using the subtree node as a leaf substructure, but without the high cost of using large leaf substructures in the AMLS transformation.

As an example, Figure 4.4(a) presents a substructure tree of the Trim-Body model which is the same model used for the effect of maximum leaf substructure size in *Phase3* in Figure 4.3. This substructure tree has 4121 substructures as nodes on 22 levels. From the substructure tree in Figure 4.4(a), we can define 14 subtrees by selecting subtree root substructures (small red circles) and combining all of their descendant substructures, targeting a maximum subtree size of 5000. After computing and truncating the eigenspace for subtrees we have the truncated substructure tree shown in Figure 4.4(b), where big blue circles represent subtrees after truncation of the substructure tree in subtree levels. The largest subtree among

(a) Substructure tree for Trim-Body model

(b) Truncated substructure tree for Trim-Body model

Figure 4.4: Substructure tree versus truncated substructure tree at subtree levels for Trim-Body model

Figure 4.5: Substructure tree truncation process. (a) Defining subtrees in the original substructure tree. (b) Truncated substructure tree after defining subtrees and truncating subtree eigenspace.

the 14 subtrees in this model contains 509 substructures, and the total number of FE degrees of freedom corresponding to this subtree is 218, 230. Therefore, defining subtrees after the AMLS transformation has an effect of defining significantly larger leaf substructures, and makes it possible to achieve the same accuracy with a lower substructure eigenvalue cutoff.

For “branch substructures”, which are substructures that are not included in subtrees represented with small red dots in Figure 4.4(b), we do not need to solve an eigenproblem but merely truncate the substructure eigenspace using the same cutoff frequency as for subtrees. With eigenspace truncation for both subtrees and branch substructures, we can achieve reduction of the substructure eigenvector subspace ( $\mathcal{A}$  or the AMLS subspace), sacrificing little accuracy. Hence, the new distilled subspace contains subtree eigenvectors for subtrees and Boolean vectors for branch substructures. The distillation cutoff frequency  $\omega_D$  should be chosen based on the accuracy we want to achieve.

To illustrate the distilling process, we use the same example model which was used in the AMLS transformation in Section 2.2. For the plate model with seven substructures as shown in Figure 2.1, we begin the distilling process of the substructure eigenvector subspace by identifying subtrees of the original substructure tree shown in Figure 4.5(a). We select substructures 3 and 6 from Figure 4.5(a) as root nodes for subtrees as the simplest possible examples. Each subtree has stiffness and mass matrices that are simply the appropriate submatrices of  $K_A$  and  $M_A$ , with as many rows and columns as the total number of substructure eigenvectors for the subtree. Let us recall the AMLS transformed stiffness matrix  $K_A$  in Equation (2.25) and the AMLS transformed mass matrix  $M_A$  in Equation (2.26). According to the truncated substructure tree as shown in Figure 4.5(b), the stiffness matrix  $K_A$  can be partitioned as

$$K_A = \left[ \begin{array}{ccc|cc|c} \Lambda_1 & 0 & 0 & & & \\ & \Lambda_2 & 0 & \mathbf{0} & & \mathbf{0} \\ & & \Lambda_3 & & & \\ \hline & & & \Lambda_4 & 0 & 0 \\ & & & & \Lambda_5 & 0 \\ & & & & & \Lambda_6 \\ & (sym.) & & & & \\ \hline & & & & & \Lambda_7 \end{array} \right] \quad (4.1)$$

$$= \left[ \begin{array}{c|cc} (K_A)_{s_3} & \mathbf{0} & \mathbf{0} \\ \hline & (K_A)_{s_6} & \mathbf{0} \\ & & \\ (sym.) & & (K_A)_{s_7} \end{array} \right] \quad (4.2)$$

Similarly, the mass matrix  $M_A$  can be partitioned as

$$M_A = \left[ \begin{array}{ccc|ccc|c} I_1 & 0 & (M_A)_{1,3} & & & & (M_A)_{1,7} \\ & I_2 & (M_A)_{2,3} & & & & (M_A)_{2,7} \\ & & I_3 & & & & (M_A)_{3,7} \\ \hline & & & I_4 & 0 & (M_A)_{4,6} & (M_A)_{4,7} \\ & & & & I_5 & (M_A)_{5,6} & (M_A)_{5,7} \\ & (sym.) & & & & I_6 & (M_A)_{6,7} \\ \hline & & & & & & I_7 \end{array} \right] \quad (4.3)$$

$$= \left[ \begin{array}{c|cc} (M_A)_{s_3} & \mathbf{0} & (M_A)_{s_{3,7}} \\ \hline & (M_A)_{s_6} & (M_A)_{s_{6,7}} \\ \hline (sym.) & & (M_A)_{s_7} \end{array} \right] \quad (4.4)$$

where the subscript  $s_{i,j}$  denotes the coupling between the subtree  $i$  (or possibly branch substructure  $i$ ) and the branch substructure  $j$ , and the subscript  $s_i$  is an abbreviation of the subscript  $s_{i,i}$ . Therefore, the stiffness matrix of the subtree rooted at substructure 3 is simply a diagonal matrix of the form

$$(K_A)_{s_3} = \begin{bmatrix} \Lambda_1 & 0 & 0 \\ 0 & \Lambda_2 & 0 \\ 0 & 0 & \Lambda_3 \end{bmatrix} \quad (4.5)$$

and the mass matrix of the subtree rooted at substructure 3 is:

$$(M_A)_{s_3} = \begin{bmatrix} I_1 & 0 & (M_A)_{1,3} \\ & I_2 & (M_A)_{2,3} \\ (sym.) & & I_3 \end{bmatrix} \quad (4.6)$$

where  $I_i$  represents an identity matrix corresponding to substructure  $i$ . The stiffness and mass matrices for the subtree rooted at node 6 are similar. The eigenvalue problem for each subtree is defined in terms of the subtree stiffness and mass matrices as

$$(K_A)_{s_i} \Phi_{s_i} = (M_A)_{s_i} \Phi_{s_i} \Lambda_{s_i}, \quad i = 3, 6. \quad (4.7)$$

In practice, the main consideration in the selection of a node as the root of a subtree is the dimension of the resulting subtree eigenvalue problem. A target dimension for the subtree eigenvalue problems will likely depend on how the cost of the eigensolution increases with eigenvalue problem size. Suppose, for example, that the cost of solving one of these problems increases as the cube of its dimension. If root nodes for subtrees are too close to the root of the entire substructure tree, the subtree eigenvalue problems can become too large and therefore excessively expensive to solve. A partial eigensolution for subtrees is computed for eigenvalues up to the distillation cutoff value  $\omega_D^2$ .

Solving the subtree eigenvalue problems and truncating their eigenspaces has the effect of cutting off the branches of the substructure tree at the subtree root nodes. The subtree effectively becomes a leaf substructure in the substructure tree, and the tree becomes much simpler and smaller as a result of this truncation process as illustrated in Figure 4.5.

In the example, node 7 is the only node in the substructure tree that has not been included in subtrees 3 and 6, because it is “above” the subtree level. For this branch substructure, truncating its eigenspace does not require an eigenvalue problem to be solved because the truncation is simply done by deciding which substructure eigenvectors to keep, based on whether its eigenvalues are below the distillation cutoff value  $\omega_D^2$ .

For the tree in Figure 4.5(b), the distilled subspace containing the subtree eigenvectors and the Boolean vectors for the branch substructure is represented by the matrix

$$T_D = \begin{bmatrix} \Phi_{s_3} & 0 & 0 \\ 0 & \Phi_{s_6} & 0 \\ 0 & 0 & \begin{bmatrix} I \\ 0 \end{bmatrix}_{s_7} \end{bmatrix} = \begin{bmatrix} \Phi_{s_3} & 0 & 0 \\ 0 & \Phi_{s_6} & 0 \\ 0 & 0 & B_{s_7} \end{bmatrix} \quad (4.8)$$

Here the submatrices  $\Phi_{s_3}$  and  $\Phi_{s_6}$  are rectangular and contain subtree eigenvectors. The submatrix  $B_{s_7}$ , containing identity and null matrices, has the effect of selecting the substructure eigenvectors whose eigenvalues are below the cutoff value  $\omega_D^2$ , for the branch substructure (node 7). The sparsity of this transformation matrix  $T_D$ , makes it inexpensive to project the matrices  $K_A$  and  $M_A$  onto its subspace.

By using this transformation matrix  $T_D$ , the projection of the stiffness matrix  $K_A$ , shown in Equation (4.2), is given by

$$\begin{aligned}
K_D &= T_D^T K_A T_D \\
&= T_D^T \begin{bmatrix} (K_A)_{s_3} & 0 & 0 \\ & (K_A)_{s_6} & 0 \\ (sym.) & & (K_A)_{s_7} \end{bmatrix} T_D \\
&= \begin{bmatrix} \Lambda_{s_3} & 0 & 0 \\ & \Lambda_{s_6} & 0 \\ (sym.) & & \Lambda_{s_7} \end{bmatrix}
\end{aligned} \tag{4.9}$$

assuming the orthonormality of subtree eigenvectors with respect to subtree mass matrix. Similarly, the projection of the mass matrix  $M_A$  in Equation (4.4) becomes

$$\begin{aligned}
M_D &= T_D^T M_A T_D \\
&= T_D^T \begin{bmatrix} (M_A)_{s_3} & 0 & (M_A)_{s_3,7} \\ & (M_A)_{s_6} & (M_A)_{s_6,7} \\ (sym.) & & (M_A)_{s_7} \end{bmatrix} T_D \\
&= \begin{bmatrix} I & 0 & \Phi_{s_3}^T (M_A)_{s_3,7} B_{s_7} \\ & I & \Phi_{s_6}^T (M_A)_{s_6,7} B_{s_7} \\ (sym.) & & I \end{bmatrix}
\end{aligned} \tag{4.10}$$

Eigenpairs of the problem  $K_A \Phi_A = M_A \Phi_A \Lambda_A$  can be approximated, using the distilled subspace represented by the matrix  $T_D$ , by projecting  $K_A$  and  $M_A$  onto

this subspace and solving the eigenvalue problem

$$K_D \Phi_D = M_D \Phi_D \Lambda_D. \quad (4.11)$$

The accuracy of this approximation will depend on the cutoff frequency  $\omega_D$  used in truncation, where  $\omega_D$  is the cutoff frequency for subtree eigenproblems and for branch substructure truncation. Note that instead of simply solving the eigenproblem in Equation (4.11), we will approximate the solution of the eigenvalue problem in Equation (4.11) using a truncated subspace, one subspace iteration, and one Rayleigh-Ritz analysis as described in the following sections.

This projection onto the distilled subspace results in system matrices  $K_D$  and  $M_D$ , which retain advantageous properties of  $K_A$  and  $M_A$ . The stiffness matrix,  $K_D$ , remains diagonal and its diagonal elements contain subtree eigenvalues, and truncated sets of substructure eigenvalues for branch substructures. The mass matrix,  $M_D$ , also keeps the sparsity pattern according to the truncated substructure tree shown in Figure 4.5(b), but nonzero off-diagonal elements in  $M_A$  within a subtree are eliminated by solving the subtree eigenvalue problem. Therefore, the mass matrix  $M_D$  has fewer nonzero elements than the mass matrix  $M_A$ . Furthermore, the computational cost of multiplying  $V_1$  by  $M_D$  in Rayleigh-Ritz analysis would be inexpensive due to the reduced number of nonzero elements of the mass matrix  $M_D$ . The cost of projecting the reduced eigenproblem onto the distilled subspace depends mostly on the cost of solving subtree eigenvalue problems, which strongly depends on the target dimension of these eigenvalue problems. The effect of the target size of subtrees on the eigensolution accuracy and the timing performance is investigated for two models in Chapter 6.

There are many reasons for projecting the eigenvalue problem onto the distilled subspace. First, the main cost is that of solving perhaps a few dozen small subtree eigenproblems, which are inexpensive to solve because of their size and can be solved in parallel. Because the distilled subspace is represented by the block

diagonal rectangular matrix,  $T_D$ , the projection onto this subspace is inexpensive. The stiffness matrix  $K_A$  becomes the smaller diagonal matrix  $K_D$ . For the mass matrix  $M_A$ , the projection is done by simply premultiplying off-diagonal submatrices corresponding to ancestor of a subtree in  $M_A$  by the subtree eigenvectors and truncating the columns according to the Boolean matrices for branch substructures as shown in Equation (4.10). Since we just truncate the substructure eigenpairs for branch substructures, we do not need to compute any branch substructure eigenpairs whose eigenvalues are above the distillation cutoff value  $\omega_D^2$  in the initial AMLS transformation. This fact reduces the cost of the AMLS transformation for branch substructures. Since the system matrices  $K_D$  and  $M_D$  are reduced and simplified in subtree levels, we can more reliably identify good vectors for a starting subspace in subtree levels. As a result, we can have a smaller starting subspace for the final Rayleigh-Ritz eigenproblem on the distilled subspace.

## 4.4 Starting Subspace

The choice of the starting subspace plays a critical role in our eigensolution analysis because the dimension of the starting subspace determines the cost of the entire eigensolution process. Hence, we want to minimize the starting subspace dimension while achieving acceptable accuracy with one subspace iteration. A starting subspace should be very close to the eigenspace of the distilled eigenproblem of Equation (4.11).

In the distilled subspace, we have the diagonal matrix  $K_D$  and the block-sparse matrix  $M_D$  that has values of unity on the diagonal elements and values less than unity on the off-diagonal elements. In a crude approximation, the mass matrix  $M_D$  resembles an identity matrix. If the system matrices  $K_D$  and  $M_D$  are diagonal, the unit vectors with the values of unity corresponding to those degrees of freedom that have the smallest ratios  $(K_D)_{ii}/(M_D)_{ii}$ , are the eigenvectors corre-

sponding to the smallest eigenvalues. Since we have the system matrices  $K_D$  and  $M_D$  which are diagonal and close to a diagonal form, respectively, we can expect a good starting subspace by collecting unit vectors corresponding to the smallest ratios  $(K_D)_{ii}/(M_D)_{ii}$ . Therefore, a good starting subspace can be constructed by collecting unit vectors that have ones in the rows corresponding to the eigenvalues less than some cutoff value for subtrees and branch substructures.

To construct a starting subspace, we might need two different cutoff frequencies. One is  $\omega_V^{st}$  for subtrees and the other is  $\omega_V^{bs}$  for branch substructures. Since we improve the eigenproperties in the subtree levels by computing subtree eigensolution, the subtree cutoff frequency,  $\omega_V^{st}$ , for selecting initial vectors being included in the starting subspace might be very close to the global cutoff frequency  $\omega_G$ . For branch substructures, however, a cutoff frequency  $\omega_V^{bs}$  might be larger than the subtree cutoff frequency  $\omega_V^{st}$  for accuracy because we do just truncate the branch substructure eigenspace in the distillation process. The effects of the two cutoff frequencies for subtrees and branch substructures in forming a starting subspace are investigated later for two models in Chapter 6.

After we select the cutoff frequencies for a starting subspace, the initial vectors are collected based on the cutoff values for subtrees and branch substructures to form a matrix. The dimension of the starting subspace is the dense eigenproblem dimension in Rayleigh-Ritz analysis. Since the cost of solving the Rayleigh-Ritz eigenproblem increases as the cube of its dimension, the cutoff frequencies for the starting subspace must be determined to achieve the minimum dimension of starting space with acceptable accuracy and affordable computational costs. If a more accurate eigensolution is required, the size of the starting subspace should be increased by choosing higher cutoff values for the subtrees and branch substructures, but this will result in more computational costs.

As a result of selecting unit vectors for subtrees and branch substructures,

the matrix representing the starting subspace for solving the eigenvalue problem shown in Equation (4.11) can be expressed as

$$V_0 = \begin{bmatrix} \begin{bmatrix} I \\ 0 \end{bmatrix}_{s_3} & 0 & 0 \\ 0 & \begin{bmatrix} I \\ 0 \end{bmatrix}_{s_6} & 0 \\ 0 & 0 & \begin{bmatrix} I \\ 0 \end{bmatrix}_{s_7} \end{bmatrix} \quad (4.12)$$

The null submatrix in the rectangular matrix,  $[I \ 0]_{s_i}^T$ , indicates that the eigenvalues for subtrees 3 and 6 are truncated based on the cutoff value for subtrees  $\omega_V^{st}$ . Similarly, the eigenvalues for the substructure 7 are truncated based on the other cutoff value for branch substructures  $\omega_V^{bs}$ . Due to the block identity submatrices in the matrix  $V_0$  and the fact that the matrices  $K_D$  and  $M_D$  are diagonal and block-sparse, respectively, the new subspace improved by one “inverse iteration”, is still represented by a sparse matrix, as will be shown in the next section.

## 4.5 Subspace Improved by One “Inverse Iteration”

The improved (or refined) subspace can be obtained by using one “inverse iteration” (or subspace iteration) of the form

$$\begin{aligned}
 V_1 &= K_D^{-1} (M_D V_0) \\
 &= K_D^{-1} \begin{bmatrix} \begin{bmatrix} I \\ 0 \end{bmatrix} & 0 & \circledast \\ 0 & \begin{bmatrix} I \\ 0 \end{bmatrix} & \circledast \\ \circledast & \circledast & \begin{bmatrix} I \\ 0 \end{bmatrix} \end{bmatrix}
 \end{aligned} \tag{4.13}$$

where a “ $\circledast$ ” represents a nonzero block in the product  $(M_D V_0)$ .

Multiplying  $V_0$  by  $M_D$  produces a matrix that is just a collection of the columns of  $M_D$  corresponding to nonzero rows of the matrix  $V_0$ . Also, premultiplying this matrix by  $K_D^{-1}$  simply scales the rows of the product  $(M_D V_0)$  with the eigenvalues of subtrees and branch substructures. We simply delete some columns of  $M_D$  based on the sparsity of  $V_0$  to form  $(M_D V_0)$ , so that there is no floating point operation at all in this sparse iteration process. The only cost in this sparse iteration is the cost of scaling with diagonal  $K_D^{-1}$ , resulting in a number of multiplications equal to the number of nonzero off-diagonal elements in  $(M_D V_0)$ . So computing the matrix  $V_1$  representing the refined subspace is very economical and the matrix  $V_1$  is still sparse due to the identity submatrices in the matrix  $V_0$  representing the starting subspace. The sparse matrix  $V_1$  shown in Equation (4.13) requires much less memory and disk space, if we store only nonzero submatrices, than a full matrix would.

One more refinement by inverse iteration, possibly using a shifting strategy, would improve the accuracy of the eigensolution, but it would cost much more since

the matrix representing the new subspace would be fully populated. Therefore, our goal is to choose  $\omega_V$  just high enough to achieve acceptable accuracy with only one iteration.

## 4.6 Rayleigh-Ritz Analysis

Rayleigh-Ritz analysis for a given Ritz subspace involves three phases: (1) *projection onto Ritz subspace* – project the given system matrices onto the given Ritz subspace, (2) *eigenproblem for Ritz values* – compute the required eigenpairs of the projected problem, (3) *computation of Ritz eigenvectors* – convert eigenvectors of the projected problem to eigenvectors of the larger original problem. Each phase is explained in detail for our problem below.

To extract an approximate eigensolution, the eigenvalue problem must be solved on the refined subspace ( $\mathcal{V}_1$ ) represented by the matrix  $V_1$ . The stiffness and mass matrices are projected onto the subspace represented by the matrix  $V_1$  as

$$K_V = V_1^T K_D V_1 \quad \text{and} \quad M_V = V_1^T M_D V_1. \quad (4.14)$$

This leads to the following projected eigenvalue problem

$$K_V Q_V = M_V Q_V \Lambda_V, \quad (4.15)$$

where  $\Lambda_V$  is a diagonal matrix containing eigenvalues and the columns of  $Q_V$  are the  $M_V$ -orthonormalized eigenvectors.

The generalized eigenvalue problem in Equation (4.15) can be reduced to a standard symmetric eigenvalue problem, using a Cholesky factorization of the mass matrix,  $M_V = U^T U$ , as

$$A_V X_V = X_V \Lambda_V \quad (4.16)$$

where

$$A_V = U^{-T} K_V U^{-1}, \quad X_V = U Q_V \quad (4.17)$$

and  $U$  is an upper triangular matrix. Due to the dimensional reduction to the distilled subspace and then to the starting subspace, the dimension of this final eigenproblem is not much larger than the number of eigenpairs required. Hence, this is a dense eigenvalue problem requiring almost the full eigensolution that can appropriately use Householder reduction to tridiagonalize the matrix  $A_V$ .

After tridiagonalization of the matrix  $A_V$ , we have the eigenproblem  $TS = S\Lambda$ , where  $T = Q^T A_V Q$  and  $Q$  is the orthogonal matrix which was used to tridiagonalize the matrix  $A_V$ . For this tridiagonal eigenproblem, we can use the new algorithm by Dhillon [63] which requires only  $\mathcal{O}(n_v^2)$  operations for a partial or full eigensolution, where  $n_v$  is the dimension of the eigenproblem. The algorithm is referred to as Algorithm MRRR (*multiple relatively robust representations*) [66, 67, 68]. Using the bidiagonal factorization  $T = LDL^T$  as an RRR, desired eigenvalues are computed to high relative accuracy and partitioned into clusters according to their relative gaps [63, 67, 68]. Here,  $L$  is a unit lower triangular matrix and  $D$  is a diagonal matrix. For clusters with one eigenvalue, i.e., well separated eigenvalues, the corresponding eigenvectors are computed by inverse iterations and twisted factorization without any orthogonalization process based on the fact that the computed eigenvectors are numerically orthogonal when the eigenvalues have large gaps. For clusters with multiple eigenvalues, i.e., the eigenvalues have small relative gaps, Algorithm MRRR uses multiple factorizations ( $L_c D_c L_c^T = LDL^T - \tau_c I$ ) by choosing the shifts  $\tau_c$  to make relative gaps between clustered eigenvalues bigger. This process is recursively performed until the relative gaps between clustered eigenvalues are big enough to ensure orthogonality between eigenvectors.

The eigenvectors of the tridiagonal matrix are backtransformed by using Householder reflectors which were generated in the tridiagonal reduction stage. Therefore, we can solve the final standard eigenvalue problem in Equation (4.16) using the most efficient and reliable dense eigensolver.

Figure 4.6: Algorithm for Rayleigh-Ritz analysis on the Ritz subspace  $\mathcal{V}_1$

After we have computed the eigenpairs of the standard eigenvalue problem, the eigenvectors corresponding to those of the generalized eigenproblem of Equation (4.15) are computed. This requires  $U Q_V = X_V$  to be solved for  $Q_V$ .

The Ritz eigenvectors in the subspace  $\mathcal{D}$  are finally approximated as follows:

$$\Phi_D \approx V_1 Q_V \quad (4.18)$$

This matrix-matrix multiplication can be done on the level of individual subtrees and branch substructures, if the sparse column block of  $V_1$  corresponding to each subtree or branch substructure is stored appropriately. This multiplication can be done economically due to the sparsity of  $V_1$  and is easy to parallelize because the matrix  $V_1$  has already been divided into column blocks corresponding to subtrees and branch substructures, and the matrix  $Q_V$  is available for all the processors. The algorithm for the Rayleigh-Ritz analysis is summarized in Figure 4.6.

## 4.7 Computation of Eigenvectors on the Subspace $\mathcal{A}$

Once we obtain the eigensolution in the distilled subspace, we need to recover the eigenvectors  $\Phi_A$  as

$$\Phi_A \approx T_D \Phi_D \quad (4.19)$$

and the eigenvalues as  $\Lambda_A \approx \Lambda_D$ . As shown in Equation (4.8),  $T_D$  is a block diagonal matrix with  $\Phi_{s_i}$  or  $B_{s_i}$  on its diagonal block. Due to this sparsity of  $T_D$ , the computation in Equation (4.19) is inexpensive and easily parallelizable. More detailed algorithm for this computation is shown when the parallelism of this algorithm is explained in Chapter 5.

## 4.8 Practical Issues in Numerical Implementation

When we factor the projected mass matrix  $M_V$  (step 1 in Figure 4.6) we have observed that the factorization sometimes fails because the matrix  $M_V$  is not positive definite. There are two reasons for factorization failure in the projected mass matrix  $M_V$ :

- linearly dependent vectors (or nearly linearly dependent vectors) in the refined subspace represented by the matrix  $V_1$ .
- indefiniteness of the mass matrix resulting from poor finite element modelling practice.

These practical issues must be properly handled so that we are guaranteed to have a good approximation of the eigensolution. We explain why these problems occur and show remedies of the problems.

#### 4.8.1 Low Frequency Modes

Rigid body modes and low frequency modes cause the stiffness matrix to be singular or ill-conditioned. This singular or ill-conditioned stiffness matrix  $K_D$  can cause problems in forming a refined subspace represented by  $V_1$  by inverse iteration. Since the entries in the diagonal stiffness matrix  $K_D$  corresponding to rigid body modes are zeros, the inverse of  $K_D$  does not exist. Singularity of  $K_D$  can be addressed by deflating the system matrices [1]. Since the eigenvectors for the substructure at the root of the tree corresponding to zero eigenvalues represent the global rigid body modes [1], we can easily separate the rigid body modes from the flexible modes of the system to avoid singularity of  $K_D$ .

Columns of  $V_1$  might become nearly linearly dependent due to very small substructure eigenvalues. The near linear dependence of columns of  $V_1$  comes from premultiplying by the inverse of the nearly singular stiffness matrix  $K_D$ . For example, if  $(\lambda_1)_{s_7}$  (the first eigenvalue in substructure 7 in the tree of Figure 4.5) is very small, all the column vectors in  $V_1$  have a nonzero in  $(\lambda_1)_{s_7}$ 's row because of multiplication of  $V_0$  by  $M_D$ , and this nonzero becomes very large after multiplication by the diagonal matrix  $K_D^{-1}$  as shown in Equation (4.13). Therefore, all columns of  $V_1$  become near multiples of  $(e_1)_{s_7}$ , which is the Euclidean unit vector with one in  $(\lambda_1)_{s_7}$ 's row in substructure 7. Because of this near linear dependence in  $V_1$ , Cholesky factorization can fail for the projected mass matrix which is formed by the matrix triple product  $M_V = V_1^T M_D V_1$ .

We can eliminate near linear dependence in  $V_1$ , by zeroing the row corresponding to unity in  $(e_1)_{s_7}$ , except in the column corresponding to  $(\lambda_1)_{s_7}$ , and

obtain the new matrix  $\tilde{V}_1$ :

$$\tilde{V}_1 = \left[ \begin{array}{cc|c|c} \begin{bmatrix} \bar{\Lambda}_{s_3}^{-1} \\ 0 \end{bmatrix} & 0 & 0 & \otimes \\ 0 & \begin{bmatrix} \bar{\Lambda}_{s_6}^{-1} \\ 0 \end{bmatrix} & 0 & \otimes \\ \hline 0 & 0 & 1 & 0 \\ \hline \otimes & \otimes & 0 & \begin{bmatrix} \tilde{\Lambda}_{s_7}^{-1} \\ 0 \end{bmatrix} \end{array} \right] \quad (4.20)$$

where  $\bar{\Lambda}_{s_i}$  denotes a diagonal matrix of truncated eigenvalues of the  $i$ th subtree, where  $i = 3, 6$ , and truncation is based on the cutoff values  $\omega_V^{st2}$ . The matrix  $\tilde{\Lambda}_{s_7}$  denotes a diagonal matrix of truncated eigenvalues of the branch substructure 7 excluding the first eigenvalue  $(\lambda_1)_{s_7}$ , where truncation is based on the cutoff values  $\omega_V^{bs2}$ . If  $(\mathbf{e}_1)_{s_7}$  is still in the subspace, the subspace spanned by the columns of  $\tilde{V}_1$  represents the same subspace spanned by the columns of  $V_1$  although we have changed the vectors and have eliminated near linear dependence. If we iterate on  $(\mathbf{e}_1)_{s_7}$ , so that we have  $(\mathbf{v}_1)_{s_7} = K_D^{-1} M_D (\mathbf{e}_1)_{s_7} \neq (\mathbf{e}_1)_{s_7}$ , its accuracy as a global mode improves slightly, but it was probably already very accurate since  $(\lambda_1)_{s_7}$  is small, because the substructure eigenvector corresponding to a small eigenvalue represents the global quasi-static response of a full FE model accurately to forces applied to degrees of freedom of the root substructure due to the static completeness of the AMLS transformation [1]. Therefore, the vector  $(\mathbf{e}_1)_{s_7}$  changes very little in the iteration, so the change to the subspace from zeroing the row corresponding to unity in  $(\mathbf{e}_1)_{s_7}$  except  $(\mathbf{v}_1)_{s_7}$  is small, but the near linear dependence is eliminated.

We need to define the cutoff frequency for low frequency modes,  $\omega_L$ . The cutoff frequency for low frequency modes should be determined based on the global cutoff frequency  $\omega_G$  because the near linear dependence in the column vectors of  $V_1$  caused by low frequency modes depends on the condition number of the stiffness

matrix  $K_D$ . The condition number of  $K_D$  is determined by the ratio of the largest eigenvalue to the smallest eigenvalue in the diagonal elements of  $K_D$ . Therefore, the ratio  $\omega_G/\omega_L$  should be maintained for the large value of  $\omega_G$  to avoid the near linear dependence in the column vectors of  $V_1$ . By applying this technique we can avoid factorization failures for the mass matrix  $M_V$  resulting from near linear dependence in  $V_1$ . In the next subsection, we will discuss a remedy for non-positive definite mass matrices  $M_V$  caused by indefiniteness of FE mass matrices.

#### 4.8.2 Indefinite Mass Matrix

Occasionally, we encounter an indefinite mass matrix in some FE models. From the physical point of view, the mass matrix should be positive definite, as discussed in Chapter 3. An indefinite mass matrix,  $M_V$ , results from poor FE modelling practice. Nearly zero or negative eigenvalues of  $M_V$  result from, as an example, FE model updating using experimental modal test data in some FE degrees of freedom to get good correlation between FE model and experimental model. We should be able to handle this problem in numerical computation for robustness of implementation.

When we have an indefinite mass matrix  $M_V$  in Rayleigh-Ritz analysis, the Cholesky factorization for transforming generalized eigenproblem to a standard form would fail for this matrix so that we cannot solve the eigenvalue problem. To overcome this difficulty in the projected mass matrix  $M_V$ , we need to construct positive definite matrix by using a shifting strategy. We can find the shifting parameter  $\rho$  such that the shifted mass matrix  $(M_V + \rho K_V)$  is positive definite since the linear combination of  $K_V$  and  $M_V$  should be positive definite in engineering practice.

By shifting, the eigenvalue problem becomes

$$K_V \mathbf{p} = \mu (M_V + \rho K_V) \mathbf{p}. \quad (4.21)$$

If we rearrange the equation above, we can recover the original eigenvalue problem

of the form

$$K_V \mathbf{q}_V = \lambda_V M_V \mathbf{q}_V \quad (4.22)$$

where

$$\lambda_V = \frac{\mu}{1 - \rho\mu}, \quad \mathbf{q}_V = \frac{1}{\sqrt{1 - \rho\mu}} \mathbf{p} \quad (4.23)$$

and scaling the vector  $\mathbf{p}$  by  $\frac{1}{\sqrt{1 - \rho\mu}}$  is for mass-normalization. The shift  $\rho$  can be determined large enough to avoid indefiniteness of the mass matrix, but it should be small enough that the eigenproperties of  $M_V$  is not much affected. For example, if we set  $\rho = 1/\omega_G^2 = 1/\lambda_G$  and we are looking for the eigenvalues between zero and  $\lambda_G$  ( $= \omega_G^2$ ), then the range of  $\mu$  becomes

$$0 \leq \mu \leq \mu_G = \frac{\lambda_G}{1 + \rho\lambda_G} = \frac{\lambda_G}{2}. \quad (4.24)$$

Therefore, the effect of shifting is to reduce the radius of the original spectrum by half. After solving the eigenvalue problem of Equation (4.21), we can backtransform the eigenpairs to the unshifted eigenpairs using the relations between the eigenpairs in Equation (4.23).

# Chapter 5

## Parallel Implementation of the New Algorithm

In this chapter, we focus on parallelization of the new eigensolution algorithm on shared memory multiprocessors (SMM). As a popular example of SMM, there are server workstations manufactured by many computer companies which have typically 2 to 8 processors with a large amount of shared memory. The machine used for numerical results and performance in Chapter 6 is a server workstation that has 4 processors with 8 gigabytes of shared memory. These types of machines are used heavily in industry for AMLS because they are so cost-effective, and because AMLS made it possible to use these machines instead of Cray supercomputers for large-scale vibration analysis [1, 6]. The parallelization on distributed memory multiprocessors (DMM) will be discussed in Chapter 7 as future work for improving the computer implementation of the new eigensolution algorithm.

As a tool for parallel implementation on SMM, the *OpenMP* Application Program Interface (API) is used for the new eigensolution algorithm. *OpenMP* consists of a set of compiler directives that manage the parallelism in the source code, along with supporting runtime library routines and environment variables [50].

For 2 to 8 processor shared memory machines, *OpenMP* provides good scalability with affordable effort and minimal changes in the source code. *OpenMP* requires a special compiler and a runtime library that supports *OpenMP*. Due to the popularity of SMM, every major computer vendor has provided a compiler and runtime library for *OpenMP*.

There are many opportunities for parallelizing the new eigensolution algorithm due to the nature of substructuring. In other words, the data that we handle are naturally partitioned into blocks corresponding to subtrees and branch substructures, so that the computation in each step of the eigensolution algorithm in Figure 4.1 can be performed for subtrees and branch substructures. To achieve high performance on a SMM, major considerations for parallelism are to reduce the communication cost compared to the computational cost and to localize the computational data as much as possible. Multiple processors communicate with each other through ordinary reads and writes to shared variables in the program with the *OpenMP* API for SMM machines. It is necessary to coordinate the access to the shared variables across multiple processors. Because multiple processor simultaneous accesses to the same shared variables can potentially cause incorrect values, explicit coordination between processors, which is called “synchronization”, is needed. By avoiding synchronization and localizing the data for computation as much as possible we can reduce the communication cost. Therefore, we need an algorithm that lets each processor perform as much computation as possible on its own local data. The new eigensolution algorithm satisfies this requirement to a great extent, because the computation for different subtrees and branch substructures can be performed independently and simultaneously.

Before a sequential code is parallelized, it should be optimized as a sequential code first. The sequential code of the new eigensolution algorithm was initially optimized to a great extent for good sequential performance. In practice, by profiling

Table 5.1: Sequential performance of the new algorithm implementation for “Full-Vehicle” model.

| step  | elapsed time(sec.) | percent(%) |
|---|--------------------|------------|
| (a) Getting basic data                                  | 18                 | 0.47       |

| (e) Computing approximate eigenvectors on $\mathcal{A}$ | 498                | 13.11      |
| (f) Writing out eigensolution                           | 50                 | 1.32       |
| total   | 3798               | 100.00     |

which operations take the most time in optimized sequential implementation, we can determine which parts of the new algorithm should be parallelized to speed up the overall timing performance. Table 5.1 shows the overall timing profile for all the steps in sequential mode. A “Full-Vehicle” model, which will be discussed in detail in Chapter 6, was used for this performance data.

The Rayleigh-Ritz analysis accounts for most of the elapsed time as shown in Table 5.1. So we have to look at the algorithm of the Rayleigh-Ritz analysis in more detail for parallelization. Projecting the reduced eigenproblem onto the distilled subspace ( $\mathcal{D}$ ) and computing approximate eigenvectors on the AMLS subspace ( $\mathcal{A}$ ) also have significant percentages in the timing profile. Therefore, we investigate parallel algorithms for those steps in more detail in the following sections.

## 5.1 Parallelism for Projection onto the Distilled Subspace

Solving subtree eigenproblems to form the distilled subspace  $\mathcal{D}$  and projecting system matrices onto the distilled subspace are the significant parts of the computation in steps 1 and 2 of the new algorithm in Figure 4.1. Almost 24% of the total elapsed time is spent in this step as shown in Table 5.1. By considering the algorithm more

where  $\mathcal{P}_i$  denotes the set of indices for all ancestor branch substructures of the  $i$ th subtree or branch substructure.

Figure 5.1: Parallel algorithm for building  $T_D$  implicitly and projecting  $K_A$  and  $M_A$  onto the distilled subspace  $\mathcal{D}$

carefully, we can develop a good parallel algorithm for this step.

Figure 5.1 shows the loop for these procedures. In the figure,  $n_s$  denotes the total number of subtrees and branch substructures in the truncated substructure tree, and  $B_{s_i}$  denotes a Boolean matrix specifying the truncation for the  $i$ th branch substructure. The computations for solving subtree eigenproblems and projecting onto the distilled subspace can be easily separated into two parts, one for subtrees and the other for branch substructures. Each subtree eigenproblem can be solved independently and its eigensolution is truncated based on the distillation cutoff value  $\omega_D^2$ . Then, the transformed stiffness matrix of the  $i$ th subtrees,  $(K_D)_{s_i}$ , is a diagonal matrix containing the subtree eigenvalues that are less than the distillation cutoff value. The transformed mass matrix corresponding to the  $i$ th subtrees,  $(M_D)_{s_{i,j}}$ , can be computed by premultiplying  $(M_A)_{s_{i,j}}$  by the subtree eigenvectors  $\Phi_{s_i}^T$  and

postmultiplying  $\Phi_{s_i}^T(M_A)_{s_{i,j}}$  by the Boolean submatrix  $B_{s_j}$  corresponding to the  $j$ th branch substructure, which is the ancestor of the  $i$ th subtree. Since  $B_{s_j}$  is a Boolean matrix corresponding to the  $j$ th branch substructures, we can form this last product by simply deleting the columns of  $\Phi_{s_i}^T(M_A)_{s_{i,j}}$  corresponding to null rows in  $B_{s_j}$ . For branch substructures, the transformation matrices are Boolean matrices, which represent truncation effects. So the projection is done by simply deleting the rows and columns corresponding to the eigenvalues that are larger than the distillation cutoff value  $\omega_D^2$ .

For efficient parallel performance, the parallelism for projection onto the distilled subspace  $\mathcal{D}$  can be applied to the outermost loop in the algorithm shown in Figure 5.1. For multiple processors, the work inside the outermost loop is partitioned into units of the work according to subtrees and branch substructures. The units of the work, partitioned according to subtrees and branch substructures, are distributed to all the processors in order, and then each processor executes the assigned units of the work. This partitioning of the work in the loop over the subtrees and branch substructures among the processors is called *work-sharing* [50]. The heaviest part of the work inside the outermost loop is computing subtree eigenproblems. The dimensions of the subtree eigenproblems are not the same because the subtree eigenproblems are determined by how subtrees are defined in the given substructure tree. In other words, different subtrees contain different number of substructures having different number of substructure eigenpairs. This fact introduces the load imbalance issue in parallelization of this algorithm.

In order to overcome this load imbalance problem, we need to use *dynamic scheduling* [50, 51] for subtrees and branch substructures. In *dynamic scheduling*, the assignment of subtree eigenproblems to processors is made at runtime. Not all subtree eigenproblems are assigned to processors at the start of the loop. Instead, each processor requests another subtree eigenproblem after it has completed

Figure 5.2: Dynamic scheduling and efficient ordering examples for parallelization of subtree eigenproblems. (a) Efficient ordering with dynamic scheduling. (b) Inefficient ordering with dynamic scheduling.

the work already assigned to it. For example, suppose we have 2 processors and 3 subtree eigenproblems as shown in Figure 5.2(a), where the length of a subtree red box represents the elapsed time for a subtree eigenproblem. At the beginning, two subtree eigenproblems are assigned to two processors, respectively. Then the last eigenproblem for subtree 1 is assigned to processor 1, which finishes to solve the assigned subtree 2 eigenproblem first, instead of waiting for processor 0 to finish. Figure 5.2(a) shows that dynamic scheduling helps to reduce the idle time of processors in parallel region.

For optimal performance, we need to efficiently distribute the subtree eigen-

problems of different size to the processors by reordering the subtree eigenproblems according to their dimension, so that the largest subtree eigenproblem is solved first [54]. If the subtree eigenproblems are distributed in a different way, however, the parallel performance is degraded due to an increase of processor idle time. Suppose subtree 1 is assigned first instead of subtree 3 as shown in Figure 5.2(b). When processor  $P_1$  is about to finish solving the subtree 2 eigenproblem, processor  $P_0$  has finished solving the subtree 1 eigenproblem and has started to solve the eigenproblem for subtree 3. Until processor  $P_0$  finishes solving the final eigenproblem for subtree 3, processor  $P_1$  has to wait. Therefore, the idle time of processor  $P_1$  increases by the time required to solve the last subtree eigenproblem. Hence, reordering of subtree eigenproblems helps to reduce the idle time of all the processors.

Therefore, dynamic scheduling for solving subtree eigenproblems can achieve an optimal parallel performance by using the descending order of exact computational costs of subtree eigenproblems. However, it is impossible to obtain exact computational cost for individual subtree eigenproblem because the computational cost of individual subtree eigenproblem depends not only on the dimension of the subtree eigenproblem, but also on the number of eigenpairs kept for the subtree eigenproblem, which is not known in advance. We will evaluate this approach for three industrial FE models in Chapter 6.

## 5.2 Parallelism for Rayleigh-Ritz Analysis

Rayleigh-Ritz analysis takes about 60% of the total elapsed time as shown in Table 5.1 and also has many opportunities for parallelization. As we pointed out in Chapter 4, there are three phases in the Rayleigh-Ritz analysis: (1) projecting the eigenproblem onto Ritz subspace, (2) solving the projected eigenproblem on Ritz subspace, and (3) computing Ritz eigenvectors. We will discuss a parallel strategy for each phase in the following subsections.

Figure 5.3: Parallel algorithm for projecting the mass matrix  $M_D$  onto the Ritz subspace  $\mathcal{V}_1$  in Rayleigh-Ritz analysis

### 5.2.1 Parallelism for Projecting the Eigenproblem onto Ritz Subspace

The matrix triple product,  $M_V = V_1^T M_D V_1$ , can be easily and efficiently parallelized for subtrees and branch substructures because the matrix  $V_1$  is very sparse and stored separately by subtrees and branch substructures. Figure 5.3 shows the parallel algorithm for projecting the mass matrix  $M_D$  onto the refined subspace represented by  $V_1$ .

As in the case of projection onto the distilled subspace  $\mathcal{D}$  in Section 5.1, the partitioning of the work is based on the partitioning of the data for subtrees and branch substructures. To reduce the synchronization cost at the end of the loops in the algorithm shown in Figure 5.3, parallelization of the outer loop over  $j$  is preferable to the inner loop over  $i$ . Also, it is better to distribute the expensive mass matrix multiplication in step 3 to the processors, instead of distributing the relatively inexpensive sparse-dense matrix multiplication in step 6. If the distilled mass matrix  $M_D$  and the refined subspace represented by  $V_1$  are accessible by all the

processors simultaneously, the blocks of the projected mass matrix  $(M_V)_{s_{i,j}}$ , which is the submatrix of  $M_V$  corresponding to the  $i$ th subtree or branch substructure in row blocks and the  $j$ th subtree or branch substructure in column blocks, are computed individually without any communication between processors. In other words,  $(M_V)_{s_{1:j},j}$ , which is the  $j$ th column block of  $M_V$  corresponding to the  $j$ th subtree or branch substructure, is computed with  $(P)_{s_j}$  and  $(V_1)_{s_{1:j}}$ . Here, the subscript  $s_{1:j}$  in  $(V_1)_{s_{1:j}}$  indicates the column blocks of  $(V_1)$  from the first block to the  $j$ th one. Similar to  $(V_1)_{s_{1:j}}$ , the subscript  $s_{1:j}$  in  $(M_V)_{s_{1:j},j}$  indicate the row blocks of the column block  $(M_V)_{s_j}$  from the first block to the  $j$ th one.

Since each column block of  $V_1$  corresponding to a branch substructure or a subtree does not have the same number of nonzero elements, we need to carefully distribute the computational work for subtrees and branch substructures to the processors in order to avoid a load imbalance problem, as we discussed in the previous section for parallelizing projection onto the distilled subspace. For good parallel performance in this step, we need to rearrange the computational order of the subtrees and branch substructures according to the number of operations for multiplications inside the outermost parallel do-loop. The major cost of multiplications inside the parallel do-loop contains multiplying  $(V_1)_{s_j}$  by  $M_D$  and premultiplying  $(P)_{s_j}$  by  $(V_1)_{s_i}^T$ , where  $i = 1, 2, \dots, j-1$ . Since we form just the upper triangular matrix of  $M_V$  and the last branch substructure has the greatest number of multiplications in the inner loop, the computations might be naturally arranged in reverse order from  $n_s$  to 1.

The stiffness matrix  $K_D$  can be transformed in the same way as for the mass matrix  $M_D$  in Figure 5.3. Step 2 in the algorithm in Figure 5.3 is not necessary for  $K_D$  since it is diagonal and is stored in memory, and step 3 in the algorithm is replaced by  $(R)_{s_j} = K_D(V_1)_{s_j}$ . Since  $K_D$  is a diagonal matrix, the computation for  $K_D(V_1)_{s_j}$  is very inexpensive. The similar ordering scheme as for forming the mass

matrix  $M_V$  can be applied for forming  $K_V$ .

### 5.2.2 Parallelism for Solving the Projected Eigenproblem on Ritz Subspace

In the second phase in Rayleigh-Ritz analysis, which is for solving the projected eigenproblem on the Ritz subspace, there are four steps as shown in Figure 4.6: (1) Cholesky factorization of the mass matrix  $M_V$ , (2) transforming the generalized eigenproblem to a standard form by forming the matrix  $A_V = U^{-T}K_VU^{-1}$  using the Cholesky factor of  $M_V = U^TU$ , (3) solving the dense standard eigenproblem  $A_VX_V = X_V\Lambda_V$ , and (4) backtransforming the eigensolution for the standard eigenproblem to that of the generalized eigenproblem. In step (3), there are also three subphases as we discussed in Chapter 4. The implementation for the tridiagonal eigensolution is very fast due to the  $\mathcal{O}(n_V^2)$  algorithm by Dhillon [63]. For example, solving a tridiagonal eigenproblem of order 9708 takes only 32 seconds on a single processor for the Full-Vehicle model that we used at the beginning of this chapter to demonstrate sequential performance of the new algorithm implementation. So there is little motivation to parallelize the routine *DSTEGR* in *LAPACK*. In addition, the Householder reduction to tridiagonal form and the backtransformation have been parallelized with the *OpenMP* API by C. W. Kim [65]. Therefore, the parallelization of the Householder eigensolution process in step 3 is not within the scope of this dissertation, so the performance will only be checked in Chapter 6.

Cholesky factorization in step 1 in Figure 4.6 can be easily parallelized using *OpenMP*. For good parallel performance, the best sequential block version of a left-looking algorithm, which is used in *DPOTRF* of *LAPACK*, is modified for parallelization as shown in Figure 5.4. Here we assume that the full symmetric matrix  $M_V$  is evenly partitioned with an optimal blocksize which is computed by *DLAENV* in *LAPACK*, so that  $(M_V)_{i,j}$  represents the submatrix corresponding to the  $i$ th row

```

for  $i = 1, 2, \dots, nb$  do
1   if  $i > 1$  then
      Update  $(M_V)_{i,i} \leftarrow (M_V)_{i,i} - (U)_{1:i-1,i}^T (U)_{1:i-1,i}$ 
    end
2   Factor  $(M_V)_{i,i} \rightarrow (U)_{i,i}^T (U)_{i,i}$ 
      for  $j = i+1, \dots, nb$  parallel do
3      $(M_V)_{i,j} \leftarrow (M_V)_{i,j} - (U)_{1:i-1,i}^T (U)_{1:i-1,j}$ 
4      $(M_V)_{i,j} \leftarrow (U)_{i,i}^{-T} (M_V)_{i,j}$ 
      end
    end

```

---

where the subscript  $i$  (or  $j$ ) denotes the  $i$ th (or  $j$ th) column block or row block  
in the matrices

Figure 5.4: Parallel block Cholesky factorization algorithm for  $M_V = U^T U$

block and  $j$ th column block, and  $nb$  denotes the number of column blocks (or row blocks). Since the inner loop over  $j$  in Figure 5.4 accounts for more than 90% of the total elapsed time, it is better to parallelize the loop over  $j$ . Using a constant blocksize is favorable for load balancing in this loop because each processor performs the same amount of work inside the parallel loop. Updating  $(M_V)_{i,i}$  in step 1 in the algorithm might be parallelized by updating it using the different  $k$ th row block in  $(U)_{k,i}$ , where  $k = 1, 2, \dots, i-1$ . To do that, however, we need extra space to save the temporary results of  $(U)_{k,i}^T (U)_{k,i}$  and strict synchronization in updating  $(M_V)_{i,i}$  by using  $(U)_{k,i}^T (U)_{k,i}$  to prevent each processor from updating the same memory location at the same time.

The process of forming  $A_V$  to transform the generalized eigenproblem to a standard form should be parallelized because it takes about 10% of the total elapsed time of the new eigensolution algorithm. The sequential block algorithm which is implemented in *DSYGST* of *LAPACK* is somewhat complicated to parallelize due to the nature of the algorithm for solving triangular systems. We want to parallelize all the steps in this algorithm by considering multiple right-hand sides of typical column dimension 12,000. The block algorithm for forming  $A_V$  is shown in Figure 5.5. As

```

for  $i = 1, 2, \dots, nb$  do
1    $(A_V)_{i,i} \leftarrow (U)_{i,i}^{-T} (A_V)_{i,i} (U)_{i,i}^{-1}$ 
2   for  $j = i+1, \dots, nb$  parallel do
       $(A_V)_{i,j} \leftarrow (U)_{i,i}^{-T} (A_V)_{i,j}$ 
       $(A_V)_{i,j} \leftarrow (A_V)_{i,j} - \frac{1}{2} (A_V)_{i,i} (U)_{i,j}$ 
    end
3   Parallel rank- $2k$  update :
      for  $j = i+1, \dots, nb$  parallel do
        for  $k = i+1, \dots, j$  do
           $(A_V)_{k,j} \leftarrow (A_V)_{k,j} - (A_V)_{i,k}^T (U)_{i,j} - (U)_{i,k}^T (A_V)_{i,j}$ 
        end
      end
4   for  $j = i+1, \dots, nb$  parallel do
       $(A_V)_{i,j} \leftarrow (A_V)_{i,j} - \frac{1}{2} (A_V)_{i,i} (U)_{i,j}$ 
    end
5   for  $k = 1, \dots, nrb$  parallel do
       $(A_V)_{i_k, i+1:nb} \leftarrow (A_V)_{i_k, i+1:nb} (U)_{i+1:nb, i+1:nb}^{-1}$ 
    end
end

```

Figure 5.5: Parallel block algorithm for forming  $A_V = U^{-T} K_V U^{-1}$

shown in the algorithm, there are five steps for parallelization. The first step is to form  $(A_V)_{i,i}$  using an unblocked algorithm. The second step is to update  $(A_V)_{i,j}$  over  $j (= i+1, \dots, nb)$  for the given  $i$ th block, which can be parallelized by letting each processor work on a different column block of  $(A_V)_{i,i+1:nb}$ . The third step is to update the upper triangular part of  $(A_V)_{i+1:nb, i+1:nb}$ , which is a symmetric rank- $2k$  update. This step takes almost 65% of the total elapsed time of this algorithm. This symmetric rank- $2k$  update, consisting of two matrix-matrix multiplications, can be easily parallelized by letting each processor work on a different column block of  $(A_V)_{i+1:nb, i+1:nb}$ , using different column blocks of  $(U)_{i, i+1:nb}$  and  $(A_V)_{i, i+1:nb}$ . As the fourth step,  $(A_V)_{i,j}$  blocks are updated again, similar to the second line in step 2 and this step can be parallelized over each column block  $j$ . The fifth step is to solve a triangular system for multiple right-hand sides. In this step,  $(A_V)_{i, i+1:nb}$  is partitioned into  $nrb$  row blocks and each processor performs the

operation  $(A_V)_{i_k, i+1:nb}(U)_{i+1:nb, i+1:nb}^{-1}$  by calling a serial version of a triangular solver for multiple right-hand sides. Here,  $(A_V)_{i_k, i+1:nb}$  represents  $k$ th row block within  $i$ th row block of  $A_V$ .

To parallelize the backtransformation of the eigenvectors of the standard form to those of the generalized eigenproblem in step 4 in Figure 4.6, we simply divide the  $X_V$  matrix into several column blocks and parallelize the computation of solving a triangular system  $U(Q_V)_j = (X_V)_j$  for  $(Q_V)_j$ . Here,  $(X_V)_j$  and  $(Q_V)_j$  are the  $j$ th column block of  $X_V$  ( $\in \mathbb{R}^{n_V \times n_E}$ ) and  $Q_V$  ( $\in \mathbb{R}^{n_V \times n_E}$ ), respectively, and  $U$  ( $\in \mathbb{R}^{n_V \times n_V}$ ) is an upper triangular matrix which is the Cholesky factor of  $M_V$ . Each processor solves a triangular system with a block of multiple right hand sides in  $X_V$  by calling the optimized single processor version of the triangular solver. We can take different parallelism for this backtransformation, for example, parallelizing the loop of the triangular-solve process. However, that approach is not good for our case because we have typically 12,000 vectors on the right-hand side.

### 5.2.3 Parallelism for Computing the Ritz Eigenvectors

Computing the Ritz eigenvectors,  $\Phi_D = V_1 Q_V$ , using the Ritz subspace matrix  $V_1$  and the matrix  $Q_V$  of eigenvectors of the Rayleigh-Ritz eigenproblem, requires a reduction operation in parallel implementation. A sum of a global variable that can be computed by collecting local data from processors is an example of a reduction operation. The multiplication  $V_1 Q_V$  can be done by the subtrees and the branch substructures as

$$\begin{aligned} \Phi_D &= V_1 Q_V = \left[ (V_1)_{s_3} \mid (V_1)_{s_6} \mid (V_1)_{s_7} \right] \begin{bmatrix} Q_{V_{s_3}} \\ Q_{V_{s_6}} \\ Q_{V_{s_7}} \end{bmatrix} \\ &= (V_1)_{s_3} Q_{V_{s_3}} + (V_1)_{s_6} Q_{V_{s_6}} + (V_1)_{s_7} Q_{V_{s_7}} \end{aligned} \quad (5.1)$$

```

    Make a priority list for subtrees and branch substructures
for  $j = 1, 2, \dots, nb$  do
    Read in  $(Q_V)_j$ 
    Allocate and initialize  $(V_T)_k$  for  $k$  processors
    for  $i = 1, 2, \dots, n_s$  parallel do
        Select  $s_i$  from the priority list
        Read in  $(V_1)_{s_i}$ 
1       $(V_T)_k = (V_T)_k + (V_1)_{s_i}(Q_V)_j$ 
    end
    Initialize  $(\Phi_D)_j$ 
    for  $k = 0, 1, \dots, (nproc-1)$  do
2       $(\Phi_D)_j = (\Phi_D)_j + (V_T)_k$        $\leftarrow$  implicit reduction operation
    end
    Write out  $(\Phi_D)_j$ 
end

```

Figure 5.6: Parallel algorithm for computing Ritz eigenvectors in Rayleigh-Ritz analysis

In Equation (5.1), using the simple plate model as used in Chapter 4, the matrix  $Q_V$  is partitioned into three row blocks corresponding to two subtrees and one branch substructure. Similarly, the matrix  $V_1$  is partitioned into three column blocks. The final product  $\Phi_D$  can be computed by summing the results of  $(V_1)_{s_i}Q_{V_{s_i}}$ , where  $i = 3, 6$ , and  $7$ .

Figure 5.6 shows the parallel algorithm for computing the Ritz eigenvectors. The multiplication of the  $j$ th full column block  $(Q_V)_j$  by the sparse column block  $(V_1)_{s_i}$ , corresponding to the  $i$ th subtree or branch substructure, can be assigned to the  $k$ th processor, so that this processor performs the multiplication  $(V_1)_{s_i}(Q_V)_j$  and overwrites the result into its temporary memory space  $(V_T)_k$ . Then, the final result can be computed by summing the results of multiplications  $(V_T)_k$  from all the processors. Here,  $Q_V$  is also partitioned into  $nb$  column blocks to save the memory usage because  $Q_V$  might fit into memory but  $\Phi_D$  does not fit into memory due to its excessive size, which is typically larger than 3.0 gigabytes.

Since the numbers of non-zero elements in the column blocks of  $V_1$ , corre-

sponding to subtrees and branch substructures, are different, we need to reorder the matrix-matrix multiplications in step 1 shown in Figure 5.6 for good parallel performance. Step 2 in Figure 5.6, which consists of summing the results of multiplications  $(V_T)_k$  from all the processors, indicates the synchronization cost as an implicit reduction operation of the parallel loop. To minimize the synchronization cost at the reduction operation, we need to minimize the number of synchronization points for summing  $(V_T)_k$  from all the processors. The number of synchronization points should be the smaller number between the number of processors  $nproc$  and the total number of subtrees and branch substructures  $n_s$  in the parallel loop in the algorithm. Typically,  $nproc$  is smaller than  $n_s$  for our target machines and models.

### 5.3 Parallelism for Computing Approximate Eigenvectors on the Subspace $\mathcal{A}$

For computing the approximate eigenvectors on the substructure eigenvector subspace, we need to premultiply  $(\Phi_D)_j$ , which is the  $j$ th column block of  $\Phi_D$ , by  $T_D$ . Since  $T_D$  is a block diagonal rectangular matrix and its diagonal blocks contain subtree eigenvectors for subtrees and Boolean vectors for branch substructures, the matrix multiplication  $\Phi_{s_i}(\Phi_D)_j$  can be done independently for the  $i$ th subtree. For branch substructures, only copying the parts of  $(\Phi_D)_j$  corresponding to the identity submatrix in  $B_{s_i} = [ I \ 0 ]_{s_i}^T$  is required to form  $\Phi_A$ .

For the same example used in Chapter 4, the eigenvectors in the substructure

```

Make a priority list for subtrees and branch substructures
for  $j = 1, 2, \dots, nb$  do
  Read in  $(\Phi_D)_j$ 
  Initialize  $(\Phi_A)_j$ 
  for  $i = 1, 2, \dots, n_s$  parallel do
    Select  $s_i$  from the priority list
    if  $s_i$  is subtree then
      Read in  $\Phi_{s_i}$ 
       $(\Phi_A)_j = \Phi_{s_i}(\Phi_D)_j$ 
    else
       $(\Phi_A)_j = B_{s_i}(\Phi_D)_j$ 
    end
  end
  Write out  $(\Phi_A)_j$ 
end

```

Figure 5.7: Parallel algorithm for computing approximate eigenvectors on the substructure eigenvector subspace ( $\mathcal{A}$ )

eigenvector subspace can be given by

$$\begin{aligned}
\Phi_A &\approx T_D \Phi_D = \begin{bmatrix} \Phi_{s_3} & 0 & 0 \\ 0 & \Phi_{s_6} & 0 \\ 0 & 0 & B_{s_7} \end{bmatrix} \begin{bmatrix} \Phi_{Ds_3} \\ \Phi_{Ds_6} \\ \Phi_{Ds_7} \end{bmatrix} \\
&= \begin{bmatrix} \Phi_{s_3} & \Phi_{Ds_3} \\ \Phi_{s_6} & \Phi_{Ds_6} \\ B_{s_7} & \Phi_{Ds_7} \end{bmatrix} \tag{5.2}
\end{aligned}$$

The row blocks of  $\Phi_A$  corresponding to subtrees and branch substructures can be formed independently by multiplying  $\Phi_{Ds_i}$  by  $\Phi_{s_i}$  for subtrees and by copying a part of  $\Phi_{Ds_i}$  for branch substructures. Therefore, each processor updates a different row block of  $\Phi_A$  without any communication between processors. The parallel algorithm of this process is shown in Figure 5.7.

Since each subtree eigenvector matrix  $\Phi_{s_i}$  has a different size, the order of parallel computations should be carefully organized to avoid waiting for synchronization at the end of the parallel do-loop in Figure 5.7. The dynamic scheduling

should be used in order to efficiently distribute subtree eigenvectors to all the processors, and the reordering of the computation of  $\Phi_{s_i}(\Phi_D)_j$  must be done carefully based on the size of the subtree eigenvectors to avoid unnecessary idle times of the processors. Note that the column blocksize for  $\Phi_D$  should be set large enough to avoid multiple readings of subtree eigenvectors represented by  $\Phi_{s_i}$ , but small enough to avoid large memory usage.

# Chapter 6

## Numerical Results and Performance

In this chapter, three FE models developed by the automotive industry are used as test cases for the new algorithm presented in Chapter 4 and Chapter 5. Here we focus on practical applications from the automotive industry as the main driving force behind this new eigensolver design. The first two models have around 2 million FE degrees of freedom (DOF), which has been a typical dimension of FE models of car bodies in recent years. However, their modal densities, which are of greater importance to the eigensolution algorithm, are very different. The first model has 4,216 modes below the user-specified cutoff frequency, and the second model has 7,451 modes below the user-specified cutoff frequency. The third model has 8.4 million FE DOF and more than 11,000 modes below the user-specified cutoff frequency, and was recently developed in the automotive industry for practical structural analysis. It has been used for benchmarking computer software and hardware in the automotive industry. This is the most challenging model of the three for the AMLS software, not only because this model has a large number of FE degrees of freedom, but also because this model has so many modes.

For each FE model, the frequency range of interest is defined by the analyst for modal frequency response analysis, which requires a partial eigensolution of the FE model. It is obviously important to maintain good accuracy of approximate natural frequencies up to the highest excitation frequency  $\omega_F$ , because the natural frequencies below  $\omega_F$  determine the locations of peaks in the frequency response function [48]. Approximate natural frequencies should be accurate at least to within a relative error of 0.01 compared to the exact natural frequencies of the system. The global cutoff frequency for natural frequencies computed in the eigensolution is denoted by  $\omega_G$ . Following standard practice in the automotive industry [69], we use the value  $\omega_G = 1.5 \omega_F$  for all the models in this chapter, for good accuracy in the modal frequency response analysis.

We will use two of the models to determine operational parameters for the new eigensolution algorithm described in the previous two chapters, for achieving near-optimal performance with acceptable accuracy. The third model is used to demonstrate the performance of *Phase4* for the models of our target size, which have about 10M FE degrees of freedom, 100K substructure modes, and 10K eigenpairs below an user-defined cutoff frequency. The performance and accuracy of the new eigensolution algorithm implementation will be compared to that of the shift-invert block Lanczos eigensolver as implemented in the commercial software *MSC.Nastran* (version 2001). From results obtained for the “8.4M DOF” model, we will show that this new eigensolution algorithm, used within AMLS, significantly extends the capability of solving eigenproblems for large structural systems with high modal density, since solving this problem using any existing eigensolver is not practical, particularly on microprocessor-based computer hardware.

There are several operational parameters affecting the eigensolution accuracy in the new eigensolution algorithm, as explained in Chapter 4. Our goal for choosing optimal parameter values is to minimize the computational cost for solving

a variety of practical eigenproblems while satisfying the minimum requirements on eigensolution accuracy. For this parameter optimization for our complex algorithm, it is hard to quantify the objective functions for performance indices, like elapsed time, memory usage, disk usage, and amount of data transferred. In addition, there are tradeoffs among those performance indices. For example, bigger disk space and larger amount of data transferred are required to reduce maximum memory usage, while increasing total elapsed time due to increased amount of I/O. During the course of developing this new eigensolution algorithm, we have learned a great deal about the factors that are important to its performance, although not in a very predictable or systematic manner. So, near-optimal parameter values for various industrial problems have been found. However, it is still worthwhile to examine the effect of each parameter in turn, to understand the sensitivity of each parameter. Based on the near-optimal values of the parameters resulting from the initial optimization study, we will present a detailed discussion of the effects of the parameters, moving sequentially from the most impacting parameter to the least, for the next two industrial models.

Performance is primarily measured in terms of elapsed time, memory usage, disk usage, and data transfer. Elapsed time is the most important performance metric for large-scale industrial vibration analysis since the most important practical objective is to reduce job turnaround time. We will express the elapsed time either in seconds (sec.) or in hours, minutes, and seconds (hh:mm:ss) as appropriate. Memory usage is simply the maximum amount of physical memory used during the execution of the program. If a program or algorithm requires too much memory, this limits the size of jobs that can be run on a given hardware platform. Disk usage is the maximum amount of disk space used during the execution of the program. If the amount of disk space required exceeds the capacity of physical disk storage, it is impossible to run the program. Data transfer is the amount of data that is either

read in or written out by the program during the execution of the program. If the program requires excessive amounts of data to be transferred between disk and memory, this data transfer creates a performance bottleneck since the CPU has to wait for data to be read from or written to disk.

Accuracy is evaluated by comparing the results produced by the new eigen-solution algorithm with those obtained using the block Lanczos eigensolver in *MSC.Nastran*. The accuracy of eigenvalues will be measured in two ways: (1) relative error of the natural frequencies computed by *Phase4*, which are the square roots of approximate eigenvalues, compared with the natural frequencies computed by the block Lanczos eigensolver, and (2) the number of approximate natural frequencies found below the global cutoff frequency. Since the Rayleigh-Ritz approximate eigenvalues computed by the new eigensolver provide upper bounds to the exact eigenvalues, the approximate eigenvalues, especially those close to the global cutoff value  $\omega_G^2$ , are shifted to values slightly higher than the exact ones. Hence, we would not obtain as many eigenvalues below the cutoff value as the exact number of eigenvalues below the cutoff value. The number of approximate eigenvalues found is related to the accuracy of the frequency response function. Therefore, we will require that the number of approximate eigenvalues below the global cutoff value  $\omega_G^2$  should be more than 99.5% of the number of actual eigenvalues below the global cutoff value on the substructure eigenvector subspace.

The quality of the set of approximate eigenvectors can be evaluated by computing the principal angles between subspaces containing (virtually) “exact” eigenvectors and the approximate ones [45, 46, 62]. This is done by computing the singular value decomposition of  $\Phi_L^T M_A \Phi_A$ , where  $\Phi_L$  is a matrix containing eigenvectors computed by the block Lanczos eigensolver in *MSC.Nastran*,  $\Phi_A$  is a matrix containing the approximate eigenvectors computed by *Phase4*, and  $M_A$  is the AMLS transformed mass matrix. If the eigenvectors are nearly equal, the singular values,

Figure 6.1: Finite element representation of Trim-Body model

which equal the cosines of the principal angles between the two eigenspaces, will be close to unity.

Performance was evaluated on an HP rx5670 server containing four 900 MHz IA-64 (Itanium2) processors. This is a shared memory machine which has 8 gigabytes (GB) of physical memory and 500 GB of disk space. The operating system is HP-UX version B.11.22.

The new eigensolution algorithm was implemented primarily in Fortran90, with C for I/O. As was mentioned at the beginning of this dissertation, the new algorithm is designed for solving the reduced eigenvalue problem that AMLS produces, so the computer implementation is a part of the commercial AMLS software package.

## 6.1 Trim-Body Model

The first model is a “trim body” model that has 1.58 million FE degrees of freedom. A trim body model is a model of a car body that has a steering mechanism, moving parts (doors, hood, trunk lid), and seats. As shown in Figure 6.1, this model represents the cab of a full size truck without any parts of the truck behind the cab. We will refer to this model as the Trim-Body model. There are three forced degrees of freedom for this model, which can be used for residual flexibility computation as explained in Appendix A. The number of “output” degrees of freedom requested by the user is 116, so the frequency response is computed for only 116 selected degrees of freedom.

The frequency range of interest for frequency response analysis is from zero to 400 Hz. Since the highest excitation frequency of interest for frequency response analysis is 400 Hz, the cutoff for natural frequencies of global modes used in the modal frequency response analysis is 600 Hz for this model. The cutoff frequency for the substructure eigenvalue problems is set to 3,000 Hz, which is five times as high as the global cutoff frequency. Throughout this chapter, we will use the value 5.0 as the default for the ratio  $\omega_A/\omega_G$  between substructure and global cutoff frequencies.

Since *Phase4* is a part of the AMLS software, its performance is affected by the results of *Phase2* and *Phase3*. The numerical results of *Phase2* and *Phase3* are explained below, and the performance results of *Phase2* and *Phase3* are summarized in Table 6.1. *Phase2* of the AMLS software automatically divides this model into 4,121 substructures on 22 levels. The substructure tree is shown in Figure 4.4(a) in Chapter 4. The substructure sizes range up to 1,500 degrees of freedom based on the target size of 1,500 for leaf substructures, and 1,000 for branch substructures, which are substructures having descendant substructures in the substructure tree. *Phase2* performance is not related to any specified excitation or cutoff frequencies, because

Table 6.1: *Phase2* and *Phase3* performance for Trim-Body model

| <i>Phase</i>  | Elapsed time<br>(sec.) | Memory usage<br>(MB) | Disk usage<br>(GB) | Data transfer<br>(GB) |
|---------------|------------------------|----------------------|--------------------|-----------------------|
| <i>Phase2</i> | 310.6                  | 346.4                | 3.014              | 2.401                 |
| <i>Phase3</i> | 1430.2                 | 2476.4               | 24.710             | 52.231                |

*Phase2*'s function is to automatically partition models into substructures based on the sparsity structure of  $K$  and  $M$ . For the given substructure cutoff frequency of 3,000 Hz, *Phase3* keeps a total of 45,122 substructure eigenvectors and projects the system matrices  $K$  and  $M$  onto this substructure eigenvector subspace. Therefore, the dimension of the reduced eigenproblem becomes 45,122, and *Phase4* solves this eigenproblem, looking for 4,216 eigenpairs, according to the inertia of the matrix  $(K_A - \omega_G^2 M_A)$ , computed from a factorization of the matrix.

The accuracy of the eigensolution of the new algorithm is affected by various parameters: (1) *the maximum subtree size*, (2) *the cutoff frequency for the distilled subspace*, (3) *the starting subspace cutoff frequency for subtrees*, and (4) *the starting subspace cutoff frequency for branch substructures*. The maximum subtree size determines the number of subtrees and branch substructures, so it determines the truncated substructure tree and the sparsity of the mass matrix  $M_D$ . Along with the maximum subtree size, the distillation cutoff frequency determines the dimension of the distilled subspace. The cutoff frequencies for the starting subspace determine the dimension of the starting subspace, which is a dominant factor for the cost of the Rayleigh-Ritz analysis. Based on the approximate optimal values of the parameters resulting from the initial optimization study, we will carefully investigate the effects of all the parameters on the accuracy of the approximate eigensolution and the performance of *Phase4* in the following subsections.

Table 6.2: Effect of maximum subtree size on the dimension and quality of the distilled subspace  $\mathcal{D}$  for Trim-Body model

| Maximum subtree size | Number of subtrees | Number of branch substructures | Dimension of $\mathcal{D}$ | $\nu(K_D - \omega_G^2 M_D)$ |
|----------------------|--------------------|--------------------------------|----------------------------|-----------------------------|

### 6.1.1 Effect of Maximum Subtree Size

The maximum subtree size is used to define the terminal subtrees for the given substructure tree. As discussed in Chapter 4, a subtree is formed by merging substructures together starting at the leaf nodes of the substructure tree as long as the number of accumulated substructure eigenvectors does not exceed the maximum subtree size. To see the effect of the maximum subtree size, we set the other three parameters to their approximate optimal values for this model. The approximate optimal values for these parameters are:  $\omega_D = 0.8 \omega_A$ ,  $\omega_V^{st} = 1.1 \omega_G$ , and  $\omega_V^{bs} = 1.7 \omega_G$ . If more than 4,195 eigenvalues out of 4,216 below the global cutoff are found by the new eigensolution algorithm, we consider the approximate eigensolution to have achieved acceptable accuracy.

An increase in the maximum subtree size decreases the total number of subtrees and branch substructures and the dimension of the distilled subspace, as shown in Table 6.2. However, it increases the accuracy in terms of the number of actual eigenpairs below the global cutoff value on the distilled subspace. In Table 6.2,  $\nu(K_D - \omega_G^2 M_D)$  denotes the number of negative eigenvalues of the matrix  $(K_D - \omega_G^2 M_D)$ , which is the same as the number of the actual eigenvalues below the cutoff value,  $\omega_G^2$ , for the generalized eigenvalue problem  $K_D \Phi_D = M_D \Phi_D \Lambda_D$ . The

| 6000                 | 5581                                   | 4203                           | 75.3          | 1938.3                            |
| 7000                 | 5484                                   | 4204                           | 76.6          | 2639.2                            |

number of actual eigenvalues below the global cutoff value on the distilled subspace does not change for the cases using maximum subtree sizes of more than 5,000. This indicates that increasing the maximum subtree size to more than 5,000 does not affect on the eigensolution accuracy below the global cutoff value on the distilled subspace with the near-optimal values of the other parameters.

Table 6.3 shows the effect of the maximum subtree size on the eigensolution accuracy and performance of *Phase4* for this model. Because the eigenproblem on the distilled subspace  $\mathcal{D}$  is only solved approximately, the number of approximate eigenpairs found is less than the number of exact eigenvalues below the global cutoff value determined by  $\nu(K_D - \omega_G^2 M_D)$ . Since we need more than 4,195 eigenpairs below the global cutoff value for acceptable accuracy, using a maximum subtree size of more than 3,000 results in acceptable eigensolution accuracy for this model. However, as the maximum subtree size increases, the rate of increase in the number of approximate eigenvalues, diminishes and eventually stops for maximum subtree sizes of more than 5,000. Using a maximum subtree size of more than 6,000 has little benefit on the accuracy of the eigensolution, but degrades the timing performance significantly with only a small improvement in “computational efficiency of the Rayleigh-Ritz analysis”,  $(n_E/n_V)$ , where  $n_E$  is the number of eigenpairs found by

the new eigensolution algorithm and  $n_V$  is the dimension of the starting subspace. Here, the computational efficiency of the Rayleigh-Ritz analysis is considered as one minor factor that determine the near-optimal performance of *Phase4* because the goal of the new eigensolution algorithm is to minimize the total computational cost by maximizing the efficiency of the Rayleigh-Ritz analysis.

Solving subtree eigenproblems accounts for a large proportion of the total elapsed time in *Phase4* for this model, which will be shown in a later subsection. Since the subtree eigenproblems are solved by using Householder reduction to tridiagonal form, the cost of solving a subtree eigenproblem is proportional to the cube of the dimension of the subtree eigenproblem. Since we need approximately 45% of the eigenpairs for a subtree problem based on the near-optimal distillation cut-off frequency  $\omega_D$ , an eigensolution algorithm suitable for full eigensolution of dense problems is likely to perform better than the block Lanczos method for subtree eigenproblems of small dimension. However, the block Lanczos method could be faster for subtree eigenproblems of large dimension if a smaller percentage of the eigenpairs were needed.

Figure 6.2 illustrates the effect of various maximum subtree sizes on the relative error of the approximate natural frequencies compared to the natural frequencies computed by the block Lanczos eigensolver on the substructure eigenvector subspace ( $\mathcal{A}$ ). The relative errors of the natural frequencies for all the cases up to the frequency 600 Hz, are less than 0.01. Moreover, the relative error of the natural frequencies less than 400 Hz, which is the highest excitation frequency, is less than 0.001 for all the cases. For this model, we conclude that the maximum subtree size of 5,000 is nearly optimal when both accuracy and timing performance are considered.

Figure 6.2: Effect of maximum subtree size on the accuracy of the natural frequencies by *Phase4* for Trim-Body model

### 6.1.2 Effect of the Distillation Cutoff Frequency

For this model, along with the fixed maximum subtree size of 5,000, which results in 14 subtrees and 15 branch substructures, the distillation cutoff frequency,  $\omega_D$ , determines the dimension of the distilled subspace. The substructure eigenvector subspace is distilled by solving subtree eigenproblems and truncating the subtree eigenspaces, and by simply truncating eigenspaces for branch substructures based on the distillation cutoff frequency  $\omega_D$ . For dimensional reduction of the given substructure eigenvector subspace, the distillation cutoff frequency should be less than or equal to the substructure cutoff frequency  $\omega_A$ .

Table 6.4: Effect of the distillation cutoff frequency  $\omega_D$  for Trim-Body model

Table 6.4 summarizes the effect of various distillation cutoff frequencies. Note that the substructure cutoff frequency  $\omega_A$  is 5.0  $\omega_G$ , and so  $\omega_D = 0.2 \omega_A = \omega_G$  is a lower bound for  $\omega_D$ , because a good global eigensolution accuracy can not be expected with a lower cutoff for subtree eigenproblems and branch substructure eigenspaces. As  $\omega_D$  increases, the dimension of the distilled subspace grows rapidly, but the number of negative eigenvalues of the matrix  $(K_D - \omega_G^2 M_D)$  increases quickly at first and stops increasing after  $\omega_D = 0.8 \omega_A$ . Considering the requirement of computing 99.5% (4195) of the number of eigenvalues below the global cutoff value, the cases with  $\omega_D$  higher than  $0.6 \omega_A$  generate acceptable approximate eigensolutions. However, there is little benefit on the eigensolution accuracy from increasing  $\omega_D$  beyond  $0.8 \omega_A$  because the number of eigenvalues below the global cutoff value is improved little while elapsed time increases dramatically. The number of eigenvalues below  $\omega_G^2$  for the matrix pencil  $(K_D, M_D)$ , as determined by the inertia of  $(K_D - \omega_G^2 M_D)$ , is not improved.

The elapsed time for each case in Table 6.4 shows the cost of increasing the distillation cutoff frequency. The cost of increasing the distillation cutoff frequency  $\omega_D$  is associated with projecting system matrices  $K_A$  and  $M_A$  onto the distilled

Figure 6.3: Effect of the distillation cutoff frequency  $\omega_D$  on the accuracy of the approximate natural frequencies for Trim-Body model

subspace and expanding approximate eigenvectors on the distilled subspace to those on the substructure eigenvector subspace in the algorithm shown in Figure 4.1. If we collect many eigenvectors for subtrees and branch substructures by increasing the value of  $\omega_D$ , the dimension of the distilled subspace grows quickly and so does the cost of computations using subtree eigenvectors.

The relative errors of the approximate natural frequencies computed by *Phase4* for five different values of  $\omega_D$ , with respect to the (virtually exact) natural frequencies computed by the block Lanczos eigensolver for the reduced eigenproblem on the subspace  $\mathcal{A}$ , are shown in Figure 6.3. The distillation cutoff frequency  $\omega_D$

has a strong effect on the accuracy of approximate natural frequencies. The relative errors of the natural frequencies below the global cutoff frequency ( $\omega_G = 2\pi \cdot 600$  Hz) for all the cases except for  $\omega_D = 0.2 \omega_A = \omega_G$ , are less than 0.01. Below the highest excitation frequency, 400 Hz, the relative errors of the natural frequencies for the cases in which  $\omega_D \geq 0.6 \omega_A$ , are less than 0.001. Therefore,  $\omega_D = 0.8 \omega_A$  is chosen as a near-optimal value for this model based on acceptable accuracy and affordable timing performance.

### 6.1.3 Effect of Starting Subspace Cutoff Frequencies

In Chapter 4, two cutoff frequencies were introduced in forming a starting subspace in the distilled subspace ( $\mathcal{D}$ ). One is  $\omega_V^{st}$  for subtrees and the other is  $\omega_V^{bs}$  for branch substructures. These starting subspace cutoff frequencies determine the dimension of the starting subspace, which is a decisive factor for the cost of the Rayleigh-Ritz analysis. We need to determine near-optimal values for these two cutoff frequencies based on the numerical experiments that follow.

Throughout this section, the effect of the starting subspace cutoff frequencies is examined by assuming the dimension and quality of the distilled subspace have been determined by setting the maximum subtree size to 5,000 and the distillation cutoff frequency  $\omega_D$  to  $0.8 \omega_A$ . Table 6.5 shows the effect of various choices of  $\omega_V^{st}$  along with the fixed  $\omega_V^{bs} = 1.7 \omega_G$ . As  $\omega_V^{st}$  increases, the dimension of the starting subspace increases rapidly, but the number of approximate eigenvalues below the global cutoff value increases slowly and stops increasing for the cases for which  $\omega_V^{st} \geq 1.3 \omega_G$ . Considering the requirement of computing more than 4,195 approximate eigenpairs, the values of  $\omega_V^{st}$  greater than  $1.1 \omega_G$  satisfy this requirement. On the other hand, as  $\omega_V^{st}$  increases, the elapsed time and the maximum memory usage for the cases for which  $\omega_V^{st} \geq 1.1 \omega_G$  increase without significant accuracy improvement. Therefore,  $\omega_V^{st} = 1.1 \omega_G$  shows the best timing performance and the best ratio (74.6%) of the

Figure 6.4: Effect of starting subspace cutoff frequency  $\omega_V^{st}$  for subtrees on the accuracy of the approximate natural frequencies for Trim-Body model

computational efficiency of the Rayleigh-Ritz analysis among the cases for which the requirement of computing more than 4,195 approximate eigenpairs is satisfied.

In Figure 6.4, the relative error of the approximate natural frequencies computed by *Phase4* is not very sensitive except at the high frequencies close to the global cutoff frequency 600 Hz. Below the highest excitation frequency 400 Hz, the relative errors of all the cases are less than 0.001 since the choice of  $\omega_V^{st}$  has little effect on accuracy of the natural frequencies below 400 Hz. We choose  $\omega_V^{st} = 1.1 \omega_G$  as a near-optimal value for this model based on the elapsed time, memory usage and the computational efficiency of the Rayleigh-Ritz analysis.

Table 6.6 summarizes the effect of various choices of  $\omega_V^{bs}$ , setting  $\omega_V^{st} = 1.1 \omega_G$ . This cutoff frequency  $\omega_V^{bs}$  has a much smaller effect than the cutoff frequency for subtrees,  $\omega_V^{st}$ , on accuracy in the high frequency range close to the global cutoff frequency. The dimension of the starting subspace,  $n_V$ , and the number of approximate eigenvalues,  $n_E$ , increase slightly as the cutoff frequency  $\omega_V^{bs}$  increases by  $0.2 \omega_G$ . This cutoff frequency has an almost negligible effect on elapsed times and memory usage of *Phase4* for this model.

The relative errors of the approximate natural frequencies are not very sensitive to an increase of this starting subspace cutoff frequency for branch substructures as shown in Figure 6.5. The difference in the relative errors of the approximate natural frequencies among the cases for different cutoff frequencies  $\omega_V^{bs}$  is most noticeable in the frequency range from 400 Hz through 600 Hz. However, the difference is very minor. Therefore, based on the requirement on the number of approximate eigenpairs we can choose any value of  $\omega_V^{bs}$  greater than  $1.3 \omega_G$  for this model. To get the maximum number of approximate eigenpairs below the global cutoff frequency with affordable performance penalty and reasonable computational efficiency of Rayleigh-Ritz analysis, we select  $\omega_V^{bs} = 1.7 \omega_G$ .

#### 6.1.4 Parallel Performance

Parallel performance can be measured by “speedup”, which is defined as the ratio of elapsed time with multiple processors to single processor elapsed time. Also, “efficiency”, which is the ratio of speedup to the number of processors used, is used as another measure of parallel performance. Table 6.7 summarizes parallel performance of *Phase4* for the Trim-Body model on our shared memory machine with up to 4 processors.

We have very nice speedup for 2 processors, but the speedup for 4 processors is not as good. One of the causes for low speedup for 4 processors comes from the I/O costs due to the large size of the problem. Since we cannot handle most of the data in core, substantial I/O costs are the explanation for low speedup for this model. We cannot avoid reading or writing intermediate data from or to temporary disk space in blocks of code executed by multiple processors in parallel. As a result, the I/O in a block of code executed by multiple processors causes multiple processors to wait for a longer time for data to be read or written out due to the limited I/O buffer size. Also, the necessary I/O in a block of code executed by a single processor, becomes more dominant in the parallel performance as the number of processors used increases.

As discussed in Chapter 5, the parallel regions of the new algorithm are divided into three parts as shown in Table 6.8. The speedup for projection onto the distilled subspace is not as good as we expected. One major reason for low speedup

Table 6.8: Timings and speedups for parallelized steps in the new eigensolution algorithm for Trim-Body model

| Step   | No. of processors |          | Speedup |
|--|-------------------|----------|---------|
|  | 1                 | 4        |         |
| Projection onto subspace $\mathcal{D}$             | 756 sec.          | 319 sec. | 2.37    |

| Computation of eigenvectors $\Phi_A$               | 255 sec.          | 84 sec.  | 3.03    |
| total  | 1746 sec.         | 713 sec. | 2.44    |

Table 6.9: Timings and speedups of Rayleigh-Ritz analysis in the new algorithm for Trim-Body model

| Step  | No. of processors |          | Speedup |
|---|-------------------|----------|---------|
|   | 1                 | 4        |         |
| (a) projecting $K_D$ and $M_D$ onto $\mathcal{V}_1$ | 217 sec.          | 66 sec.  | 3.28    |
| (b) factoring projected $M_V$                       | 28 sec.           | 8 sec.   | 3.50    |
| (c) forming $A_V$                                   | 74 sec.           | 26 sec.  | 2.84    |
| (d) reduction to tridiagonal matrix                 | 102 sec.          | 71 sec.  | 1.43    |
| (e) solve tridiagonal eigenproblem                  | 11 sec.           | 11 sec.  | 1.00    |
| (f) backtransform to eigenvectors of $A_V$          | 102 sec.          | 29 sec.  | 3.51    |
| (g) backtransform to eigenvectors of $(K_V, M_V)$   | 42 sec.           | 12 sec.  | 3.50    |
| (h) computation of Ritz eigenvectors $\Phi_D$       | 97 sec.           | 29 sec.  | 3.34    |
| total   | 685 sec.          | 267 sec. | 2.56    |

with 4 processors is that since the data size for each subtree or branch substructure is not the same and the number of subtrees is not a multiple of the number of processors used, the idle time for all the processors increases.

The speedup for computing the approximate eigenvectors  $\Phi_A$  is quite good because the matrix-matrix multiplication  $(\Phi_{s_i} \Phi_D)$  for subtrees can be easily parallelized without any communication between processors. Dynamic scheduling and reordering of the subtrees according to the size of their eigenvectors help to improve the parallel performance to overcome load imbalance due to the different sizes of subtree eigenvector matrices  $\Phi_{s_i}$ .

A performance analysis for the Rayleigh-Ritz analysis is done in detail for this model since the Rayleigh-Ritz analysis takes 38% of the total elapsed time, and involves several steps as explained in Section 5.2. Table 6.9 shows the speedup for each step in the Rayleigh-Ritz analysis. We have very nice speedups for steps (a), (b), (f), (g), and (h) as shown in Table 6.9. Forming  $A_V$  in step(c) shows low speedup due to the nature of parallelizing solving a triangular system in the algorithm as discussed in Section 5.2.2. However, the real bottleneck in the parallel performance for this model is the process of reduction to tridiagonal form in step (d). More detailed explanation about parallelization with the *OpenMP* API of Householder tridiagonal reduction procedure can be found in [65]. This Householder tridiagonalization can be improved by using a different parallel algorithm [68].

### 6.1.5 Overall Performance and Eigensolution Accuracy

The eigensolution accuracy and the performance of the new eigensolution algorithm are evaluated by comparing with two other algorithms for this model. The other two algorithms are the subspace iteration (SI) method and the block Lanczos method. In addition to these two eigensolution algorithms, the block Lanczos eigensolver was executed for the projected eigenproblem on the distilled subspace in Equation (4.11), to evaluate the distillation effect in terms of the eigensolution accuracy and compare the performance of the block Lanczos method on the eigenproblem on the distilled subspace  $\mathcal{D}$  with the corresponding part of *Phase4*.

Table 6.10 summarizes the performance comparison among the implementations of three different algorithms for solving the reduced eigenproblem on the substructure eigenvector subspace ( $\mathcal{A}$ ). The performance of *Phase4* summarized in Table 6.10 reflects a substructure cutoff frequency of 3,000 Hz, a global cutoff frequency of 600 Hz, a distillation cutoff frequency of 2,400 Hz, a maximum subtree size of 5,000, a starting subspace cutoff frequency for subtrees of 660 Hz, and a

Table 6.10: Performance comparison between *Phase4* and two other algorithms on the different subspaces for Trim-Body model

| Performance metric | <i>Phase4</i> | SI on $\mathcal{A}$ | Lanczos on $\mathcal{D}$ | Lanczos on $\mathcal{A}$ |

| No. of eigenpairs  | 4202          | 4199                | 4215                     | 4216                     |

starting subspace cutoff frequency for branch substructures of 1,020 Hz.

In Table 6.10, the performance results of the subspace iteration method on the substructure eigenvector subspace are shown for comparison with other methods. The solution of the reduced eigenproblem on the subspace  $\mathcal{A}$  was approximated by performing one subspace iteration on a truncated subspace in the subspace  $\mathcal{A}$  and one Rayleigh-Ritz analysis on the refined subspace in the subspace  $\mathcal{A}$ . Here, the truncated starting subspace in the subspace  $\mathcal{A}$  is obtained by collecting unit vectors each of which has a value of unity in a degree of freedom with the smallest ratios  $(K_A)_{ii}/(M_A)_{ii}$ . The substructure truncation cutoff frequency for a starting subspace was set to  $1.5 \omega_G (= 2\pi \cdot (900 \text{ Hz}))$  for this algorithm. With this cutoff value for a starting subspace, the subspace iteration method obtains an approximate eigensolution, after one iteration, having similar accuracy in terms of the number of eigenpairs found (4,199) below the global cutoff value to that of the approximate eigensolution computed by *Phase4*. This method is similar to the subspace iteration method on the distilled subspace in the new eigensolution algorithm.

The “exact” eigensolution by the block Lanczos eigensolver on the substructure eigenvector subspace was obtained by solving the reduced eigenvalue problem in Equation (2.3). We can solve a reciprocal eigenproblem in order to exploit the sparsity of the diagonal stiffness matrix  $K_A$ . However, this model has 6 rigid body

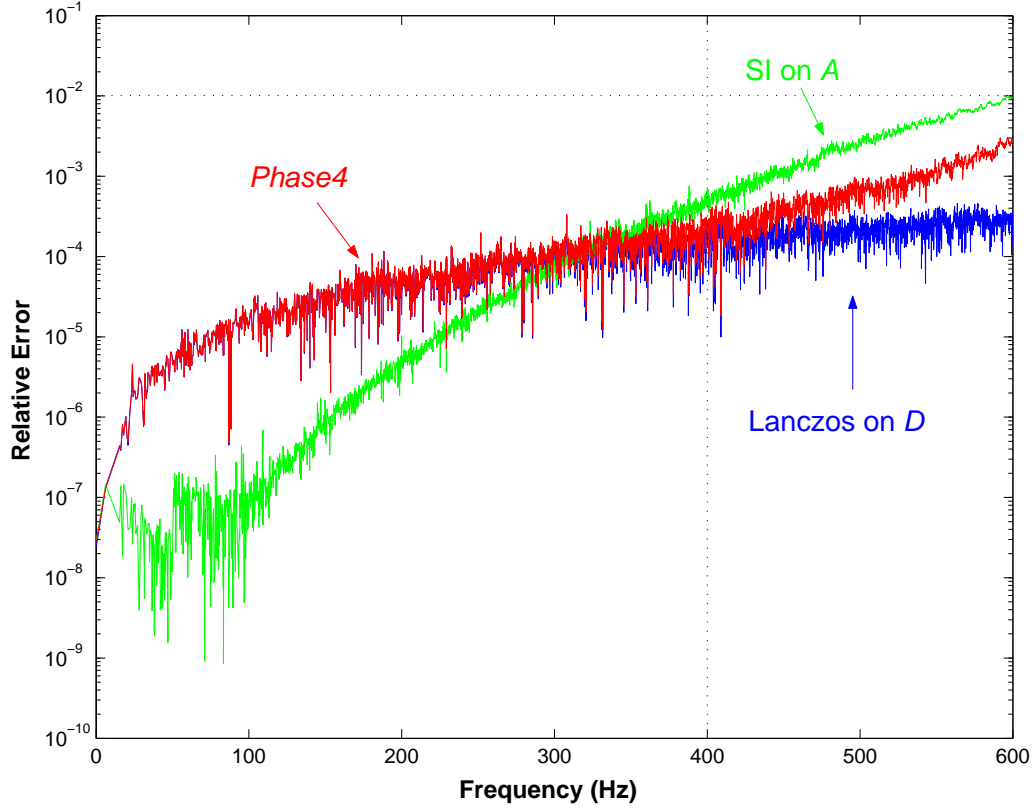

Figure 6.6: Accuracy of the approximate natural frequencies by three different algorithms on two different subspaces with the same global cutoff frequency 600 Hz for Trim-Body model

modes, so it is impossible to solve the reciprocal eigenvalue problem due to the singularity of the matrix  $K_A$  by the block Lanczos eigensolver in *MSC.Nastran* unless the user can use a reverse communication interface, in which the user is free to express the action of the matrix on a block of vectors through a subroutine call within Lanczos iterations [24].

The maximum memory size for the block Lanczos runs within *MSC.Nastran* was set to 2.0 gigabytes for comparison purpose with *Phase4*. As shown in Table 6.10, the difference in elapsed time between *Phase4* and the block Lanczos eigensolver on the subspace  $\mathcal{A}$  is about a factor of 96. More than 6 hours of the total

elapsed time of the Lanczos run on the subspace  $\mathcal{A}$  was spent in the reorthogonalization of the Lanczos vectors with respect to the mass matrix  $M_A$ . Since there was significant I/O activity due to the high modal density and long length of Lanczos vectors, the system time in the Lanczos run is 31.6% of the total elapsed time, but the system time in *Phase4* is just 96 seconds and is only 13.3% of the total elapsed time. Here, the system time indicates the CPU time spent by the operating system for the run and it mainly reflects the time spent for I/O. The Lanczos eigensolver uses 8.8 GB of disk space and most disappointingly performs more than 9.1 terabytes data transfer, which explains the substantial system time. *Phase4* transfers 31.1 gigabytes of data to save memory usage during the runtime. Compared to *Phase4*, the subspace iteration method on the subspace  $\mathcal{A}$  requires more than twice the memory usage and 6.58 times the amount of data transferred, and almost 14 times the execution time to achieve a similar level of eigensolution accuracy to that obtained by *Phase4*.

Figure 6.6 shows the relative errors of the approximate natural frequencies compared to the “exact” natural frequencies from the block Lanczos eigensolver on the substructure eigenvector subspace. Every approximate natural frequency from *Phase4* has a relative error less than 0.0031 even though 14 fewer natural frequencies below the global cutoff frequency are found compared to the number of actual eigenpairs (4216) on the substructure eigenvector subspace. We should note that the maximum relative error in the natural frequencies computed by *Phase4* below 400 Hz is less than  $0.34e-3$  and *Phase4* finds all of the 2,381 eigenpairs whose natural frequencies are below 400 Hz.

The numerical results on the distilled subspace  $\mathcal{D}$  computed by the block Lanczos eigensolver show the effect of the distillation process as discussed in Chapter 4. By projecting onto the subspace  $\mathcal{D}$ , the dimension of the reduced eigenproblem on the subspace  $\mathcal{A}$  is reduced from 45,122 to 26,965, which is a 40% reduction. At

Figure 6.7: Cosines of the principal angles between two eigenspaces computed by *Phase4* and the Lanczos eigensolver for Trim-Body model

the same time, the distillation process achieves an acceptable accuracy of the approximate eigensolution throughout the frequency range up to 600 Hz as shown in Figure 6.6. The maximum relative error of the natural frequencies approximated from the distilled subspace ( $\mathcal{D}$ ) compared to the natural frequencies approximated from the substructure eigenvector subspace ( $\mathcal{A}$ ) by the block Lanczos eigensolver is  $0.45e-3$ . No natural frequency within the frequency range of interest (from 0 Hz to 400 Hz) is missed, and only one mode below the global cutoff frequency 600 Hz is missed by the distillation process. Therefore, by the distillation process we can obtain a smaller distilled subspace without losing much eigensolution accuracy.

To verify the accuracy of the eigenvectors approximated by *Phase4*, the

Figure 6.8: Finite Element Representation of Full-Vehicle Model

principal angles between eigenspaces computed by *Phase4* and the block Lanczos eigensolver can be obtained by computing singular values of  $\Phi_L^T M_A \Phi_A$ , because the singular values of the triple-product are the cosines of the principal angles between the two subspaces. Here,  $\Phi_L$  is the matrix containing the eigenvectors obtained by the block Lanczos eigensolver, and  $\Phi_A$  is the matrix containing the eigenvectors approximated by *Phase4*. Figure 6.7 shows how close the cosines of the principal angles between the two eigenspaces are to unity. The eigenspace approximated by *Phase4* is very close to the eigenspace approximated by the block Lanczos eigensolver on the substructure eigenvector subspace, especially up to 580 Hz.

## 6.2 Full-Vehicle Model

The second model is a “full vehicle” model that has 1.81 million FE degrees of freedom, and its FE representation is shown in Figure 6.8. Here, a full vehicle model

Table 6.11: *Phase2* and *Phase3* performance for Full-Vehicle model

| <i>Phase</i>  | Elapsed time<br>(sec.) | Memory usage<br>(MB) | Disk usage<br>(GB) | Data transfer<br>(GB) |
|---------------|------------------------|----------------------|--------------------|-----------------------|
| <i>Phase2</i> | 362                    | 400.0                | 4.170              | 3.567                 |
| <i>Phase3</i> | 2141                   | 2189.1               | 34.953             | 50.796                |

denotes a car body model that has almost every part, i.e., engine, suspension, tires, exhaust system, a steering mechanism, seats, and moving parts (door, hood, trunk lid). We will refer to this model as the Full-Vehicle model. This model has 147 forced degrees of freedom, and the number of “output” degrees of freedom requested by the user is 344.

The frequency range of interest for frequency response analysis is from 0 Hz to 500 Hz, so the highest excitation frequency  $\omega_F$  is  $2\pi \cdot (500 \text{ Hz})$ . For this model, the cutoff frequency for global modes used in the modal frequency response analysis is 750 Hz. The cutoff frequency for substructure eigenproblems used in *Phase3* is set to  $5.0 \omega_G = 2\pi \cdot (3750 \text{ Hz})$ . Again, we keep the value 5.0 as the default for the ratio  $\omega_A/\omega_G$  between the cutoff frequency for substructure eigenproblems and the global cutoff frequency. This model has 7 low frequency modes under 5.25 Hz. Without handling these seven low frequency modes as explained in Section 4.8, the near linear dependence in the subspace  $\mathcal{V}_1$  results in unacceptable error in the eigensolution.

*Phase2* of the AMLS software automatically partitions this model into 4,133 substructures on 24 levels. The substructure size ranges from 6 to 1,638 degrees of freedom based on the target sizes of 1,500 for leaf substructures, and 1,000 for branch substructures. For the given substructure cutoff frequency  $\omega_A$ , *Phase3* of the AMLS software computes 68,521 substructure eigenvectors, and projects the system matrices  $K$  and  $M$  onto this substructure eigenvector subspace. Therefore, the dimension of the reduced eigenproblem to be solved by *Phase4* is of order 68,521 and 7,451 eigenpairs must to be found according to the inertia of the matrix

$(K_A - \omega_G^2 M_A)$ . This model has higher modal density than the Trim-Body model on the substructure eigenvector subspace  $\mathcal{A}$ . The performance characteristics of *Phase2* and *Phase3* are shown in Table 6.11.

The accuracy and performance of the new eigensolution algorithm is affected by four parameters as discussed in the section for the Trim-Body model. To investigate the effects of these parameters for this model we run *Phase4* initially with a single processor, and compare accuracy and performance with that of the block Lanczos eigensolver in the commercial software *MSC.Nastran*. The parallel performance of *Phase4* is discussed in detail in Section 6.2.4.

### 6.2.1 Effect of Maximum Subtree Size

As was done for the Trim-Body model, a preliminary study of the parameters has been done for this model, and the approximate optimal values for the parameters were determined from that study. To examine the sensitivity of the maximum subtree size on the eigensolution accuracy and the performance of *Phase4*, the approximate optimal values for the other parameters are set as follows:  $\omega_D = 0.6 \omega_A$ ,  $\omega_V^{st} = 1.1 \omega_G$ , and  $\omega_V^{bs} = 1.7 \omega_G$ .

In order to check the accuracy of the eigensolution, we look at the relative errors of the natural frequencies approximated by *Phase4* compared to the natural frequencies obtained by the block Lanczos eigensolver, and the number of approximate eigenpairs computed by *Phase4* compared to the actual number of eigenpairs below the global cutoff frequency  $\omega_G$  on the substructure eigenvector subspace. According to the inertia of the matrix  $(K_A - \omega_G^2 M_A)$ , there are 7,451 eigenpairs below the global cutoff frequency. Therefore, an approximate eigensolution having more than 7,414 approximate eigenpairs, which corresponds to 99.5% of the actual number of eigenpairs below the global cutoff value, has achieved acceptable accuracy in terms of the number of approximate eigenvalues for modal frequency response

Table 6.12: Effect of maximum subtree size on the dimension and quality of the distilled subspace  $\mathcal{D}$  for Full-Vehicle model

| 5000                 | 9708                                   | 7418                           | 76.4          | 3798                              |
| 6000                 | 9567                                   | 7421                           | 77.5          | 4283                              |
| 7000                 | 9556                                   | 7421                           | 77.6          | 4766                              |

Table 6.12 summarizes the effect of the maximum subtree size on the dimension and quality of the distilled subspace for this model. We can observe the same trends for this model as for the Trim-Body model. An increase in the maximum subtree size decreases the dimension of the distilled subspace, if the same distillation cutoff frequency  $\omega_D$  is maintained, and decreases the numbers of subtrees and branch substructures, but the actual number of eigenpairs below the global cutoff frequency on the distilled subspace, which is obtained by the inertia of the matrix  $(K_D - \omega_G^2 M_D)$ , increases. So, we confirm that the dimension of the substructure

eigenvector subspace can be reduced by more than a factor of two by the distillation process without losing much accuracy.

In Table 6.13, using a maximum subtree size of more than 5,000 generates acceptable accuracy in the approximate eigensolution for this model, considering the requirement on the number of approximate eigenpairs of more than 7,414 below the global cutoff frequency. Increasing the maximum subtree size beyond 6,000 does not increase the number of approximate eigenpairs found, but the elapsed time increases significantly. The maximum subtree size also has an effect on the dimension of the starting subspace. A larger subtree size results in a smaller starting subspace and generates better eigensolution accuracy in terms of the number of approximate eigenpairs below  $\omega_G$ , as shown in Table 6.13.

Figure 6.9 illustrates the effect of four maximum subtree sizes on the relative errors of the natural frequencies approximated by *Phase4* compared to the natural frequencies obtained by the block Lanczos eigensolver. The relative errors of all the cases are less than 0.01 (horizontal dotted line indicates the 0.01 relative error). The relative errors of the natural frequencies obtained by *Phase4* below the highest excitation frequency of 500 Hz, are less than 0.001 for maximum subtree sizes larger than 5,000. Considering the affordable performance and acceptable accuracy of the approximate natural frequencies, we choose a maximum subtree size of 5,000 for the near-optimal value for this model.

### 6.2.2 Effect of the Distillation Cutoff Frequency

For the Trim-Body model, we observed that the distillation cutoff frequency  $\omega_D$  has a strong effect on the accuracy of the approximate natural frequencies computed by *Phase4*. We observe the same trend for the Full-Vehicle model, as shown in Table 6.14 and Figure 6.10.

Table 6.14 shows the effect of the distillation cutoff frequency  $\omega_D$  on the per-

Figure 6.9: Effect of the maximum subtree size on the accuracy of the natural frequencies computed by *Phase4* for Full-Vehicle model

formance and eigensolution accuracy of *Phase4* for the Full-Vehicle model. As  $\omega_D$  increases, the dimension of the distilled subspace  $\mathcal{D}$  increases dramatically, and the dimension of the starting subspace  $\mathcal{V}_0$  increases slightly except for the case from  $0.2 \omega_A$  to  $0.3 \omega_A$ . The rate of increase in the number of approximate eigenpairs below the cutoff frequency diminishes significantly after  $\omega_D = 0.6 \omega_A$ . If we consider the requirement on the number of approximate eigenpairs (7,413), the case for which  $\omega_D \geq 0.6 \omega_A$  generates an acceptable eigensolution in terms of the number of approximate eigenpairs below the global cutoff frequency. However, the elapsed time of *Phase4* increases significantly from  $\omega_D = 0.6 \omega_A$  to  $\omega_D = 0.7 \omega_A$  without any

| 0.8                          | 42708                         | 7447                        | 9735                            | 7424                    | 4553 sec.                     |
| 0.9                          | 47323                         | 7449                        | 9747                            | 7426                    | 4666 sec.                     |
| 1.0                          | 50861                         | 7450                        | 9759                            | 7427                    | 4886 sec.                     |

significant improvement in the eigensolution accuracy.

As shown in Figure 6.10, the relative error of the natural frequencies approximated by *Phase4* compared to the natural frequencies approximated by the block Lanczos eigensolver on the substructure eigenvector subspace is very sensitive in the low frequencies, but less sensitive in the high frequencies above 500 Hz, which is the highest excitation frequency for the frequency response analysis. When  $\omega_D \geq 0.6 \omega_A$ , the relative errors of the natural frequencies below the highest excitation frequency (500 Hz) are less than 0.001.

### 6.2.3 Effect of Starting Subspace Cutoff Frequencies

Two cutoff frequencies,  $\omega_V^{st}$  and  $\omega_V^{bs}$ , are needed to form a starting subspace  $\mathcal{V}_0$  as discussed for the Trim-Body model. These two cutoff frequencies for the starting subspace determine the dimension of the starting subspace and also the cost of the Rayleigh-Ritz analysis, which is proportional to the cube of the dimension of the starting subspace. We will examine whether the same values of  $\omega_V^{st}$  and  $\omega_V^{bs}$  for the Trim-Body model can be applied for the Full-Vehicle model.

Table 6.15 shows the effect of varying the starting subspace cutoff frequency

Figure 6.10: Effect of distillation cutoff frequency  $\omega_D$  on accuracy of the approximate natural frequencies by *Phase4* for Full-Vehicle model

for subtrees  $\omega_V^{st}$  for the Full-Vehicle model, while keeping the branch substructure cutoff frequency  $\omega_V^{bs}$  fixed at  $1.7 \omega_G$ . Considering the requirement on the number of approximate eigenpairs below the global cutoff frequency, using  $\omega_V^{st}$  greater than or equal to  $1.1 \omega_G$  generates acceptable eigensolution accuracy in terms of the number of approximate eigenpairs below  $\omega_G$ . Among these cases, using  $\omega_V^{st} = 1.1 \omega_G$  shows the best timing performance, and the near-optimal computational efficiency of the Rayleigh-Ritz analysis as for the Trim-Body model.

Figure 6.11 shows the relative errors of the natural frequencies approximated by *Phase4* compared to the natural frequencies obtained by the block Lanczos eigensolver for five different values of  $\omega_V^{st}$ . The relative errors of the approximate nat-

Figure 6.12: Effect of starting subspace cutoff frequency  $\omega_V^{bs}$  for branch substructures on the accuracy of the natural frequencies computed by *Phase4* for Full-Vehicle model

ural frequencies below 500 Hz are nearly indistinguishable for all the cases. The maximum relative error of the approximate natural frequencies below the highest excitation frequency, 500 Hz, is 0.001. Therefore,  $\omega_V^{st} = 1.1 \omega_G$  is chosen as a near-optimal value for this model based on the eigensolution accuracy, the performance measured by elapsed time and memory usage, and the computational efficiency of the Rayleigh-Ritz analysis.

For branch substructures of this model, the effect of changing the starting subspace cutoff frequency  $\omega_V^{bs}$  for branch substructures is shown in Table 6.16 and Figure 6.12. Here,  $\omega_V^{st}$  is fixed at  $1.1 \omega_G$ . The starting subspace cutoff frequency  $\omega_V^{bs}$  for branch substructures does not have as great an effect on the approximate eigensolution accuracy and the performance of *Phase4* as the starting subspace cutoff frequency for subtrees  $\omega_V^{st}$ , as was observed for the Trim-Body model. As the starting subspace cutoff frequency for branch substructures  $\omega_V^{bs}$  increases, the dimension of the starting subspace increases slightly, and the number of the approximate eigenpairs below the global cutoff frequency increases slightly, as well. The relative errors of the natural frequencies approximated by *Phase4*, although small, are most visible in the frequency range between 500 Hz and 750 Hz as shown in Figure 6.12. Considering the requirement on the number of approximate eigenpairs (7,413), the cases for which  $\omega_V^{bs} \geq 1.5 \omega_G$  generate acceptable eigensolutions in terms of the number of approximate eigenpairs below the global cutoff frequency. However, the dimension of the starting subspace, along with the elapsed time, increases significantly from  $\omega_V^{bs} = 1.7 \omega_G$  to  $\omega_V^{bs} = 1.9 \omega_G$  without any significant improvement in the eigensolution accuracy. Therefore, we choose  $\omega_V^{bs} = 1.7 \omega_G$  as a near-optimal value for this model.

Table 6.17: Parallel Performance of the new eigensolution algorithm implementation for Full-Vehicle model

| Number of processors | <i>Phase4</i><br>elapsed time (sec.) | Speedup | Efficiency |

#### 6.2.4 Parallel Performance

The parallel performance can be measured in terms of speedup and efficiency as in the case of the Trim-Body model. Table 6.17 summarizes the parallel performance on our target machine, which is a shared memory multiprocessor machine having 4 processors.

As with the Trim-Body model, the speedup for 2 processors is very good, but the speedup for 4 processors has some bottlenecks in parallel performance. Since the dimension of the problem is very large and all the data cannot fit in memory, about 57.0 GB of data must be transferred between disk and memory for this model in *Phase4*. This fact slows down the parallel performance of *Phase4* and limits parallel speedup as the number of processors increases, because the amount of time spent in sequential I/O becomes increasingly dominant.

In Table 6.18, the parallel portions of *Phase4* are divided into three parts as

Table 6.19: Timings and speedups of the Rayleigh-Ritz analysis in the new eigen-solution algorithm for Full-Vehicle model

| Stage  | No. of processors |          | Speedup |
|--|-------------------|----------|---------|
|  | 1                 | 4        |         |
| (a) forming projected $K_V$ and $M_V$              | 415 sec.          | 123 sec. | 3.37    |
| (b) factoring projected $M_V$                      | 102 sec.          | 28 sec.  | 3.64    |
| (c) forming $A_V$                                  | 318 sec.          | 129 sec. | 2.46    |
| (d) reduction to tridiagonal matrix $T$            | 522 sec.          | 361 sec. | 1.44    |
| (e) solve tridiagonal eigenproblem $TS = S\Lambda$ | 31 sec.           | 31 sec.  | 1.00    |
| (f) backtransform to eigenvectors of $A_V$         | 458 sec.          | 128 sec. | 3.57    |
| (g) backtransform to eigenvectors of $(K_V, M_V)$  | 216 sec.          | 60 sec.  | 3.60    |
| (h) computation of Ritz eigenvectors $\Phi_D$      | 242 sec.          | 71 sec.  | 3.40    |
| total  | 2337 sec.         | 969 sec. | 2.41    |

discussed for the Trim-Body model. The parallel performance for projection onto the distilled subspace shows lower speedup compared to the other two steps. The main reason is that as the number of processors used increases, the competition for the cache memory between processors in the parallel region intensifies, and so each processor spends more time on a given task than the single processor does in sequential mode. For example, the single processor elapsed time for solving all the subtree eigenproblems is 803 seconds, but the total processing time for solving all the subtree eigenproblems, with four processors in parallel, is 1450 seconds, which is about an 80.5% increase compared to the single processor elapsed time. Also, the idle time of all the processors increases as the number of processors increases due to the different dimensions of subtree eigenproblems. For this model, 4,133 substructures are regrouped into 20 subtrees and 22 branch substructures, and the 20 subtree eigenvalue problems have dimensions from 1,245 to 4,972. For computing approximate eigenvectors represented by the matrix  $\Phi_A$ , we have good speedup because of dynamic scheduling with special reordering of the matrix-matrix multiplications for  $\Phi_{s_i} \Phi_D$ , as explained in Section 4.7.

More detailed parallel performance results for the Rayleigh-Ritz analysis are shown in Table 6.19. We have good speedups for steps (a), (b), (f), (g), and (h) as shown in the table. Forming  $A_V$  in step(c) shows low speedup due to the nature of parallelizing solving a triangular system as for the Trim-Body model. However, the bottleneck in parallel performance is the step for reduction of a dense matrix to tridiagonal form, step (d), as we have seen for the Trim-Body model. We need to improve the parallel performance of the tridiagonalization process of a full dense matrix.

### 6.2.5 Overall Performance and Eigensolution Accuracy

The performance of *Phase4* for the Full-Vehicle model is summarized in Table 6.20, reflecting a cutoff frequency of 3,750 Hz for substructure eigenproblems, a global cutoff frequency of 750 Hz, a distillation cutoff frequency of 2,250 Hz, a maximum subtree size of 5,000, a starting subspace cutoff frequency for subtrees of 825 Hz, and a starting subspace cutoff frequency for branch substructures of 1,275 Hz.

Table 6.20 summarizes the performance comparison between *Phase4* and the block Lanczos eigensolver on two different subspaces. In this table, the maximum memory size in the Lanczos runs is set to 2.0 GB for the purpose of comparison with *Phase4* because *Phase4* uses less than 2.0 GB of memory. For the Lanczos runs, the reciprocal eigenvalue problem was solved to exploit the diagonal stiffness matrices  $K_A$  and  $K_D$  since this model does not have any rigid body modes causing the singularity of the stiffness matrices. This indicates that we can save the very expensive reorthogonalization cost of Lanczos vectors by reorthogonalizing the Lanczos vectors with respect to the diagonal stiffness matrices  $K_A$  and  $K_D$  instead of reorthogonalizing them with respect to the block-sparse mass matrices  $M_A$  and  $M_D$ . The subspace iteration (SI) method on the substructure eigenvector subspace cannot complete the job to get an acceptable accuracy of the approximate eigenso-

Table 6.20: Performance comparison of *Phase4* with the block Lanczos eigensolver on two different subspaces for Full-Vehicle model

| Performance        | <i>Phase4</i> | Lanczos on $\mathcal{D}$ | Lanczos on $\mathcal{A}$ |
|--------------------|---------------|--------------------------|--------------------------|
| Elapsed time       | 0:26:47       | 4:26:20                  | 9:22:25                  |
| System time        | 0:02:51       | 1:24:48                  | 2:54:49                  |
| Memory usage (MB)  | 1913.5        | 2000.0                   | 2000.0                   |
| Disk usage (GB)    | 14.1          | 11.9                     | 19.8                     |
| Data transfer (GB) | 55.7          | 2493.2                   | 5058.7                   |
| No. of eigenpairs  | 7418          | 7447                     | 7451                     |

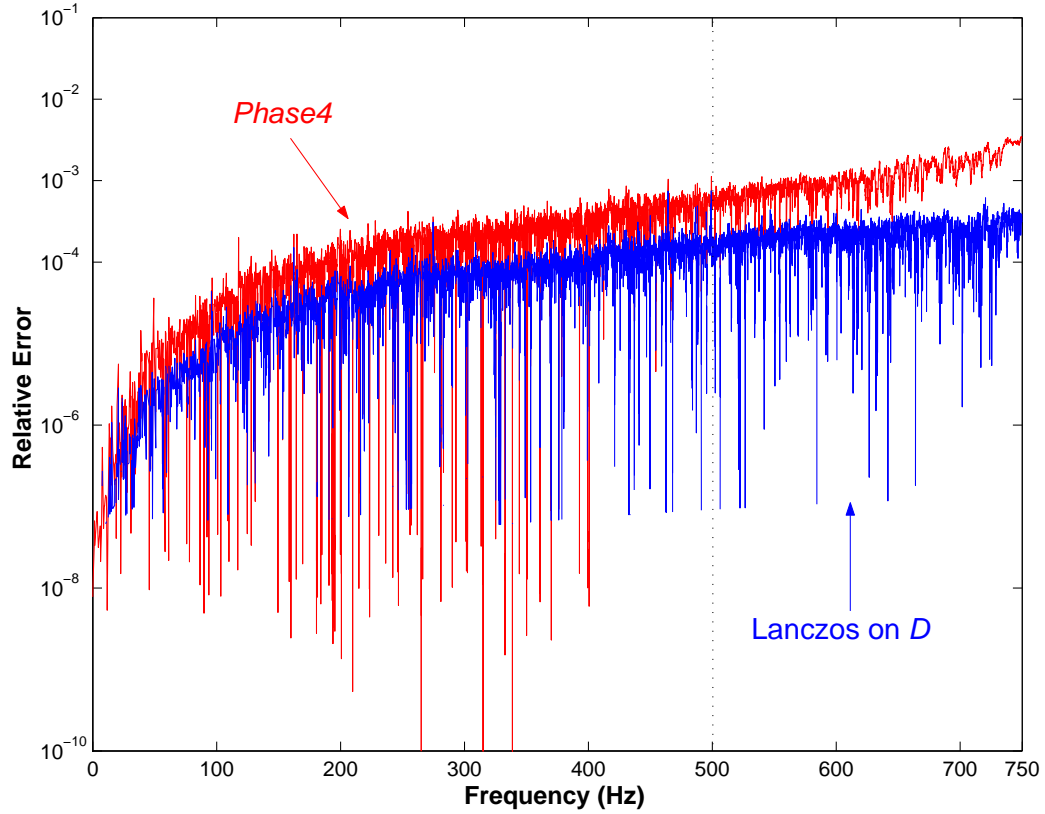

Figure 6.13: Accuracy of the natural frequencies computed by *Phase4* and the block Lanczos eigensolver on the distilled subspace ( $\mathcal{D}$ ) for Full-Vehicle model

lution because the final Rayleigh-Ritz analysis requires more than 8.0 GB memory, which is the maximum memory space available for our target machine.

Apparently, *Phase4* outperforms the Lanczos eigensolver for the reduced eigenvalue problem on the two different subspaces in terms of the elapsed time and data transfer with a small sacrifice in eigensolution accuracy. *Phase4* is about 10 times faster than the Lanczos eigensolver on the distilled subspace  $\mathcal{D}$  and is about 21 times faster than the Lanczos eigensolver on the substructure eigenvector subspace  $\mathcal{A}$ . Since a significant amount of I/O is required during the Lanczos iterations in the block Lanczos eigensolver, the system time of the block Lanczos runs on the subspace  $\mathcal{A}$  is 30.9% of the total elapsed time. By contrast, the system time in *Phase4* is only 11.1% of the total elapsed time, which is less than 3 minutes. The block Lanczos eigensolver on the subspace  $\mathcal{A}$  uses 19.8 GB of disk space, and, significantly, transfers more than 5.0 terabytes of data. Compared to the block Lanczos performance on the subspace  $\mathcal{A}$ , *Phase4* transfers only 55.7 GB of data using 14.1 GB of disk space.

Figure 6.13 shows the relative errors of the approximate natural frequencies computed by *Phase4* compared to the natural frequencies computed by the block Lanczos eigensolver on the substructure eigenvector subspace. Every approximate natural frequency computed by *Phase4* has a relative error less than  $0.35e-2$  even though 33 fewer modes are found than the actual number of eigenpairs on the substructure eigenvector subspace, according to the inertia of the matrix  $(K_A - \omega_G^2 M_A)$ . Note that *Phase4* computes 4,034 approximate eigenpairs below the highest excitation frequency of 500 Hz, which is only three fewer than the actual number of natural frequencies.

The distilled subspace for the block Lanczos run on the distilled subspace is formed by using the maximum subtree size of 5,000 and the distillation cut-off frequency of 3,000 Hz. The maximum relative error of the natural frequencies approximated on the distilled subspace compared to the natural frequencies approx-

Figure 6.14: Cosine of the principal angles between two eigenspaces computed by *Phase4* and the block Lanczos eigensolver on the subspace  $\mathcal{A}$  for Full-Vehicle model

imated on the substructure eigenvector subspace by the block Lanczos eigensolver is  $0.75e-3$ . This indicates that the distillation process produces a reduced subspace (31,698 reduced from 68,521) containing almost all the eigenpairs below the global cutoff frequency of 750 Hz. Only one fewer natural frequency below the highest excitation frequency of 500 Hz is found as a result of the distillation process.

We can verify the accuracy of the eigenvectors approximated by *Phase4* by computing the singular values of  $\Phi_L^T M_A \Phi_A$  to obtain the principal angles between the two eigenspaces as explained for the Trim-Body model. Figure 6.14 shows the cosines of the principal angles between the two eigenspaces computed by *Phase4* and the block Lanczos eigensolver. Closeness of cosines of the principal angles to unity indicates the two eigenspaces represented by  $\Phi_A$  and  $\Phi_L$  are very close together.

Therefore, a very good approximate eigenspace for modal frequency response analysis is obtained by the new eigensolution algorithm.

### 6.3 8.4M DOF Model

The last model is another full vehicle model that has 8.4 million FE degrees of freedom. This model is a typical model for which we are aiming to compute the eigensolution for modal frequency response analysis. We will refer to this model as the “8.4M DOF” model. The block Lanczos eigensolver of *MSC.Nastran* cannot solve the eigenproblem of this model on the FE discretization subspace because of its size. Even the eigenproblem on the substructure eigenvector subspace ( $\mathcal{A}$ ) of order 135,924 cannot be solved by the block Lanczos eigensolver of *MSC.Nastran* because of the 8 GB memory constraint of the machine. Hence, the completion of the AMLS run for this model using the new eigensolution algorithm demonstrates that the new eigensolution algorithm extends the capability of solving eigenproblems for large structural systems with high modal density on our target machine. For this model we are not optimizing parameters as with the other two models. Instead, we use the default parameter values from the Full-Vehicle model.

For the 8.4M DOF model, the frequency range of interest is from zero to 500 Hz for modal frequency response analysis. The highest excitation frequency  $\omega_F$  is  $2\pi \cdot (500 \text{ Hz})$ . The global eigenproblem cutoff frequency  $\omega_G$  is  $1.5 \omega_F$ . A cutoff frequency for substructure eigenproblems  $\omega_A$  is  $5.0 \omega_G$ , a distillation cutoff frequency  $\omega_D$  is  $0.6 \omega_A$ , a starting subspace cutoff frequency for subtrees  $\omega_V^{st}$  is  $1.1 \omega_G$ , a starting subspace cutoff frequency for branch substructures  $\omega_V^{bs}$  is  $1.7 \omega_G$ , and a maximum subtree size is 5,000. The number of output degrees of freedom requested by the user is 245, and the number of forced degrees of freedom is 7. This model has no rigid body modes, but 7 low frequency modes with natural frequencies below 5.25 Hz.

*Phase2* of the AMLS software automatically divides this FE model into

Table 6.21: Overall performance of the AMLS software for 8.4M DOF model

| Phase         | Elapsed time<br>(hh:mm:ss) | Memory usage<br>(GB) | Data transfer<br>(GB) | Disk usage<br>(GB) |
|---------------|----------------------------|----------------------|-----------------------|--------------------|
| <i>Phase2</i> | 00:34:58                   | 2.270                | 11.7                  | 14.5               |
| <i>Phase3</i> | 03:32:53                   | 3.921                | 238.9                 | 93.8               |
| <i>Phase4</i> | 01:36:08                   | 3.944                | 286.2                 | 46.8               |
| <i>Phase5</i> | 00:25:39                   | 3.104                | 106.4                 | 17.2               |

18,373 substructures on 31 levels. The substructure size ranges up to 2,190 degrees of freedom. For the given substructure eigenproblem cutoff frequency  $\omega_A$ , *Phase3* computes 135,924 substructure eigenvectors and projects the system matrices  $K$  and  $M$  onto this substructure eigenvector subspace. *Phase4* solves the reduced eigenproblem of order 135,924, looking for more than 11,000 eigenpairs. Since the number of output FE degrees of freedom requested by the user for this model is only 245, the time spent in *Phase5*, which computes only these entries in the approximate eigenvectors on the FE subspace, is not as great as the time spent in other phases.

Table 6.21 shows the overall performance of the AMLS software. Here, four processors are used during the execution of each phase. For this large model with high modal density, the elapsed time for *Phase3* is greater than for all of the other phases combined. *Phase3* uses the largest amount of disk space among the phases to save memory usage. Each phase uses a maximum memory space of less than 4.0 GB. Note that *Phase4* is designed to use the maximum memory space needed for solving the Rayleigh-Ritz eigenproblem because memory usage in *Phase4* usually reaches the maximum during solving Rayleigh-Ritz eigenproblem for those models having high modal density.

Since we cannot solve the reduced eigenproblem on the substructure eigenvector subspace by the block Lanczos eigensolver, we cannot obtain numerical results on the substructure eigenvector subspace to compare with those computed by *Phase4*. To get eigensolution results for an accuracy comparison with *Phase4* we run the

Table 6.22: Performance comparison between *Phase4* and the block Lanczos eigensolver on the distilled subspace for 8.4M DOF model

| Performance             | <i>Phase4</i> | Lanczos on $\mathcal{D}$ |
|-------------------------|---------------|--------------------------|
| Elapsed time (hh:mm:ss) | 01:36:08      | 26:16:06                 |
| System time (hh:mm:ss)  | 00:15:54      | 05:42:42                 |
| User time (hh:mm:ss)    | 04:25:20      | 74:06:21                 |
| Memory usage (GB)       | 3.9           | 4.0                      |
| Disk usage (GB)         | 46.8          | 25.3                     |
| Data transfer (GB)      | 286.2         | 9443.9                   |

block Lanczos eigensolver on the distilled subspace obtained with a maximum subtree size of 5,000 and a distillation cutoff frequency of  $0.6 \omega_G$ . The performance and eigensolution accuracy of the *Phase4* results are compared with the results from the block Lanczos solver on the distilled subspace in the following subsections. Also, the parallel performance of *Phase4* is investigated in the last subsection.

### 6.3.1 *Phase4* Performance

The performance of *Phase4* compared to the block Lanczos eigensolver on the distilled subspace is summarized in Table 6.22. For this run, *Phase4* approximates 11,027 eigenpairs below the global cutoff frequency and the Lanczos eigensolver on the distilled subspace approximates 11,073 eigenpairs below  $\omega_G^2$ . *Phase4* obtains over 99.5% of the actual number of eigenpairs below the global cutoff frequency on the distilled subspace, and shows excellent timing performance compared to the block Lanczos eigensolver on the distilled subspace. The results of the block Lanczos eigensolver were obtained by solving the reciprocal eigenvalue problem as for the Full-Vehicle model.

Table 6.22 shows the performance comparison between *Phase4* and the block Lanczos eigensolver on the distilled subspace. The maximum memory size for the block Lanczos eigensolver was set as 4.0 gigabytes for comparison with *Phase4*. The

block Lanczos eigensolver performed 54 factorizations, 53 Lanczos runs, and 3,320 Lanczos iterations with a blocksize of 7. *Phase4* is 16.4 times faster than the block Lanczos eigensolver even on the distilled subspace of dimension 57,188. With a similar maximum memory usage, the block Lanczos eigensolver uses 21.5 GB less disk space than *Phase4* uses, but requires more than 9.4 terabytes of data transfer, which is 33 times as much data transfer as the amount of data transfer required by *Phase4*.

### 6.3.2 Eigensolution Accuracy of *Phase4*

The accuracy of the approximate natural frequencies computed by *Phase4* is measured by computing the relative errors of the natural frequencies compared to the natural frequencies computed by the block Lanczos eigensolver on the distilled subspace.

As shown in Figure 6.15, the maximum relative error of approximate natural frequencies compared to those obtained by the block Lanczos eigensolver is  $0.27e-2$  over the frequency range from zero to 750 Hz. Compared to the actual number of eigenpairs (11,073) on the distilled subspace, according to the inertia of the matrix  $(K_D - \omega_G^2 M_D)$ , 46 fewer global modes are found by *Phase4*. Below the highest excitation frequency 500 Hz, the number of approximate natural frequencies computed by *Phase4* is 6,112 and the number of natural frequencies obtained by the block Lanczos eigensolver on the distilled subspace is 6,114. Also, the maximum relative error of approximate natural frequencies below 500 Hz is less than  $0.34e-3$ . Therefore, we can conclude that a good approximate eigensolution below the highest excitation frequency of 500 Hz is obtained by the new eigensolution algorithm, along with excellent timing performance.

Figure 6.15: Accuracy of the approximate natural frequencies computed by *Phase4* compared to the natural frequencies approximated by the block Lanczos eigensolver on the distilled subspace for 8.4M DOF model.

### 6.3.3 Parallel Performance of *Phase4*

As for the Full-Vehicle model, the parallel performance results of *Phase4* for the 8.4M DOF model are generated on our target machine having 4 processors. The overall parallel performance of *Phase4* is shown in Table 6.23. The speedups and efficiencies with 2 and 4 processors are similar to those for the Full-Vehicle model.

Table 6.24 summarizes the parallel performance of the new eigensolution algorithm in detail. As discussed for the previous two models, the parallel performance of projecting the eigenproblem onto the distilled subspace  $\mathcal{D}$  is affected by more multiple processor idle times due to the I/O requested by multiple processors and the different dimensions of subtree eigenproblems. We have good speedup for

Table 6.23: Parallel Performance of the new eigensolution algorithm for 8.4M DOF model

| Number of processors | <i>Phase4</i><br>elapsed time (sec.) | Speedup | Efficiency |
|----------------------|--------------------------------------|---------|------------|
| 1                    | 14274                                | 1.00    | 1.00       |
| 2                    | 8706                                 | 1.63    | 0.81       |
| 4                    | 5766                                 | 2.47    | 0.61       |

Table 6.24: Timings and speedups of Rayleigh-Ritz analysis in the new eigensolution algorithm for 8.4M DOF model

computing approximate eigenvectors represented by  $\Phi_A$  even though each processor have to wait until more than 1.4 GB of eigenvector data is written to the disk by a single processor.

The detailed performance results for Rayleigh-Ritz analysis are summarized in Table 6.24. Speedups for all the steps in the Rayleigh-Ritz analysis are similar to those for the Full-Vehicle model. The bottleneck of parallel performance is reduction of the full matrix  $A_V$  to a tridiagonal form as we observed for the previous two models. The computational routine for tridiagonal reduction should be improved by

using different parallelism for shared memory multiprocessor machines, as discussed in [65].

## 6.4 Summary of Numerical Results

In this chapter, numerical results for three practical FE models from automotive industry have been presented. For the first two models, the sensitivity of four parameter values on the performance and accuracy of the approximate eigensolution algorithm was investigated. We observed that the most sensitive parameter on timing performance is the maximum subtree size and the most sensitive parameter on eigensolution accuracy is the distillation cutoff frequency  $\omega_D$ . The starting subspace cutoff frequencies,  $\omega_V^{st}$  and  $\omega_V^{bs}$ , are less sensitive than those two parameters.

The parallel performance of *Phase4* is demonstrated for three models. Overall speedup and efficiency of *Phase4* for three models are about 2.4 and 60%, respectively, when 4 processors are used. However, we can improve the parallel performance of *Phase4* by resolving the parallel performance bottlenecks in the algorithm. Householder reduction to tridiagonal form in Rayleigh-Ritz analysis is a significant parallel performance bottleneck, and its parallel implementation must be revised for performance improvement.

For the Trim-Body model, *Phase4* computes all the natural frequencies (2,381) below the highest excitation frequency 400 Hz with the relative error less than  $0.34e-3$  compared to the natural frequencies computed by the block Lanczos eigensolver. By computing the principal angles between two eigenspaces computed by *Phase4* and the block Lanczos solver, we verify the good quality of the eigenspace computed by *Phase4*. The new eigensolution algorithm solves the reduced eigenproblem in less than 15 minutes, and uses about 2.0 GB of memory space and 10.0 GB of disk space. Through the distillation process, we achieve 40% dimensional reduction of the reduced eigenproblem from 45,122 to 26,965 without losing

much accuracy.

For the Full-Vehicle model, which has more substructure eigenvectors below the cutoff (68,521) than the Trim-Body model, *Phase4* computes only three fewer eigenpairs than the number of actual eigenpairs below 500 Hz (4037). The relative errors of the approximate natural frequencies below 500 Hz are less than 0.001 compared to those obtained by the block Lanczos eigensolver. *Phase4* solves the reduced eigenproblem in less than 30 minutes, using less than 2.0 GB of memory space and 15.0 GB of disk space. The good quality of the eigenspace computed by *Phase4* was demonstrated by computing the principal angles between the two eigenspaces computed by *Phase4* and the block Lanczos eigensolver. By means of the distillation process, 54% dimensional reduction of the reduced eigenproblem has been done within  $0.75e-3$  relative error of approximate natural frequencies.

Finally, the new eigensolution algorithm was tested for an 8.4M DOF model, which is a typical FE model that we are aiming to solve for many eigenpairs. The block Lanczos eigensolver in the commercial software *MSC.Nastran* cannot solve this problem on our target machine due to the size of the problem ( $135,924 \times 135,924$ ). However, *Phase4* solves this problem within 2 hours with good accuracy, using 4.0 GB of memory space and 50.0 GB of disk space. Using the same global and distillation cutoff frequencies used for the Full-Vehicle model, 62% dimensional reduction of the reduced eigenproblem has been done through the distillation process. Therefore, the numerical results for this model demonstrates that the new eigensolution algorithm and its implementation present capabilities for solving large eigenproblems with many eigenpairs.

## Chapter 7

# Conclusions and Future Work

### 7.1 Conclusions

In this dissertation, a new eigensolution algorithm for the reduced eigenproblem produced by the AMLS transformation is presented for large structural systems with many eigenpairs. The new eigensolver in combination with AMLS is advantageous for solving huge FE models with many eigenpairs because it takes much less computer time and resource than the state-of-the-art eigensolver while maintaining acceptable eigensolution accuracy. To verify the efficiency of the new eigensolution algorithm, a sequential version of the new eigensolution algorithm has been implemented and optimized. A parallel implementation with *OpenMP* API for shared memory multiprocessor machines has been completed for performance improvement.

In Chapter 4, using the properties of the stiffness and mass matrices  $K_A$  and  $M_A$  from the AMLS transformation, a new distilled subspace of the substructure eigenvector subspace is built by defining subtrees, solving subtree eigenproblems, and truncating subtree and branch substructure eigenspaces. The reduced eigenproblem is then projected onto this distilled subspace, utilizing the sparsity of the system matrices  $K_A$  and  $M_A$ . Using a good initial guess of a starting subspace on

the distilled subspace, which is represented by a very sparse matrix, one subspace iteration recovers as much accuracy as needed for approximation. Hence, the dimension of the Ritz subspace for Rayleigh-Ritz analysis is minimized and the Ritz subspace is represented by a sparse matrix. Approximate global eigenvalues can be computed by solving the Rayleigh-Ritz eigenproblem, and the corresponding global eigenvectors are recovered by inexpensive matrix-matrix multiplications. In addition, remedies for a nearly singular stiffness matrix and an indefinite mass matrix are presented for robustness of the implementation of the new eigensolution algorithm.

In Chapter 5, a parallel algorithm of the new eigensolution method is proposed using the *OpenMP* API for shared memory multiprocessor machines. Opportunities for parallelization of each step in the new eigensolution algorithm are carefully investigated and exploited. Due to the nature of substructuring, projecting the reduced eigenproblem onto the distilled subspace and computing approximate eigenvectors on the substructure eigenvector subspace can be done simultaneously by subtrees and branch substructures without any communication among the processors. For the steps of projecting the eigenproblem onto Ritz subspace  $\mathcal{V}_1$  and computing Ritz eigenvectors  $\Phi_D$  in the Rayleigh-Ritz analysis, the operations for those steps can be done individually and simultaneously by subtrees and branch substructures with very few communication cost. The parallelism for the eigenproblem for Ritz values is different from the rest of the algorithm. It involves a more fine-grain type of parallelism, which denotes a refined parallelism on a lower loop level.

In Chapter 6, numerical results for three practical FE models from automotive industry are presented to demonstrate the performance and accuracy of the new eigensolution algorithm compared to those of the block Lanczos algorithm. For the Trim-Body model, the new eigensolution algorithm computes all the natural frequencies (2,381) below the highest excitation frequency 400 Hz, maintaining the

relative error of the natural frequencies less than  $0.34e-3$ . The new eigensolution algorithm in combination with AMLS solves the FE eigenproblem of this model in less than 50 minutes, using about 2.5 GB of memory space and 25.0 GB of disk space. Compared to the previous algorithm [1] for the reduced eigenproblem of this model, the new eigensolution algorithm solves this eigenproblem with much less computer time with improved eigensolution accuracy in terms of relative errors of the natural frequencies. For the Full-Vehicle model, *Phase4* computes 4034 eigenpairs that is only three fewer than the actual number of eigenpairs below 500 Hz. The maximum relative error of the natural frequencies below 500 Hz is less than 0.001. The new eigensolution algorithm in combination with AMLS solves this FE eigenproblem of this model within 2 hours, using about 2.2 GB of memory space and 35.0 GB of disk space. Finally, the new eigensolution algorithm was investigated for a very modally dense model having more than 11,000 eigenpairs below the global eigenproblem cut-off frequency 750 Hz. Any existing eigensolver software cannot solve this problem on our target machine due to the excessive dimension and high modal density of this problem. However, the new eigensolver in conjunction with AMLS solves this problem within 7 hours with good accuracy, using about 4.0 GB of memory space and 94.0 GB of disk space. This demonstrates that the new eigensolution algorithm and its implementation in combination with the AMLS software presents capabilities for solving for many eigenpairs of large eigenproblems. Due to the significant improvement in the eigensolution algorithm for the reduced problem, the dominant term in the cost of the AMLS software for modally dense models is shifted from solving the reduced eigenproblem to the AMLS transformation.

In the appendix, a new method for solving the augmented eigenproblem for residual flexibility is developed to mitigate the loss of accuracy in modal frequency response analysis at very little additional computational cost. This new method can achieve a significant performance improvement for the models having many

static vectors compared to the algorithm implemented in the proprietary software *MSC.Nastran*.

## 7.2 Future Work

As we discussed in Chapter 6, the parallelism of the tridiagonal reduction algorithm should be revised to improve the parallel performance of *Phase4*. Since this routine takes typically about one fourth of the total elapsed time of *Phase4*, a large performance gain is expected by improving the parallel performance of this tridiagonalization algorithm. The other parallel algorithms for tridiagonal reduction as discussed in [68, 73] might be adopted for efficient parallelization of the tridiagonal reduction for shared memory multiprocessor machines.

In solving subtree eigenproblems, a dense eigensolver is used because more than 40% of the full eigenpairs are needed for subtree eigenproblems. However, a robust shift-invert block Lanczos eigensolver might be faster than Householder eigensolution algorithm for subtree eigenproblems. If a robust non-proprietary block Lanczos eigensolver becomes available in the public domain, the shift-invert block Lanczos eigensolver can be used for solving subtree eigenproblems utilizing sparsity of the system matrices.

The AMLS software including this new eigensolution algorithm has been a commercial application in automotive industry. The current implementation was targeted for microprocessor-based workstations with shared memory multiprocessors. For this reason, the parallel implementation has been done with the *OpenMP* Application Programming Interface (API) for shared memory multiprocessor machines. Since the automotive industry requires more aggressive parallelism for distributed memory multiprocessor machines, like Linux clusters, MPI (Message Passing Interface) parallelization should be started to satisfy the near future demand of the automotive industry. The parallelism for distributed memory multiprocess-

sors might be quite different from the current implementation for shared memory multiprocessors. More sophisticated parallelism is required for massively parallel implementation of the new eigensolution algorithm for distributed memory multiprocessors. For example, the coarse-grain type of parallel algorithm for projection of the reduced eigenproblem onto the distilled subspace should be modified, so that the computation of subtree eigenproblems can be distributed to as many processors as possible to achieve good speedup and efficiency of parallelism. Currently, the MPI parallelization of the AMLS transformation (*Phase3*) is in process [2].

### 7.3 Final Remarks

The new eigensolution algorithm has some limitations as other eigensolution algorithms. How large a FE model can be handled by AMLS is dependant on the sparsity of FE matrices as well as the size of the FE model. For a very large FE model with high matrix density in the system matrices, *Phase3* of AMLS requires significant amount of computer time and resource to transform the model. For modally dense models with high global cutoff frequency, the number of substructure eigenvectors kept by *Phase3* is very large. For these models, the required number of global eigenpairs determines the dimension of Rayleigh-Ritz analysis in the new eigensolution algorithm used in *Phase4*. The eigenproblems for these models can be solved if the physical memory space is large enough for the Rayleigh-Ritz analysis because *Phase4* is designed to use the maximum memory space required for the Rayleigh-Ritz analysis.

This new eigensolution algorithm has been implemented within the AMLS software and released commercially since 2002. Since then, almost every automotive company has been using the AMLS software for NVH (Noise, Vibration, and Harshness) analysis due to the benefits of shortened job turn-around time in the solution process with acceptable eigensolution accuracy. For the past couple of years

the performance and acceptable accuracy of this new eigensolution algorithm has been approved by the automotive industry. Due to AMLS, the automotive industry can increase model size for high frequency resolution, while maintaining adequate solution turn-around time within design process times. This capability of AMLS offers great commercial advantages to automotive manufactures. Therefore, the impact of AMLS can be continuously widespread over the broad range of engineering applications.

# Appendix A

## Augmented Eigenproblem for Residual Flexibility

When the mode superposition method is used to approximate modal frequency response, the structural response of a FE model is not quite accurate due to the truncation of higher frequency modes. The contribution to the structural response from truncated high frequency modes is approximately compensated by adding static responses into the modal subspace spanned by the global eigenvectors kept [41, 48, 76]. Here, a static response is defined as a static deflection of the structure which results when a unit force is exerted on one forced degree of freedom, while the remaining degrees of freedom are force free [41]. A previous implementation [1] of adding static responses to the modal subspace spanned by the approximate eigenvectors was quite costly since the dimension of the eigenvalue problem to be solved for orthonormal static responses (or static vectors) was the sum of the number of the global eigenvectors kept and the number of force vectors for a FE model.

By doing more precise modified block Gram-Schmidt orthogonalization for static vectors against the approximate global eigenvectors kept from solving the reduced eigenproblem produced by AMLS, the numerical orthogonality condition

between the approximate global eigenvectors kept and the static vectors is well established. So, the precise orthogonality between the approximate global eigenvectors and the static vectors eventually induces a smaller eigenvalue problem for orthonormal static vectors than the eigenproblem produced by the previous algorithm of Kaplan [1]. The relationship between residual flexibility technique and block orthogonalization procedure of static vectors is explained in the first subsection. The new algorithm for computing residual flexibility eigensolution is then summarized, followed by the detailed explanation of the new algorithm in the later two subsections.

## A.1 Residual Flexibility and Block Orthogonalization

An approximation of the responses for the truncated eigenvectors [41] can be expressed as

$$X_R = (\Phi_t \Lambda_t^{-1} \Phi_t^T) F_A \quad (\text{A.1})$$

where  $\Lambda_t$  is a diagonal matrix containing truncated eigenvalues,  $\Phi_t$  is a matrix containing the corresponding truncated eigenvectors in columns, and  $F_A$  is a matrix containing force vectors in columns. The coefficient matrix of  $F_A$  in Equation (A.1) is defined as *residual flexibility matrix*, which is given by

$$G_t = \Phi_t \Lambda_t^{-1} \Phi_t^T. \quad (\text{A.2})$$

Since the residual flexibility matrix is unknown, the same value can be obtained through the knowledge of the elastic flexibility matrix and the eigenpairs kept for the system as:

$$G_t = G_e - \Phi_k \Lambda_k^{-1} \Phi_k^T, \quad (\text{A.3})$$

where

$$G_e = \Phi_e \Lambda_e^{-1} \Phi_e^T = K_A^{-1}$$

is the elastic flexibility matrix,  $\Lambda_k$  is a diagonal matrix containing kept eigenvalues,  $\Phi_k$  is a matrix containing the corresponding kept eigenvectors in columns, and  $\Phi_e$  is a matrix containing orthonormal elastic (or flexible) modes. Thus, the response for the truncated eigenvectors, which can be called as the residual flexibility vectors, represented by the matrix  $X_R$ , can be expressed by another form

$$X_R = (K_A^{-1} - \Phi_k \Lambda_k^{-1} \Phi_k^T) F_A. \quad (\text{A.4})$$

The Equation (A.4) can be rewritten as

$$\begin{aligned} X_R &= [I - \Phi_k \Lambda_k^{-1} \Phi_k^T K_A] (K_A^{-1} F_A) \\ &= [I - \Phi_k \Lambda_k^{-1} \Phi_k^T K_A] X_S \end{aligned} \quad (\text{A.5})$$

where  $X_S = (K_A^{-1} F_A)$  is a matrix containing static vectors in columns, and  $[I - \Phi_k \Lambda_k^{-1} \Phi_k^T K_A]$  can be viewed as an operator orthogonalizing  $X_S$  against  $\Phi_k$  with respect to  $K_A$ . Equation (A.5) implies that  $X_R$  is a matrix containing in columns orthonormal static vectors against  $\Phi_k$  with respect to  $K_A$ . In other words, computing residual flexibility vectors is equivalent to computing  $K_A$ -orthonormal static vectors against the kept global eigenvectors. Therefore, we can add the residual flexibility vectors, which can be obtained by orthonormalizing static vectors against the kept eigenvectors  $\Phi_k$  with respect to the stiffness matrix  $K_A$ , to the modal subspace.

## A.2 Preliminary Residual Flexibility Eigensolution Algorithm

After we obtain the approximate global eigenvectors below the global cutoff frequency, we need to add static vectors to the modal subspace spanned by the global eigenvectors as follows:

$$T_R = \left[ \Phi_k \mid X_S \right]. \quad (\text{A.6})$$

```

begin
1   Compute static vectors :  $X_S = K_A^{-1} F_A$ 
2   Compute  $U$ 
   for  $i = 1, 2, 3$  do
3     Orthogonalize static vectors against  $\Phi_k$  w.r.t.  $K_A$  :
        $X_R \leftarrow [I - \Phi_k U \Phi_k^T K_A] X_S$ 
     for  $j = 1, 2$  do
4       Orthogonalize  $X_R$  among themselves w.r.t.  $K_A$ 
     end
     if reorthogonalization is not needed then exit
   end
5   Project system matrices onto the subspace represented by  $X_R$  :
        $K_X = X_R^T K_A X_R$ ,  $M_X = X_R^T M_A X_R$ 
6   Solve the small projected eigenproblem :
        $K_X Q_X = M_X Q_X \Lambda_X$ 
7   Backtransform eigenvectors to eigenvectors on the subspace  $\mathcal{A}$  :
        $\Phi_R = X_R Q_X$ ,  $\Lambda_R = \Lambda_X$ 
8   Add orthonormalized residual flexibility vectors to the modal
       subspace :
        $\Phi_m = [\Phi_k \mid \Phi_R]$ ,  $\Lambda_m = \begin{bmatrix} \Lambda_k & 0 \\ 0 & \Lambda_R \end{bmatrix}$ 
end

```

Figure A.1: New augmented eigensolution algorithm for residual flexibility eigensolution

The question of linear dependence of augmented subspace  $T_R$ , however, arises between the global eigenvectors kept and the static vectors, and possibly between static vectors themselves. In order to avoid linear dependence in the augmented subspace, we have to orthogonalize static vectors against  $\Phi_k$  and among themselves with respect to  $K_A$ .

The new algorithm to compute residual flexibility eigenpairs is shown in Figure A.1. Here, we compute residual flexibility eigenvectors on the substructure eigenvector subspace, instead of those on the FE subspace. After solving the reduced eigenproblem on the substructure eigenvector subspace, the residual flexibility eigenpairs are computed on the same subspace using the AMLS transformed force vectors

represented by  $F_A$ . In the following sections, the detailed explanation of the new algorithm for computing the residual flexibility eigensolution is presented.

### A.3 Block Orthogonalization Procedure

The matrix  $X_S$  containing static vectors is defined by

$$\begin{aligned} X_S &= K_A^{-1} ( T_A^T F ) \\ &= K_A^{-1} F_A \end{aligned} \quad (\text{A.7})$$

where  $F$  is a matrix containing force vectors in columns on the FE discretization subspace,  $F_A$  is a matrix containing force vectors in columns on the substructure eigenvector subspace, and  $T_A$  is the AMLS transformation matrix. Using the block modified Gram-Schmidt algorithm (bMGS) by Björck [36], static vectors are orthogonalized against  $\Phi_k$  with respect to  $K_A$  by blocks as

$$X_R \leftarrow \prod_{j=1}^{nb} ( I - \Phi_{kj} U_j \Phi_{kj}^T K_A ) X_S \quad (\text{A.8})$$

where  $\Phi_k$  have been partitioned into  $nb$  column blocks, so  $\Phi_{kj}$  is the  $j$ th column block of the matrix  $\Phi_k$ . The matrix  $U_j$  is an upper triangular matrix associated with  $\Phi_{kj}$ . The Equation (A.8) can be reformulated as another form:

$$X_R \leftarrow \prod_{j=1}^{nb} ( X_{Sj} - \Phi_{kj} \alpha_j ) \quad (\text{A.9})$$

where

$$\alpha_j = U_j \Phi_{kj}^T K_A X_{Sj}, \quad (\text{A.10})$$

and  $X_{Sj}$  is the static vectors orthonormalized against the eigenvectors represented by  $(\Phi_k)_{1:j-1}$ . For the block modified Gram-Schmidt orthogonalization, the matrix  $U_j$  is used instead of  $\Lambda_{Aj}^{-1}$  in the classical Gram-Schmidt orthogonalization. If the maximum value of  $\alpha_j$  for  $j$  ( $= 1, 2, \dots, nb$ ) is less than some tolerance, then

```

$$U_j(1, 1) = \lambda_{l+1}^{-1}$$

for  $i = 2, 3, \dots, p$  do
1    $U_j(1 : i-1, i) = -U_j(1:i-1, 1:i-1) \Phi_k(:, l+1:l+i-1)^T K_e \phi_{l+i} \lambda_{l+i}^{-1}$ 
      $U_j(i, i) = \lambda_{l+i}^{-1}$ 
end

```

Figure A.2: Algorithm for computing  $U$  in the block modified Gram-Schmidt orthogonalization

```

1  $Y(:, 1 : p-1) = K_e \Phi_k(:, l+1 : l+p-1) \text{diag}(\lambda_{(l+1:l+p-1)}^{-1})$ 
2  $W(2 : p, 2 : p) = \Phi_k(:, l+1 : l+p-1)^T Y(:, 1 : p-1)$ 
    $U_j(1, 1) = \lambda_{l+1}^{-1}$ 
   for  $i = 2, 3, \dots, p$  do
3    $U_j(1 : i-1, i) = -U_j(1 : i-1, 1 : i-1) W(2 : i, i)$ 
      $U_j(i, i) = \lambda_{l+i}^{-1}$ 
   end

```

Figure A.3: More efficient algorithm for computing  $U$  in the block modified Gram-Schmidt orthogonalization

the reorthogonalization process is terminated because the maximum value of  $\alpha_j$  indicates the numerical orthogonality between  $\Phi_{k_j}$  and  $X_{S_j}$  with respect to  $K_A$ .

The matrix  $U_j$  is computed before orthogonalization process for a block of eigenvectors  $\Phi_{k_j}$ . The matrix  $U$  is defined by the recursion formulation [36] as shown in Figure A.2. In Figure A.2,  $l$  is the number of previous eigenvectors  $((j-1)p)$  before  $\Phi_{k_j}$ , and  $p$  is the number of eigenvectors in each column block of  $\Phi_k$ . The matrix  $U_j(1 : i-1, i)$  represents the row elements from 1 to  $i-1$  of the  $i$ th column vector in the matrix  $U_j$ , and  $Y(:, 1 : p-1)$  represents the column vectors from 1 to  $p-1$  in the matrix  $Y$ . The number of eigenvectors in a block is typically set to 100 by numerical experience for the optimal performance and accuracy of the block orthogonalization.

The computation for forming  $U_j$  requires matrix-vector operations, which is inefficient in memory reuse for hierarchical memory system. By simple modification, the algorithm can be improved so that it uses more matrix-matrix operations, which are more efficient in memory reuse, instead of matrix-vector operations. Therefore,

the algorithm in Figure A.2 can be modified to do more matrix-matrix operations as proposed in Figure A.3. In Figure A.3,  $Y$  is a rectangular matrix and  $W$  is an upper triangular matrix for temporary use. Step 1 in Figure A.2 can be carefully divided into three steps as shown in Figure A.3. Step 2 in Figure A.3 becomes a matrix-matrix multiplication instead of matrix-vector multiplications in step 1 in Figure A.2.

After calculation of  $U_j$  for each block, reorthogonalization process is proceeded until the coefficient matrix  $\alpha_j$  of  $\Phi_{k_j}$ , after the block modified Gram-Schmidt orthogonalization, becomes less than the tolerance  $10^{-9}$ . However, the maximum number of iteration is set to three for accuracy even though the twice Gram-Schmidt orthogonalization is usually enough [40].

After  $K_A$ -orthogonalization of the static vectors against  $\Phi_k$ , the orthogonalization among themselves is needed. Usually the number of static vectors is much smaller than the number of global eigenvectors kept and significantly smaller than their dimension. Unblocked modified Gram-Schmidt algorithm is used for orthogonalization among the static vectors themselves with respect to  $K_A$ . To avoid the linear dependence among the static vectors, the static vectors whose Euclidean norm after orthogonalization is significantly smaller than the norm before orthogonalization are eliminated.

## A.4 Small Eigenproblem for Residual Flexibility

After the orthonormalized static vectors are computed, the stiffness and mass matrices are projected onto the augmented subspace spanned by

$$T_R = [ \Phi_k \mid X_R ]. \quad (\text{A.11})$$

The stiffness matrix becomes

$$K_R = T_R^T K_A T_R = \begin{bmatrix} \Phi_k^T K_A \Phi_k & \Phi_k^T K_A X_R \\ (sym.) & X_R^T K_A X_R \end{bmatrix} \quad (\text{A.12})$$

Similarly, the mass matrix becomes

$$M_R = T_R^T M_A T_R = \begin{bmatrix} \Phi_k^T M_A \Phi_k & \Phi_k^T M_A X_R \\ (sym.) & X_R^T M_A X_R \end{bmatrix} \quad (\text{A.13})$$

Thanks to the orthogonality of  $\Phi_k$  with respect to  $K_A$ , the upper left block diagonal submatrices in  $K_R$  and  $M_R$  become diagonal as  $\Phi_k^T K_A \Phi_k = \Lambda_k$  and  $\Phi_k^T M_A \Phi_k = I_k$ . Moreover, the off-diagonal blocks of the two matrices,  $\Phi_k^T K_A X_R$  and  $\Phi_k^T M_A X_R$  become null matrices. The following derivations, using Equation (A.5) and orthogonality condition of  $\Phi_k$  with respect to  $K_A$  and  $M_A$ , explain the reason of the cancellation.

$$\begin{aligned} \Phi_k^T K_A X_R &= \Phi_k^T K_A X_S - (\Phi_k^T K_A \Phi_k) \Lambda_k^{-1} (\Phi_k^T K_A) X_S \\ &= \Phi_k^T K_A X_S - (\Lambda_k \Lambda_k^{-1}) \Phi_k^T K_A X_S \\ &= 0 \end{aligned} \quad (\text{A.14})$$

$$\begin{aligned} \Phi_k^T M_A X_R &= \Phi_k^T M_A X_S - (\Phi_k^T M_A \Phi_k) \Lambda_k^{-1} (\Phi_k^T M_A) X_S \\ &= \Phi_k^T M_A X_S - I_k \Lambda_k^{-1} (\Lambda_k \Phi_k^T M_A) X_S \\ &= 0 \end{aligned} \quad (\text{A.15})$$

Because of these cancellations, the system matrices projected onto the augmented subspace spanned by  $T_R$  can be expressed by

$$K_R = \begin{bmatrix} \Lambda_k & 0 \\ 0 & K_X \end{bmatrix} = \begin{bmatrix} \Lambda_k & 0 \\ 0 & X_R^T K_A X_R \end{bmatrix} \quad (\text{A.16})$$

and

$$M_R = \begin{bmatrix} I & 0 \\ 0 & M_X \end{bmatrix} = \begin{bmatrix} I & 0 \\ 0 & X_R^T M_A X_R \end{bmatrix} \quad (\text{A.17})$$

This leads to the small eigenvalue problem for residual flexibility eigenpairs

$$K_X Q_X = M_X Q_X \Lambda_X, \quad (\text{A.18})$$

where  $\Lambda_X \in \mathbb{R}^{n_x \times n_x}$  is a diagonal matrix containing residual flexibility eigenvalues,  $Q_X \in \mathbb{R}^{n_x \times n_x}$  is a matrix containing the corresponding eigenvectors in its columns, and  $n_x$  is the number of the orthonormal residual flexibility eigenpairs. Therefore,  $M_A$ -orthonormalized residual flexibility eigenvectors and their corresponding eigenvalues are recovered as following.

$$\Phi_R = X_R Q_X, \quad \Lambda_R = \Lambda_X \quad (\text{A.19})$$

Finally, the residual flexibility eigenvectors and the corresponding eigenvalues are added to the global eigensolution as:

$$\Phi_m = [\Phi_k | \Phi_R], \quad \Lambda_m = \begin{bmatrix} \Lambda_k & 0 \\ 0 & \Lambda_R \end{bmatrix} \quad (\text{A.20})$$

For modal frequency response analysis, the system equation can be projected onto this eigenspace represented by  $\Phi_m$  and the modal system equation can be solved on this good approximate eigenspace.

# Vita

Mintae Kim was born in Seoul, South Korea on March 16, 1967. Mintae is the son of Young-Ho Kim and Chung-ja Yang. In March 1988, Mintae enrolled Yonsei University in Seoul, Korea. After freshman year, he served military mission at the Capital Defense Head quarter for two and a half years. In March 1992, Mintae re-enrolled at Yonsei University for continuation of study in Mechanical Engineering. He received his Bachelor of Science degree in Mechanical Engineering in February 1995. Mintae enrolled at Carnegie Mellon University in Pittsburgh, Pennsylvania in September 1995. He received the degree of Master of Science in Mechanical Engineering in May 1997. In Fall 1997, he enrolled in graduate school at The University of Texas at Austin. During his graduate education in Aerospace Engineering and Engineering Mechanics, Mintae worked as both teaching assistant and graduate research assistant.

Permanent Address: 2501 Lake Austin Blvd. #F104, Austin, TX 78703
